Recently an advance has been made along these lines as far as a single type of cases is concerned. Riesenfeld has isolated a group of cases in children learning to walk who have made their first draft against the muscular reserve power. In autopsy following sudden death these children showed hypertrophy of the heart. Some form of status lymphaticus was present in each but there was no constancy of finds. Two out of five presented enlarged thymus and one hypoplasia of the adrenals. In a parallel case Celeen found that the myocardium was permeated with lymphoid tissue suggesting the cardiac lesions of lymphatic leucemia. But sudden death does not often occur in leucemia patients, so that we must assume that a defective heart muscle is itself part of the status thymicolymphaticus and its near congener the status hypoplasticus.

Professor Sternberg, who discusses the advances of our knowledge in this field in the *Wiener klinische Wochenschrift* for June 16, 1921, xxxiv, 24, introduces a note of scepticism. The doctrine of thymic death began with the discovery at autopsy after sudden death of an enlarged thymus, which fact was placed in association with socalled thymic asthma. Virchow decided that as a purely mechanical process thymic death was very rare and that other unknown factors were operative. Paltauf eliminated mechanical compression entirely, deciding that enlarged thymus was only one expression of a general constitution, the status thymicolymphaticus. The death of these patients, he thought, was probably due to heart failure. It was next learned that subjects with this constitution could be robust and vigorous. Among the many anomalies found in them was hypoplasia of the adrenals. Of great importance also was the discovery that hyperplasia of the lymphoid structures could end in atrophy. The picture of this status became widened to an exaggerated degree, so all those who perish suddenly from the most trivial causes, such as bathing and light narcosis, are placed automatically in this category. One result of the exaggeration has been a dissociation into lymphatic and true thymic cases. There are three conditions, known respectively as status lymphaticus, status thymicus, and a hybrid of the two. The

experience of the war has taught the great frequency of the first named. In fact it is so very frequent as to be almost universal and must be ruled out wholly as a factor in disease processes. It is in other words physiological to find hyperplasia of the lymphnodes in young men of military age. As a factor in sudden death it must be thrown overboard. The part in the latter of an enlarged thymus, with or without lymphatism, must be ascertained anew, but the outlook along this line is not promising.

THE SYMPTOMATOLOGY OF HERNIA OF THE FALLOPIAN TUBE.

In the majority of the reported cases of tubal hernia the condition was not suspected before operation. There is no pathognomonic sign which might give a clue to the diagnosis and many of the case histories merely give the symptoms of ordinary hernia. There is no variation in size with painful phenomena at the time of the menses, as is the case in hernia of the ovary, while during the intervals of menstruation an ovary in a hernial sac is the seat of a special sensitiveness, analogous to that of a testicle in ectopia, when pressure is made on the hernia. This is also wanting in cases of hernia of the tube alone, with very few exceptions. In one recorded case pain was present and a diagnosis of hernia of the tube was made. For some time the menses had been less abundant and palpation of the inguinal hernia gave rise to very sharp pain. Therefore, the symptomatology of this lesion requires little comment, but it is to be remarked that what symptoms there may be will differ in children and adults. In the child there is nothing to note but the physical signs. In the groin or labium majus an elongated, pedunculated tumor will be found directed toward the inguinal ring, which can be partially reduced or may be irreducible. Occasionally a rounded, pedunculated body can be felt which is assumed to be the ovary. But generally speaking the symptoms are those of ordinary congenital hernia.

In adults the great majority of cases offer no symptom by which the condition can be distinguished from ordinary inguinal or femoral hernia. The tumor varies in size from a walnut to a closed fist and when the intestine, omentum, bladder, or uterus is in the sac the size may be considerable. Some cases of tubal hernia in the adult have presented symptoms of affections of the fold of the groin. In one the lesion was mistaken for an acute abscess, in another for a bubo of venereal origin, and in a third case for an epiplocele. Even in three cases of tubal pregnancy forming the contents of the hernia a correct diagnosis was not made; therefore it is clear that the solution of the problem is one of great difficulty.

An examination of these cases from the obstetrical viewpoint should never be neglected; the external characters of the tumor should be noted and the functional disturbances ascertained. Vaginal examination and abdominal palpation may give some important data. The positions of the uterus and cervix are to be noted, and the ovaries must be located. If the uterus is drawn forward and to the side of the hernia, an ectopic tube should be thought of. In children, these diagnostic measures are out of the question. Cysts of Nuck's canal, fibromyoma of the round ligaments, and hernia of the ovary offer about the same symptomatology, excepting in the latter there are the periodical painful phenomena and swelling coinciding with the menses, and this should lead to the diagnosis of hernia of the ovary.

Should the tube in the hernial sac be the seat of cystic degeneration, or should it be in the midst of a mass of extravasated blood, the diagnosis cannot be made before operation. In some cases the tube is the seat of salpingitis, or of ectopic gestation, and in one reported case rupture of the tube had taken place into the hernial sac. In most cases strangulation occurs after a long period of tolerance. Sometimes the strangulation is sudden and is the first symptom of the tubal hernia. Adhesions are extremely rare, so that when strangulation does occur it is very acute and peculiarly serious. The tube, often in a pathological state, may pour its infectious products into the hernial sac through the patent orifice of its pavilion. It is needless to insist upon the causes and mechanisms of strangulation in these cases, as they offer nothing particular in tubal hernia; the phenomena are similar to those presented by ordinary hernia.

THE "NO MAN'S LAND" BETWEEN LIFE AND DEATH.

The subject of resuscitation from the condition of accidental death, as expertly diagnosticated, was treated recently in *Indépendance Médicale*, by Halluin of Lille, and is commented on by Cruchet, the editor of the *Journal de Médecine de Bordeaux* in the issue of July 25, 1921, xcii, 14. Halluin made some original investigations on animals killed by asphyxia or chloroform. Of death there could be no question, as controls are easily supplied in animal experiment. There is a short period of 15 or 20 minutes during which these animals may be revived completely and permanently by heart massage. The twenty-minute period is somewhat arbitrary, for in the case of certain dogs resuscitation was successful after that period. In one case an hour had elapsed after cessation of the heart beat, in another ninety minutes. But in neither of these two cases could the animals be kept alive after revival.

If we turn to the clinic, Halluin has a series of 81 collected cases of death following surgical operation in which resuscitation methods were tested. In 45 there was total failure. In the other 36 resuscitation was successful for the time, but in 19 cases it was not permanent. The remainder, 17 cases, were all eminently successful. These data are of enormous importance, says Cruchet. For one thing they show the presence of a borderline—a sort of

No Man's Land, during which resuscitation is possible with about an even chance that it will be permanent. But there is danger of a war of words, because someone will say that during this period the man is not yet dead. The comparative brevity of the interval, however, should lay the fears of those who fear inhumation alive. From another angle there is an apparent distinction between death following an accident, and death which is spontaneous. This No Man's Land—is it also present in death following pneumonia or other acute lethal affection? We know that when death seems inevitable and imminent in an acute illness, the subject is usually allowed to die in peace, and there is no attempt to give nourishment or even to stimulate organs which have apparently lost all ability to respond to treatment. No doubt to a layman it would sometimes appear that something more might have been done to prolong life for a few moments: and with life thus extended, who can be certain that something favorable might not have happened in the natural course of events?

Cruchet states that according to common sense a man is either dead or not dead. During the twenty-minute interval during which resuscitation is possible he is most certainly not dead; therefore he is still alive. But the public will be certain to make much out of this intermediate state, and in fancy prolong it to an hour, and then longer. It is one of the cases in which enlightening the public will return to plague the enlighteners and make them wonder if it is not better at times to keep certain knowledge esoteric.

INFECTION FROM SWIMMING POOLS.

Not long ago, in the newspapers of a large American city, there appeared a story to the effect that a boy had died of meningitis which his family physician ascribed to his habit of bathing in a municipal swimming-pool. This idea was at once taken up by the laity, of course, and a phobia of swimming-pools followed. For some time it made a good news story and much space was given to it. No so much room, however, was given to an open letter from the Health Officer of that city, published after he had made a complete investigation of the circumstances. He referred to the statement of the family physician and asked the latter if he had made any bacteriological investigation of the water in question, which had been frequently examined by the Health Department with negative results so far as related to the presence of pathogenic bacteria. He also called attention to the fact that the boy in question had had a middle-ear disease with a chronic discharge for some six months or so before the meningitis developed and asked quite properly whether the cause might not be sought there instead of alarming a community by guessing at a public bath as the source of infection.

While in this particular case it would seem that the pool was probably innocent, owing to the effective measures of the local Health Department, the discussion may serve to call attention to conditions not quite so ideal in other pools. The general public is too likely to regard a dip in a public swimming-pool as a sanitary and cleansing measure, ignoring the fact that the large numbers who use such a place must inevitably contaminate it. There is a popular lay idea, too, that sea-water contains in itself some substance that renders it mildly antiseptic. As a matter of fact, bacteriologists have repeatedly grown such organisms as *B. coli communis* from specimens of sea-water taken from an open beach. Naturally those enclosed sea-baths which exist at every seaside place are much more dangerous, lacking constant renewal.

It is probably true that a slight danger of infection can not be avoided, even with the most rigid cleanliness. Certain routine measures will diminish this danger to an almost negligible point, however. Refilling the tank in the morning and emptying it in the evening is of course the ideal, and where there are large crowds of bathers, it would be desirable to do this not once, but several times a day. The expense of this is, however, often prohibitive, and recourse must then be had to sterilization of the water. A very practical way of effecting this is by means of ozonization as described by Dr. Mannheimer in this issue of the Medical Record. This is Nature's method of purification of ponds and streams and man can hardly improve upon it. The precautions adopted in many private swimming pools, Y. M. C. A.'s and the like, are admirable, that is, the use of a cleansing bath before the plunge and the issuance to each bather of suits which have been cleaned and sterilized.

If purifying and preventive measures of this sort could be instituted generally in all municipal swimming-pools there is no doubt but that there would be some reflection of them in the morbidity statistics for those particular localities.

Fat-Soluble Vitamine and Plant Carotinoids.

The fact that animals must obtain their vitamines from plants has been brought into association with the belief that the yellow pigment of animal fat (lipochrome), including butter, is derived from the plant xanthophylls, which include carotin, the yellow pigment of carrots, yellow maize, etc., and the socalled carotinoids of the plant plastids. It has actually been shown, according to Palmer and Kennedy, *Journal of Biological Chemistry*, May, 1921, xlvi, 3, that this is to some extent a demonstrable fact, although at present it would be going too far to assert that all fat pigment is simply unchanged xanthophyll. Naturally the question soon came up as to the possible identity of the carotinoids and fat-soluble vitamine, and numerous experiments have been conducted with foods poor in the pigment. The results show beyond doubt that carotinoids have no vitamine functions. Two substances were especially used in the authors' experiments—the milk of ewes and eggs from a strain of White Leghorn fowls which had been fed always on foods free from carotinoids. Ewe's milk normally contains but a trace of these substances. The strain of fowl in

question had been fed since hatching on white corn, skim milk, bone meal and oyster shells. Only at long intervals were they given a little fresh pork liver, which contains lipochrome. The powdered yolk from the eggs of these fowls was quite free from coloring matter. When albino rats were fed on either ewe's milk or the eggs in question, they grew and developed as usual, showing plainly that these substances retained all of their fat-soluble vitamine. All fat-containing organs of the same animal were tested for the presence of carotinoids, and the latter were found to be completely lacking. Hence it appears to be evident that while animal lipochromes are closely related to plant xanthophylls, they have absolutely no connection with fat-soluble vitamine.

The Value of Drugs.

Has the value of drugs depreciated in the minds of the members of the medical profession? For some considerable time there have been those who have denied to all but a very few drugs any real therapeutic virtues, while there are cynics as to the merits of drugs, and there are even yet drug nihilists. Moreover, there have sprung up within recent years various other methods of treating disease and conditions of ill health, such as vaccine therapy, radiotherapy, and lastly those much overrated methods of diagnosing and treating certain affections, psychoanalysis and psychotherapy. All this at a first glance would seem to imply that belief in the efficacy of drugs in the treatment of disease has diminished. Perhaps, however, when the matter is looked into more closely it will be realized that it is not the use but the abuse of drugs that is on the wane. As is pointed out in a recent number of the *Prescriber*, it is drug superstition, a belief in the magic power of "something in a bottle," that is dying out and is being replaced by other superstitions, such as psychoanalysis. There are, indeed, a few drugs which are really specifics, or as nearly specifics as may be, such as mercury, arsphenamine, and quinine, not to mention certain sera and antitoxins, while there are not many who will deny the value of morphine in acute pain. Also when may a substance be differentiated as a drug? For example, sodium chloride is an article of diet in the first place, and is also used with good effect as an intravenous injection and in other therapeutic ways. In both cases its action is, to all intents and purposes, identical. Again, certain mineral salts and organic acids are contained in fruits. When fruits are not available these salts and acids are employed as drugs, so that in many instances the line of demarcation between drugs and foods is difficult, almost impossible to draw. Drugs are not out of date, but, on the whole, are more efficient than ever. What is required to place drug therapy on a sound basis is to reorganize the entire system, to weed out those that are useless and sometimes even dangerous, to improve and perfect those which have proved themselves of true value. Drugs also to exert their best effects must be prescribed with more or less exact knowledge of their action and especially must be furnished with discretion. It is sometimes the fault of the physician that drug therapy fails.

News of the Week.

Federal Board of Hospitalization Created.—Budget Director Dawes, with the consent of President Harding, has created a Federal Board of Hospitalization for the purpose of doing away with wasteful methods in the purchase of hospital and other surgical equipment for the hospitalization activities of the Army, Navy, Public Health Service, and United States War Veterans' Bureau. The duty of the board, as defined by Mr. Dawes, is to safeguard the Treasury against unnecessary expenditures by standardizing requirements for hospitals operated by the Government, to systematize building operations and the purchase of supplies.

Deaths From Motor Vehicle Accidents in 1920.—The Department of Commerce, through the Bureau of the Census, announces that during the year 1920, 9,106 deaths resulting from accidents caused by automobiles and other motor vehicles, excluding motorcycles, were recorded within the death-registration area of the United States, which area contains 82 per cent of the total population. This number represents a death rate of 10.4 per 100,000 population, as against 9.4 in 1919, 9.1 in 1918, 8.9 in 1917, 7.3 in 1916, and 5.8 in 1915. Between 1915 and 1920, therefore, the death rate per 100,000 population from motor vehicle accidents and injuries increased by about four-fifths. The actual number of deaths resulting from motor vehicle accidents in the twenty-five States from which data for 1915 are available increased from 3,571 in that year to 7,433 in 1920, the rate of increase being 108.1 per cent. During the same period, according to data obtained from the Bureau of Public Roads, of the Department of Agriculture, the number of registrations of automobiles, motor trucks, and commercial motor vehicles in the same States increased from 1,767,055 to 6,085,150, the rate of increase being 244.4 per cent. The death rate per 1,000 motor vehicles in use in the 25 States in question decreased from 2 in 1915 to 1.2 in 1920, being only three-fifths as great in the later as in the earlier year. In New York City last year there were 27,550 vehicular accidents, in which 23,279 persons were injured. Of these 864 were fatal. Almost three times as many men were injured as women, the men totaling 17,133 and the women 6,146.

Health Bill for Marriage in Spain.—According to the *Correspondencia España*, a bill has been prepared by the Minister of the Interior for introduction into the Spanish Parliament by which persons intending to marry will be compelled to produce a medical certificate showing that the would-be husband and wife are in good health.

Richmond Favored as Site of Merged Medical Colleges.—The Medical Society of the State of Virginia, at its annual meeting held in Lynchburg, Oct. 20-22, 1921, adopted resolutions favoring the merger of the medical department of the University of Virginia and Medical College of Virginia and the location of the institution in Richmond.

Surgeons to Make Radium Research.—The American College of Surgeons, at its recent meeting in Philadelphia, voted to devote a year of intensive research work in an effort to establish the value of radium as a cure for cancer. Specialists all over the world will be asked to furnish statistics

on the results they have obtained in the use of radium. A committee will soon be appointed to carry out the work, with a research director-general who will not only conduct experimental work in his own laboratory but will be constantly in communication with similar laboratories all over the country.

American Surgeons Honored by Royal College of Surgeons in Ireland.—At the closing session of the American College of Surgeons, held in Philadelphia during the week of October 24, Honorary Fellowship in the Royal College of Surgeons in Ireland was conferred upon eight Americans. Those receiving the honor were: Drs. George E. Brewer, New York; George W. Crile, Cleveland; John M. T. Finney, Baltimore; Robert J. Ochsner, Chicago; Charles H. Mayo and William J. Mayo, Rochester, Minn.; John B. Deaver, Richard Harte, and W. W. Keen, Philadelphia. The fellowships were conferred to Sir Harold J. Stiles, Sir William Taylor, and Sir Robert Woods.

Hospital Notes.—The Volunteer Hospital, New York, is facing foreclosure of a $65,000 mortgage on its building, and has other financial obligations bringing its indebtedness up to $150,000. A campaign is being conducted to raise funds to meet this indebtedness which, if not defrayed, will necessitate the closing of the hospital.

The entire fund for a new Community Hospital at Keene, N. H., has been pledged. Ground will be broken in April for the new building and the following December, it is believed, will find it completed.

Plans have been drawn calling for a building which will provide eighty beds as a part of the general plans for the enlargement of the South View Hospital, Milwaukee. The estimated cost of the addition is $160,000.

A new hospital is soon to be erected by Sacramento physicians with the aid of local capitalists, at a cost of $500,000. The present plans call for a 150 bed hospital with all modern conveniences.

Cancer Week in New York.—As a part of the observation of National Cancer Week during the first week in November, the American Society for the Control of Cancer, with headquarters in New York City, opened booths in the Grand Central Terminal and the Pennsylvania Station, where it circulated pamphlets explaining the nature of the disease and its cure. During the week over 4,500,000 pieces of literature were distributed, much of it in a house to house canvass. Many lectures on the subject of cancer were delivered throughout the city, the most important of which was one held at the New York Academy of Medicine on Nov. 2, at which Dr. Edward L. Keyes, Jr., presided. Addresses were made by Dr. Joseph A. Blake, Dr. Howard C. Taylor, Dr. William H. Woglom, Dr. Douglas A. Quick, and Mr. Wendell M. Strong, secretary of the Actuarial Society of America.

New Post-Graduate Courses Opened.—The new post-graduate school of medicine established at the Broad Street Hospital especially for ship's doctors desiring to obtain special instruction, has been opened. The first courses to be given are in electrotherapy and *x*-ray clinical pathology and diagnosis. Dr. William H. Dieffenbach is president of the school.

Dr. George Chaffee of Binghamton, N. Y., was presented with a case containing $222 in gold from the members of the New York and New England Association Railway Surgeons at the annual meeting of this organization held in New York on Oct. 29, in recognition of his faithful service to the association. He is founder, ex-president and corresponding secretary of the association.

Gifts and Bequests.—Under the terms of the will of the late Daniel J. Carroll, St. Vincent's Hospital and the Roman Catholic Orphan Society, New York, each receive a bequest of $100,000.

The Ohio Valley Medical Association will convene in Evansville, Ind., Nov. 15 and 16, 1921, under the presidency of Dr. Charles F. Souther of Cincinnati.

The Institute of Cancer Research (formerly the George Crocker Special Research Fund) of Columbia University, announces the appointment of a Consulting Board, the membership of which includes eminent biologists, chemists, physicists, statisticians, and surgeons who are interested in the experimental study of cancer. The surgical members of the board are Drs. William J. Mayo of Rochester, Minn., and Eugene H. Pool and George H. Semken of New York.

The American Electrotherapeutic Association and the New York Electrotherapeutic Society have arranged a mid-winter Clinical Session to be held Dec. 29 and 30, 1921, at the United States Public Health Service Hospital No. 61, at Fox Hills, Staten Island, N. Y. The purpose of this session is the demonstration of apparatus and its actual application, and of the results obtained by all physical modalities. Cards of admission may be obtained from Dr. Richard Kovacs, 223 East 68th Street, New York City.

Medical Society Elections.—THE NEW YORK AND NEW ENGLAND ASSOCIATION RAILWAY SURGEONS, at its thirty-first annual session held in New York, Oct. 29, 1921, elected the following officers for the ensuing year: *President*, Dr. Donald Guthrie, Sayre, Pa.; *First Vice-President*, Dr. J. K. Stockwell, Oswego, N. Y.; *Second Vice-President*, Dr. Edgar Vanderveer, Albany, N. Y.; *Treasurer*, Dr. J. M. Hamilton, Rutland, Vt.; *Recording Secretary*, Dr. Horace H. Le Seur, Batavia, N. Y.; *Corresponding Secretary*, Dr. George Chaffee, Binghamton, N. Y. Fifty surgeons were elected to active membership in the Association.

THE TENTH DISTRICT MEDICAL SOCIETY OF NORTH CAROLINA, at its annual meeting held at Murphy, Oct. 5, 1921, elected the following officers for the ensuing year: *President*, Dr. Guy Kirby, Marion; *Vice-Presidents*, Dr. W. B. Adams, Murphy; Dr. J. R. McCracken, Waynesville; Dr. Dan Bryson, Bryson City; Dr. A. F. Toole, Asheville; Dr. W. R. Kirk, Hendersonville; *Secretary-Treasurer*, Dr. W. H. Hunnicutt, Asheville.

THE MILWAUKEE (WIS.) PHYSICIANS' ASSOCIATION, at its annual meeting held Oct. 11, 1921, elected the following officers for the ensuing year: *President*, Dr. Hugo P. Siekert; *Vice-President*, Dr. P. G. Hankwitz; *Secretary*, Dr. Elmer Gramling; *Trustee*, Dr. B. P. Churchill.

THE STEUBEN COUNTY (N. Y.) MEDICAL SOCIETY, at its semi-annual meeting held in Bath, Oct. 11, 1921, elected the following officers for the ensuing

year: *President*, Dr. R. J. Maichle, Cohocton; *Vice-President*, Dr. Zeno S. Selleck, Bath; *Secretary-Treasurer*, L. R. Pierce, Avoca.

THE GEORGIA STATE BOARD OF MEDICAL EXAMINERS, at its fall meeting held in Atlanta, Oct. 13, 1921, eleited the following officers: *President*, Dr. J. W. Palmer, Ailey; *First Vice-President*, Dr. A. F. White, Flovilla; *Second Vice-President*, Dr. O. B. Walker, Bowman; *Secretary-Treasurer*, Dr. C. T. Nolan, Marietta.

THE MEDICAL SOCIETY OF THE STATE OF VIRGINIA, at its annual meeting held in Richmond, Oct. 20-22, 1921, elected the following officers for the ensuing year: *President*, Dr. E. C. S. Taliaferro, Norfolk; *Vice-Presidents*, Dr. John Staige Davis, University of Virginia; Dr. C. P. Jones, Newport News; Dr. I. B. DeShazo, Ridgeway; *Secretary-Treasurer*, G. H. Winfrey, Richmond.

Obituary Notes. — Dr. WILLIAM J. BRADY of Brooklyn, N. Y., a graduate of New York University Medical College in 1892, died after a prolonged illness, on Oct. 19, at the age of 56 years.

Dr. ROBERT THOMAS IRVINE of Ossining, N. Y., physician to Sing Sing prison from 1891 to 1908, and since April last connected with the War Risk Insurance Board, died suddenly of heart disease in Washington, D. C., on Nov. 1, at the age of 63 years. He was graduated from McGill University Faculty of Medicine in 1885.

Dr. ALFRED J. SCOTT of Los Angeles, Cal., a member of the State Board of Medical Examiners, died suddenly in Sacramento on Oct. 16, at the age of sixty-three years. He was a graduate of the University of Michigan Medical School, Ann Arbor, in 1882.

Dr. ISAAC B. WILSON of La Pine, Ore., a graduate of the College of Physicians and Surgeons, San Francisco, in 1910, and a lieutenant in the Medical Corps of the United States Army during the war, died on Oct. 11, at the age of thirty-eight years.

Dr. VICTOR P. CHAAPEL, a graduate of the College of Physicians and Surgeons, Baltimore, in 1892, died at his home in Williamsport, Pa., on Oct. 16, at the age of fifty-six years. He was a member of the American Medical Association and of the Medical Society of the State of Pennsylvania.

Dr. JOHN HIETT of Ione, Wash., died after a lingering illness in Spokane, Wash., on Oct. 11, at the age of forty-nine years. He was graduated from the Marion Sims College of Medicine and Surgery, St. Louis, in 1892.

Dr. THOMAS C. THORNTON of Lewisburg, Pa., a graduate of the University of Vermont College of Medicine in 1862, and an army surgeon during the Civil War, died suddenly on Oct. 21, at the age of eighty-two years.

Dr. CHARLES J. BOSWELL, a graduate of Marion Sims Medical College, St. Louis, in 1895, died at his home in Mounds, Ill., on Oct. 23, at the age of forty-five years. He was health officer of Mounds for a number of years and mayor of that city for a term of two years.

Dr. H. C. SHUTTEE of West Plains, Mo., a former president of the Missouri Medical Association, died of cancer of the throat in Chicago on Oct. 19, at the age of sixty-three years. He was graduated from the Missouri Medical College in 1881, a member of the State Board of Pensions, and division surgeon for the St. Louis and San Francisco Railway Company.

Dr. JAMES G. STERRS of Atlanta, Ga., a graduate of the Leonard Medical College, Raleigh, N. C., in 1906, died following a stroke of apoplexy on Oct. 12, at the age of forty years.

Dr. EMANUEL R. HERSHEY of Lancaster, Pa., died on Oct. 23 at the age of seventy-four years. He was graduated from Jefferson Medical College in the class of 1880. He was engaged in practice for many years at Paradise, and he served for several years as postmaster at Florin.

Dr. LOOMIS LEGRAND DANFORTH died at his home in New York City on November 8, after a long illness. He was born in Monticello, N. Y., in 1849, and was graduated from the College of Physicians and Surgeons of Columbia University, in 1874. After graduation he connected himself with the Homeopathic school of practice, and in 1886 was appointed to the chair of obstetrics in the New York Homeopathic Medical College. At the time of his death he was emeritus professor of obstetrics in that institution and was chief of the lying-in department of the Flower Hospital. He was a member of the New York Academy of Pathological Science and of the New York County Homeopathic Society.

Dr. HENRY CLAY CHISOLM of Hungtingdon, Pa., died at Niagara Falls, on Oct. 25, at the age of sixty-two years. He was graduated from Hahnemann Hospital and Medical College of Pennsylvania in 1888. He served as a member of the Pennsylvania House of Representaives from 1897 to 1900.

Dr. ROBERT WALTER of Walter's Park, Pa., died in Reading, on Oct. 26, at the age of eighty years. He was graduated from Hahnemann Hospital and Medical College of Pennsylvania in 1888.

Dr. J. ANSON SMITH, Superintendent of the Camden County Hospital for the Insane, died at Blackwood, N. J., on Oct. 27, as a result of an operation for appendicitis, at the age of fifty years. He was graduated from Jefferson Medical College in 1897. He was a member of the Camden County Medical Society, the New Jersey State Medical Society, a Fellow of the American Medical Association, and a member of the American Medico-Psychological Association.

Dr. WILLIAM MARSHALL ALRICH died of heart disease in Philadelphia on Oct. 27 at the age of fifty-eight years. He was graduated from the medical department of the University of Pennsylvania in 1889.

Dr. WILLIAM J. FIELDS of Manasquan, N. J., a graduate of the College of Physicians and Surgeons, New York, 1880, died suddenly on Nov. 3, at the age of sixty-five years.

Dr. GEORGE WAKEMAN OSBORN of Bridgeport, Conn., died of bronchial pneumonia on Oct. 25, at the age of sixty-one years. He was graduated from the College of Physicians and Surgeons, New York, in 1887. He served as city physician, surgeon to the Emergency Hospital, member of the Board of Health, surgeon of the fire department and of the department of children of St. Vincent's Hospital. He was a member of the American Medical Association and the Medical Society of the State of Connecticut.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, October 21, 1921.

Dismissal of a Married Medical Woman.—By an overwhelming majority the St. Pancras Borough Council have decided to dispense with the services of Dr. Gladys Miall-Smith, the assistant medical officer for maternity, on the ground that she has married. It appears that the council's decision is mainly based on the theory that, because there is widespread unemployment, married women whose husbands are able to support them should not compete in the labor market. This argument is ancient and musty and in many respects an economic fallacy. The belief is that people with private means ought not to work because they "take the bread out of the mouths" of those who are compelled to work for a living. The fact does not seem to be realized that when people work they may add to the common store a great deal more than they take out of it. It is more than a coincidence that Dr. Miall-Smith's dismissal was chiefly brought about by the labor members of the St. Pancras Council, the labor councillor who spoke for his party saying that he had the support of the "unemployed and the ex-service men." As said before, the view that the less work each individual does the more work there will be to go round is not founded on sound principles, but is a mischievous doctrine which appears to have been adopted by the labor party in this country. It is instructive to note that five women councillors attended the meeting, but only two voted in favor of the woman doctor.

Sir Arthur Newsholme on the Results of Prohibition in America.—Sir Arthur Newsholme, late principal medical officer to the English Local Government Board, who has been in America for the past two years, gave a lecture at the Royal Society of Medicine a few days ago, in which he told the results of his study of the working of the new prohibition law. He said, in part, that there were about 153,000 medical practitioners in the United States and each had to take out a permit to prescribe alcohol. Four out of every five had not taken out permits, and in 24 of the 48 states not one practitioner had taken out a permit. As for the results of prohibition, there were evidences of increased prosperity and of the diversion of large sums of money to the purchase of better clothing, etc., which was due, partially, at any rate, to the saving on alcohol. Rescue work in large cities had been largely replaced by preventive work. Drunkenness and admissions to hospitals for acute alcoholism also showed remarkable declines. Whether prohibition would endure the test of enforcement in America remained to be seen, but his view was that prohibition would remain in operation as the law of the land.

The First International Congress of Military Medicine and Pharmacy.—The Congress of Military Medicine and Pharmacy, the first of its kind ever held, took place in Brussels in July last. Its objects are to safeguard the health of armies and improve the treatment of wounded in warfare. The British delegates were Colonel E. M. Pilcher, Major A. D. Stirling, Surgeon Rear Admiral G. T. Meagher; the delegate from the United States was Commander William Seaman Bainbridge of New York; delegates were also present from France, Italy, Japan, China, Brazil, Spain, Morocco, Switzerland, Sweden, Denmark, Holland, Norway, Mexico, Poland, Guatemala, the Argentine Republic, Chile, the International Red Cross Committee, and the League of Red Cross Societies. The Congress was a conspicuous success and several important resolutions were passed. Among the questions dealt with was that of gas warfare, and the treatment of gas poisoning cases. The conclusion was reached that these should be placed in the hands of experts on the subject. The matter of syphilis was discussed at length and certain preventive and remedial measures recommended. These comprised educative measures, and the encouragement of sport was also advocated, as a counter attraction; likewise those measures which insured organized inquiry into the source of infection in conjunction with the civil authorities, isolation of the infected men, and treatment by specialists. Curious to relate, however, no reference was made to prevention by means of immediate or early disinfection. Resolutions with regard to tuberculosis were adopted. Greater care was advocated in selecting men for the army; any who showed signs of tuberculosis should be rejected. Moreover, not only should every candidate be carefully examined during the recruit stage, but immediately after his incorporation into the army, while from the standpoint of prophylaxis, a temporary or definite period of isolation should be imposed in all cases in which tuberculous infection was present. The report of the proceedings of the Congress lays down clear and comprehensive instructions for controlling the health of an army, and for the guidance of the medical officers of the service. A permanent committee was nominated to arrange the business of the next congress. The chairman is Dr. Wibin, Belgium, and the other members are Drs. William Seaman Bainbridge, United States; Uzac, France; Van Baumberghen, Spain; Stirling, England; Caccia, Italy; Da Fonesca, Brazil, and Thomann, Switzerland.

Pyorrhea Alveolaris in Great Britain.—The condition of the teeth of the British people is notoriously bad and pyorrhea alveolaris is extremely prevalent. This matter was discussed editorially in the *Medical Press and Circular* of October 19. According to the view of the writer of the editorial the local conditions which predispose to pyorrhea are essentially dietetic in origin. This dietetic factor consists in the consumption of too soft farinaceous food, which not only tends to collect at the gum margin, where it forms a favorable nidus for the development of bacteria, but fails to afford that healthy exercise of the teeth which is needful for the health of the periodontal membrane. When the teeth are insufficiently exercised, the circulation in periodontal membrane and surrounding bone and mucous membrane is sluggish, the flow of cleansing saliva scanty, and the opportunity for bacterial invasion correspondingly great. Preventive treatment therefore consists in keeping the blood healthy

and in maintaining a healthy local condition of the alveoli and gums. This latter desideratum is best effected by means of a suitable dietary, one, namely, which necessitates adequate mastication. A book by D. A. Crow has recently been published by Baillière, Tindall, and Cox on this disease in which the prevalence of pyorrhea is dwelt upon especially, and the results of the disease are enumerated.

Presidential Address at the Annual General Meeting of the Medical Society of London.—The 149th session of the Medical Society of London opened on October 10 last, when the president for the year, Mr. James Berry, F. R. C. S., was inducted and gave the presidential address. Mr. Berry departed from the usual custom of devoting the address to a consideration of a medical or surgical subject, and did not discuss the operative treatment of exophthalmic goitre, of which he is a pioneer and a master, nor other surgical measures with which he is conversant, but spoke of the experiences undergone by the medical men, nurses, and lay workers who comprised the unit which went to Serbia in the early part of the war under the direction of Mr. and Mrs. Berry. The title of the address was "Some Medical Experiences in South Eastern Europe." Much of this matter was included in a book written by Mr. and Mrs. Berry and Mr. Blase, which was dealt with in an editorial article in the MEDICAL RECORD a year or more ago. However, the address was not restricted to medical experiences, but touched on various happenings. Mr. Berry described the adventures of the unit, if they may be so termed, in language serious and humorous as befitted the occasion, and carried his audience with him.

The Obstetrical and Gynecological Unit at the Royal Free Hospital, London.—This unit has been described and referred to more than once in these letters. The other day the writer enjoyed the privilege of being shown over this new department of the Royal Free Hospital, the hospital of the Medical School for Women, by its director and organizer, Dr. Louise McIlroy. This unit is situated in the new wing of this somewhat ancient building and is well equipped, and doubtless owing to excellent organization is running smoothly. Dr. McIlroy is intensely interested in research work and she and that part of her staff engaged in this direction are pursuing investigations into the toxemias of pregnancy as well as into other subjects of obstetrical and gynecological concern. Unfortunately, research work to be carried on as it should be is costly, and like all the London hospitals, the Royal Free is lamentably lacking in funds. It goes without saying that there is a wide scope for most valuable research in a unit such as this, and it appears a calamity that it should be hampered, almost starved, because the money necessary to do really good work is not forthcoming. Bricks cannot be made without straw.

Obituary.—Thomas R. Morse, F. R. C. S., died at Deal, Kent, on September 7, last. He entered Guy's in 1877 and had a distinguished career as a student. In 1884 he took the F. R. C. S., England, and shortly after settled in Norwich. He was surgeon to the Norwich Dispensary and assistant surgeon to the Jenny Lind Infirmary. He took a keen and active interest in all branches of surgery, but more especially in abdominal surgery, and as he was an exceptionally skillful operator, he soon rose to be one of the leading consulting surgeons of Norwich. He was president of the Norwich Medical and Chirurgical Society. Ten years ago in the course of his duties he contracted influenza after which myelitis set in, and for ten years he had been completely paralyzed in both legs. The latter part of his life was saddened by the loss of three sons in the war.

CONGRESS OF FRENCH SOCIETIES AT STRASBOURG.

(From Our Swiss Correspondent.)

STRASBOURG, FRANCE, October 5, 1921.

FOUR congresses have just been held in the city of Strasbourg, namely the French Congress of Medicine, the French Congress of Surgery, the French Congress of Urology and the French Congress of Orthopedic Surgery, in order to honor Alsace upon the occasion of its return to France. The ancient Faculty of Medicine of Strasbourg is once more united to the National University of France.

The inaugural addresses of the three first named Congresses were delivered by their respective presidents Boeckel of Strasbourg, Bard of Strasbourg, and Jeanbrau of Montpellier.

Prof. Boeckel, the great defender of the French school and its traditions in Alsace, was the hero of a very touching ceremony upon the occasion of the presentation of a gold medal offered by the members of the French Congress of Surgery, and the greatest enthusiasm was expressed by those who witnessed the heartfelt exchanges of sentiments. One can see and sense that the general feeling here is one of relief and contentment since the burden of the German yoke has been removed.

The subject for discussion before the Urological Congress was anesthetics in urological surgery, the reporters being Rathery and Chevassu of Paris, admirably well presented and thoroughly discussed, the consensus of opinion being in favor of ether, ethyl chloride, or spinal anesthesia. Chloroform was generally tabooed.

At the Surgical Congress the subject for general discussion was the surgical treatment of traumatic epilepsy, Billet and Lenormand, reporters. The prevailing opinion was that an operation will at least improve the patient's condition when it does not cure and no lesser men than Leriche of Lyons and de Martel of Paris maintained this view.

In medicine exploration of the circulatory apparatus by the graphic method was the order of the day and unquestionably great advance has been made in the past few years both in instrumentation and otherwise. Prof. Widal's address on anaphylaxis was a masterpiece both in clearness, precision, and completeness and should be read throughout the medical world with delight.

Space forbids all that could be said of the scientific and social aspects of this reunion but it can be said that in every way the success of the meetings was manifest.

STEPHEN SMITH. M. D. LL. D.

Biographical Note.

STEPHEN SMITH, M.D., LL.D.

TEACHER, AUTHOR, EDITOR, SURGEON, FOUNDER OF INSTITUTIONS, CREATOR OF SANITARY CODES AND LAWS FOR THE BETTERMENT OF THE SICK AND INSANE.

To few human beings in this age is it given to look back over a life that spans a century. To still fewer is it given to look down such a vista of years with eyes undimmed, mental faculties alert and unimpaired, and figure unbowed by the weight of years and the cares of life. But it is indeed a unique privilege to view in retrospect five score years of life so replete with unselfish service to one's fellow men as has fallen to the lot of Dr. Stephen Smith. So numerous have been these services that their mere recording is a tribute to his boundless energy and ceaseless activity.

Dr. Smith began the study of medicine in 1848 when he entered the Geneva Medical College, Geneva, New York, having become interested in the subject because of his delicate physique. Here he was in the class with Elizabeth Blackwell. In 1849-1850 he was a resident student in Charity Hospital, Buffalo, and studied under Professor Frank H. Hamilton. He entered the College of Physicians and Surgeons, New York, in 1850 and graduated in 1851. He then entered Bellevue Hospital as an interne, and in 1854 became visiting surgeon to Bellevue. In 1855 he was appointed physician to the typhus hospital on Blackwell's Island. In those days typhus fever and Asiatic cholera were by no means the rare diseases they are to-day in New York. Dr. Smith relates that while in Charity Hospital he learned the treatment of Asiatic cholera. The customary treatment of Asiatic cholera at that time was to deny water and to give calomel and opium, though thirst was excessive. A recalcitrant patient under Dr. Smith's care persisted in disregarding all admonitions and drank large quantities of water. He recovered while all the other victims of the disease died. This taught the lesson. While in Bellevue Hospital Dr. Smith came under the immediate instruction of Dr. Alonzo Clarke, Dr. James R. Wood, Dr. John T. Metcalfe, and Dr. William H. Van Buren. The internes at that time lived five in a small room, ate almshouse food, and were exposed to typhus fever, from which ten of the staff suffered and two died. It was well for the doctor and for the typhus fever patient that there was no prohibition amendment in force in those days. Dr. Alonzo Clarke taught that in the last stages of typhus fever alcohol acted like a specific. He allowed his typhus fever patients to drift along until they reached the last stages of the disease and then literally saturated them with alcohol, administering not a pint in ten days, but almost a pint in a night, and many of the patients treated in this way recovered.

While Dr. Smith was at Bellevue he introduced the opium treatment of peritonitis which changed the records from 75 per cent of deaths to almost 100 per cent of cures. As early as 1853 he recommended the out-door life for a case of tuberculosis, declaring that he had no faith in the cod-liver oil and whiskey treatment for tuberculosis. While connected with Bellevue Hospital, Dr. Smith adopted a system of class recitations and clinics which led to the development of Bellevue as a great teaching center, and this was the foundation of the clinical method of teaching in this country.

During the early period of his professional life he did editorial work on the *American Medical Times*, his special feature being leading editorials devoted to critical comments on events of a medico-public character. During the Civil War Dr. Smith was a member of the United States Sanitary Commission and made a report on the subject of amputation through the foot at the ankle joint. He was author of the "Handbook on Surgical Practice" used in the Civil War.

In 1864 New York was in a deplorable condition from the standpoint of sanitation. In those days the mayor appointed one or other of the alderman to act as health commissioner. He, in turn, appointed health inspectors or wardens, as they were called. These were generally political hangers-on of a low type. Dr. Smith asked one of these wardens, "What is hygiene?" "The vapor rising from standing water," was the reply. This was the situation Dr. Smith set about reforming. He was asked to make a sanitary survey of the city. He went about it by dividing the city into thirty-two districts, and appointed thirty-two recently graduated physicians as inspectors. Their reports were the best of the kind on record. With these reports as a basis he prepared the Metropolitan Health bill which embodied the best features of the English and French health laws. This bill was enacted into law in 1866. The code of sanitary laws rising from this is unsurpassed in efficiency and has made New York one of the healthiest cities in the world. It has formed the basis of municipal health departments throughout the country. Dr. Smith was made Health Commissioner in 1868, which office he held for seven years. In 1870 he called a conference of health officers of the principal cities to form an association for the advancement of public sanitation. So was formed the American Public Health Association, now celebrating its semicentennial. He became the first president of this organization. At this period he began agitation for a national public health service under the auspicies of the Federal Government, but popular States' rights doctrine delayed the organization until 1878, when Dr. Smith prepared the bill which created the National Board of Health. An epidemic of yellow fever throughout the South was a factor in arousing interest in the bill and aiding in its passage by Congress. This name was changed to the Marine Hospital Service in 1881.

Dr. Smith was the first to introduce the use of antiseptics into Bellevue Hospital. The other surgeons of that time would have nothing to do with them. Lord Lister (then plain Joseph Lister) visited Dr. Smith's wards and complimented him on the excellent conditions that prevailed under his methods. When president of the Department of Charities of New York City Dr. Smith drafted the bill for a Bureau of Tree Culture, as an accessory in the reduction of infant mortality. He also drafted a bill creating the Bureau of Vaccination.

In 1882, Dr. Smith was appointed State Commissioner in Lunacy of New York by Governor Alonzo B. Cornell. In his book, "Who Is Insane?" he says that at that time there were about 12,000 insane in the State Asylums, in County Asylums, in Poor Houses, and in private institutions. They were found in every condition hitherto known in the history of this unfortunate class, from that of pauper in the County Alms House, in filthy cells, shackled hand and foot, and fed like swine, to the kindly care, good food, and sanitary dormitories, with freedom from cruel forms of restraint, of those in the State Asylums. The most important reforms effected by Dr. Smith's service were the introduction of the training school for attendants, the creation of a State Lunacy Commission, and the removal of the insane from county to State care. Through the work of the Commission in Lunacy, State institutions for the insane have been changed from *custodial* "asylums" to *curative* State "hospitals." These three reforms have not only raised the standard of care and treatment of the insane in the State of New York to the highest grade yet attained, but they have been so widely copied that they are fast bringing the institutions for the insane in this country to first rank.

President Cleveland, in 1894, appointed Dr. Smith a delegate from the United States to the Ninth International Sanitary Conference held in Paris. Here he assisted in formulating a code of rules and regulations governing the sanitary conditions under which pilgrimages were made to Mecca. Before this, owing to the bad sanitary conditions, 62 per cent. of those who made the pilgrimage never returned to their homes. As a result of this conference a commission was appointed to remain permanently at Constantinople to supervise the enforcement of the rules. Dr. Smith served as president of the Department of Charities of New York City under Mayor Strong.

Dr. Smith's writings cover a wide range of subjects having to do for the most part with surgery, sanitation, and the care and treatment of the insane, but whatever the subject, the objective sought has always been the relief of human suffering and the betterment of human living conditions.

2. Surgical Abdomen in Children.—Thomas H. Lanman presents a study of the figures of the last five years of the Surgical Service of the Children's Hospital, Boston, which bring out the fact that abdominal conditions requiring surgical intervention are much more common in children than is generally supposed. Among 4,748 admissions to the hospital in the period of five years there were 1,064 operations for hernia, 7 per cent. of which were for umbilical hernia, while the rest were for inguinal hernia of various types. Strangulation and incarceration of inguinal hernia is very rare in children. The age at the time of operation matters little, though it is the practice at the Children's Hospital to hold the hernia with a yarn truss at least until the baby is weaned or has been through its first summer. Hydrocele is treated by radical operation; in infancy uncomplicated hydrocele is likewise left unoperated until the child is weaned, or if it grows so fast as to cause pressure on the testes tapping may be resorted to as often as is necessary until the desired age is reached. Umbilical hernia, in the vast majority of cases, can be cured by strapping. There have been 362 cases in the out-patient clinic, and only 74, or 20 per cent., required operation. In malformations of the gastrointestinal tract, except for those cases which have merely an unbroken anal membrane that can be broken by finger or hemostat, or those in which the obstruction is so low that the normal gut may be brought down and sutured to the skin at the anus, the prognosis is very bad. Of twelve such cases in this series none have lived. Pyloric stenosis is not an uncommon condition; with its earlier recognition and the development of the Ramstedt operation the condition has lost much of its gravity of prognosis. In this series during the last year there were 22 operations for pyloric stenosis with no deaths. Intussusception is the commonest cause of acute obstruction in children. Of 92 cases of acute obstruction in this report, 70 were due to intussusception. The mortality of 72 cases in this series was 41 per cent. There were 223 cases of acute appendicitis. Frequently in young children the localization of pain and tenderness even if present is difficult to establish. In this type of onset vigorous catharsis is frequently given by parent or physician and this "home treatment" has played a large part in the high mortality of the disease. In this series, for all ages, without a general peritonitis the mortality was 9 per cent. General peritonitis occurs earlier and more frequently than in adults. The diagnosis of chronic appendicitis in children is almost always a matter of history. Acute peritonitis in children over two years of age is practically always due to appendicitis; in children under two years of age acute peritonitis is a grave condition and the mortality is exceedingly high. Of 35 cases of tuberculous peritonitis operated upon, 16 have died either while in the hospital or soon after discharge, a mortality of 45 per cent. From the surgical point of view the success that is often met with by a simple exploration is hard to explain but it certainly exists. Of such conditions as retroperitoneal abscess, ruptured mesentery, ruptured viscus and other traumas, mesenteric thrombosis, megacolon, subhepatic abscess, the various rare abdominal tumors, such as sarcoma of the ovary and kidney, and Gaucher's disease, there were in all 35 cases in this series with an operative mortality of 45 per cent. Deaths in abdominal conditions requiring surgical intervention, excluding hernia, are nearly 40 per cent. of the mortality of the Service. The greatest hope of reducing the mortality is in acute appendicitis and intussusception. The most important factor influencing the prognosis in these conditions is an early diagnosis and operation.

5. Some Aspects of Cancer of the Prostate.—Arthur L. Chute has found in going over his last 200 prostatectomies that in 35, or 17.5 per cent., the prostate was malignant. He deplores the present tendency among some genitourinary surgeons to regard operation as scarcely worth doing in malignancy of the prostate. He concludes that in all instances where a malignant prostate is producing obstruction to urination it should be removed unless the patient's general condition is such as to absolutely preclude this. In the cases in which patients complain of pain in the thighs or sacrum, the perineal removal of the growth will give temporary relief in a number of the cases. Operation in carcinoma of the prostate should be carried out by the perineal route and radium should be left in any bits of suspicious tissue that remain, or in the cavity from which the prostate tissue has been removed. The removal of these growths may be carried out with relatively little risk when done by the perineal route, and there is little probability of a permanent fistula.

1. Cancer of the Tongue: A Preventable Disease.—Joseph Colt Bloodgood submits statistical evidence to prove that cancer of the tongue is largely a preventable disease. Delay in proper treatment after onset of the malignant lesion reduces the chances of a cure in operable cases from 62 to 12 per cent., and increases the chances of postoperative death from 5 to 30 per cent. During the period 1889 to 1921 educational propaganda has increased the number of operable cases from 53 to 80 per cent. and decreased the inoperable and hopeless cases from 47 to 20 per cent. Evidence shows that men who develop cancer of the tongue have had warning by definite local lesions. These precancerous lesions are leucoplakia, bad teeth, areas of irritation, ulcers, syphilitis gumma, warts, fibromas, and smoker's burns. There is also the warning of the definite cancer developing in the precancerous lesion, but this may be insidious. The uninformed person, with rare exceptions, will not seek advice until cancer is in its advanced stage, when he has only 12 per cent. chances of cure and 30 per cent. chances of postoperative death. From this study of 265 lesions of the tongue in men and 33 in women Bloodgood is convinced that the only hope of decreasing deaths from cancer depends on the educational propaganda among the public and the profession. The message to the public is short and simple; but the message to the medical and dental professions must be in great detail, because if people seek advice early, the profession must be prepared to recognize the early precancerous stage when diagnosis is difficult and proper treatment simple. The precancerous lesions mentioned are discussed somewhat in detail.

6. Rôle of Diet in Etiology and Treatment of Migraine and Other Types of Headache.—Thomas R. Brown believes that in certain cases of migraine and other forms of headache, whatever the primary cause, diet plays some part in producing the symptoms of which the patient complains, and that by modifying the diet cure may be obtained in a few cases, and a very considerable amelioration of symptoms in many cases. In his series of fifty or more cases carbohydrates seemed to have played the predominant rôle in the largest number of cases; animal-protein food in almost as many; special foods, notably sugar or eggs in a few cases, while in an occasional case the headache might be regarded as a definite expression of intestinal toxemia or bacteriemia or of an error in purin metabolism. That some disturbance in liver function plays a part in these headaches is suggested by the fact that there is in some cases a temporary enlargement of the liver during and after the acute symptoms. In many cases a very careful clinical analysis, supported by certain laboratory tests, offers a clue to the etiology. In cases in which it is absolutely impossible from the clinical evidence to incriminate any special food or foods, it is wise to place the patient first on a carbohydrate-free diet for a considerable period of time, and if this proves unsuccessful, then on animal-protein-free diet. In this group of migraine cases the treatment is peculiarly unsatisfactory, by many regarded as almost hopeless; this point of view is not justifiable. We should realize that in certain of these cases diet plays a rôle and that some are benefited by proper dietetic therapy.

8. Glandular Fever.—P. F. Morse observes that some diseases seem to be peculiar in their tendency to recur after apparent periods of quiescence. These periods may be so protracted that the medical profession forgets the existence of the disease, and on recurrence of the infection cases are reported as a new disease. We have had a recent example of this in epidemic encephalitis, and at the present time another is before us in a disease first described as a clinical entity by Pfeiffer in 1889, and given the name glandular fever. Until ten or twelve years ago it was fairly well known, but it seems lately to have become so infrequent as commonly to escape diagnosis. A widespread but mild recrudescence is taking place and the affection is again quite prevalent. This affection is supposed to have an incubation period of from five to ten days. The onset is sudden with sore throat and a feeling of stiffness in the neck, and often with upper abdominal pain or discomfort in the left hypochondrium. Nausea and vomiting are common at the outset. Within a week the temperature has usually returned to normal. Physical examination reveals swollen lymph nodes as the outstanding feature. Usually the cervical chain is most involved, but the supraclavicular and infraclavicular, axillary and inguinal nodes are almost always palpable. The spleen is enlarged and tender in about 60 per cent. of the cases. The blood count is most characteristic, a rise to 17,000 to 20,000 being the rule. This increase is due entirely to mononuclear cells. The average lymphocyte percentage runs from 75 to 85. The prognosis is good but convalescence is notably slow. The blood picture and physical examination serve to differentiate glandular fever from tuberculosis, mumps, and acute cervical adenitis. The blood smear is quite different from that of acute lymphatic leucemia. There is a lack of immature, atypical, and degenerating forms of leucocytes, and the presence of large numbers of bilobed or Riedel type of white cells.

12. Gastric Symptoms. An Analysis of One Thousand Cases.—John M. Blackford concludes that in this 1000 cases 14 per cent. actually had organic gastric disease. The roentgenologic examination determined these cases accurately, and with a very small percentage of error. Its negative value is therefore very high. Thirty-four per cent. showed abdominal extragastric disease giving reflex stomach disturbance. Inflammations of the gallbladder apparently caused more stomach disturbance than any other organic abdominal lesion. Eighteen per cent. presented themselves for diagnosis of stomach trouble which, investigation showed, was due to demonstrable systemic disease. Twenty-five per cent. presented no objective pathological condition. Their complaints were considered secondary to habits of living, type of individual, or to chronic debility. One-third of all the cases in which operation was previously performed fell into the functional group. Six per cent. of all cases remained undiagnosed. Thirteen per cent. or more of patients complaining of chronic stomach trouble had lost the appendix before coming to the clinic. Ten per cent. of all women in this series had had previous pelvic operations, one-half done on frankly neurasthenic individuals.

15. Further Observations on Treatment of Scarlet Fever with Immune Human Serum.—G. H. Weaver states that before Jan. 1, 1921, he had used convalescent serum in 54 cases of scarlet fever, including 19 previously reported. All the cases were severe, representing the most severe toxic cases among about 1,200 patients. Thirty-eight were of the toxic type. The serum was usually injected instramuscularly in amounts from 60 to 90 c.c. Occasionally it was injected intravenously, but with no apparent advantage. A second dose after twenty-four hours was given in some cases in which the first dose was not followed by satisfactory improvement. To one familiar with the usual course of scarlet fever, the almost constant fall in temperature, and the rapid improvement in the general condition of the patient immediately after the serum is given is most surprising. Early administration is insisted upon by all who have had experience with the serum treatment of scarlet fever. The procedure is practical wherever scarlet fever is prevalent. The blood apparently loses a good part of its therapeutic value on keeping.

2. **Mucocele and Pyocele of the Nasal Accessory Sinuses.**—Walter G. Howarth has observed fourteen cases of this condition, all connected with the frontal sinus and the anterior part of the ethmoid labyrinth; other recorded cases seem to indicate that this may be regarded as the commonest situation. For the production of the condition partial or complete blocking of the natural ostium must occur. This may be caused by an inflammatory condition or by traumatism. But it may be wondered why everyone who gets a nasal catarrh or sustains a severe black eye does not develop a mucocele. In the writer's opinion the condition depends largely on the ethmoid, only arising when the ethmoid is of a definite anatomical configuration, that is when some of the anterior cells come much further forward than usual and are found in front of the fronto-nasal duct, even in front of the lacrymal bone, and bulge into the floor of the frontal sinus. When this condition is present and the fronto-nasal duct much narrowed by it, it would take but a small amount of plastic inflammation to block it, while a blow near the inner canthus would readily crush this cell into the fronto-nasal duct or obliterate its own ostium. One of the chief characteristics of the condition is the entire absence of symptoms until the external swelling appears. The condition may be confused with cystic dilatation of the lachrymal sac or with tumor of the frontal sinus and orbit, especially osteomata. Treatment consists in exploration of the swelling through an external incision, and the establishment of free intranasal drainage.

3. **Nutrition in Vienna. II.**—Madge R. Gribbon and D. Noel Paton, assisted by Margaret Ferguson and Annabel M. T. Tully, present this investigation, which deals with the condition of the middle classes in Vienna and the rural classes in the neighborhood of that city. Their general conclusion is that a state of undernutrition affecting the growth of these children has existed in Vienna and the adjoining country. No evidence is afforded that this has been associated with any marked increase in the incidence of rickets. The conclusions of previous investigators that rickets tends to affect the later members of large families is borne out by these observations. Life and a certain amount of activity have been sustained on a gross energy intake of a little over 2,000 calories per man per day, which must be explained in the light of Benedict's finding that undernutrition markedly decreases the basal metabolism.

5. **Vitamine a Content of Oils Prepared from Livers of the Cod, Coal-fish, and Haddock.**—S. S. Zilva and J. C. Drummond have utilized in these experiments oils prepared from the unmixed livers of the respective fishes caught this season off the Finmarken coast. The pure cod oil was found just as potent as the liver oils hitherto tested out quantitatively, a daily dose of 2 mg. being required to induce the resumption of growth in rats. Coal-fish oil was even a little more active; slightly less than 2 mg. was found to be the minimum daily dose. Haddock oil, although not so active as the cod and coal-fish oils, showed also a high potency, the minimum daily dose in this case being 10-15 mg. A lower potency than this has been observed by the authors in a well-known brand of medicinal cod liver oil. The oils investigated originated from fishes belonging to the genus Gadus, and the writers are now undertaking various analyses to determine whether the oils of certain other more or less nearly related genera will also be found to exhibit this exceptionally high fat soluble vitamine A potency.

1. **Some Common, but Often Unrecognized, Obstetrical Difficulties.**—W. Blair Bell states that while it is impossible to look upon uncomplicated occipito-posterior presentations as abnormal, the frequency with which they escape detection, and in consequence are wrongly treated, makes it worth while discussing this group of cases. This presentation, if left alone, almost invariably rotates into the occipito-anterior position. The frequency of the occipito-posterior position as a primary presentation has been much underestimated. It is important that the practitioner should recognize this presentation and prepare the patient and her friends for a somewhat longer labor than usual. If there is no doubt that the position is persistent occipito-posterior, manual rotation of the head with manual rotation of the child's body from above, must be practised and forceps applied to the head. The danger of putting forceps on the high unrotated head is so well known as to need no comment. Protracted gestation is not infrequent and the same patients show a tendency to repeat the performance. At the end of ten complete calendar months from the date of the last menstrual period no doubt need exist as to what is happening, provided always the patient has menstruated with perfect regularity except when pregnant. The treatment consists in induction of labor. This is best carried out by the *intramuscular* injection of infundibulum every night and morning for three days, at the end of which time, if parturition have not supervened, a few bougies should, with most scrupulous aseptic precautions, be inserted between the uterine wall and the membranes. Labor almost invariably follows these procedures. The slightly generally contracted pelvis and the simple funnel-shaped pelvis very often escape detection. The non-rachitic flat pelvis is far more common than is generally believed. In this type of pelvis the conjugate diameter may be, and usually is, the only measurement that gives the indication of the deviation from the normal. In this type of pelvis the external conjugate is generally below 19 cm. There is another feature which often conveys an indication of the conjugate contraction, namely, an accessory promontory below the true sacral promontory. The generally contracted pelvis is quite frequently encountered apart from rickets, and is likely to be overlooked in otherwise well-developed females unless the practitioner makes a routine practice of measuring the pelvis of his pregnant patients. The funnel-shaped pelvis is another type sometimes overlooked. In its typical form it affects only the outlet; the measurements of the superior strait are normal, but the transverse diameter between the tubera ischii may measure 8 cm. In dealing with these types of contracted pelves it must never be forgotten that the course of labor and appropriate treatment will be influenced by the size of the fetal head. In the typical funnel-shaped pelvis, while cesarean section is indicated, if the lesion be recognized before parturition, if it be discovered during labor pubiotomy should be performed. Uncomplicated uterine inertia is due to a variety of factors. One of these is insufficiency of pressor substances in the blood. Proper ante-parturitional investigation should be made and if these substances are deficient two ounces of calcium lactate should be given every night for about two weeks before parturition is due. While all these facts are commonplace knowledge, they should occupy a prominent place in the mind of the practitioner.

2. **Experimental Rickets in Rats.**—V. Korenchevsky states that these investigations were started in November, 1920, before the works of the American authors were published. He presents a preliminary report of experiments carried out on rats born at the Lister Institute from stocks that had been all the time under observation. The results obtained agree in a general way with those of Melanby, McCollum, Simmonds, Parsons, Shipley, and Park. It was found that confine-

ment in small cages does not evoke rickets in rats. The introduction of live cultures of *B. perfringens*, *B. sporogenes*, and *B. bifermentans* with the food, and of *B. sporogenes* and *B. bifermentans* subcutaneously, produces no visible effect on the development of rickets in rats. The deficiency of the diet in calcium alone can produce changes in the skeleton of rats which present some resemblances with rickets, especially when the young rats have originated from a mother kept on the same diet during lactation. Usually deficiency of food in vitamine A produces in rats impoverishment of the bones in calcium, enrichment in water, and osteoporesis with deficient osteogenesis, and in some cases a picture resembling slight rickets. Changes in the skeleton more similar to rickets and in some cases typical of rickets, were observed in young rats on a diet deficient in vitamine A, provided their parents had been fed on such a diet, during conception, pregnancy, and lactation. Vitamine A has a relation to the metabolism of cal ium in the organism and particularly in the bones, and therefore to the development of rickets. The changes typical of rickets occur most readily and most frequently in rats kept on a diet deficient in both vitamine A and calcium. It was found that castration performed before the commencement of feeding had no marked effect on the chemical and histological changes in the skeleton of rats fed on a normal diet, on diets deficient in calcium or vitamine A, or deficient in both.

2. Carcinoma of the Thoracic Esophagus Extrapleural Resection and Plastic.—Dr. Howard Lilienthal states that this operation was devised to minimize the danger of septic mediastinitis. It was recognized that before opening the esophagus the mediastinum must be sealed off by a healing process which should have advanced to the stage of granulation. The patient was a man 35 years of age, with a partially obstructing squamous cell carcinoma below the arch of the aorta. At the first step the operator lifted a skin flap about 3 inches in width and 10 inches in length which was outlined by an incision beginning at the 8th interspace close to the spine, passing obliquely forward parallel to the ribs, thence downward and then backward to a point about 3 inches below the place of beginning. This flap was used in fashioning the new esophagus to take the place of the resected part. A 6-inch subperiosteal resection of the ninth rib was then made and the pleura stripped forward away from the posterior mediastinal region. The eighth, seventh, and sixth ribs were cut through near their spinal attachments after peeling the pleura away, and then the tenth rib also was divided. The pleura could now be pushed forward, exposing the organs within the mediastinum through a wound large enough to permit the surgeon to work with both hands in its depths. With a stomach tube in the esophagus this structure was easily identified and stripped from the pleura and aorta. The fibers of the plexus gulae of the right vagus were divided. The fusiform swelling which marked the tumor within the gullet was about an inch and a half below the arch of the aorta. The skin flap was placed in the wound so that it partially encircled the mobilized esophagus, with the cutaneous surface toward the viscus. This first step of the operation was concluded by packing the wound with gauze. The patient could swallow fluids. Two weeks later, without anesthesia of any kind, the wound was spread apart and the tumor bearing section of the esophagus was resected. Nourishment was now given through a stomach tube passed into the lower esophageal opening, and later through an Einhorn tube passed from mouth to stomach through the gap left by the resection. The pedicle of the skin flap was cut across in another week. There was later contraction of the cicatricial tissue of the mucocutaneous margins, making it necessary to divide the strictures by stellate incisions and thereafter bougies were passed frequently. The final step was to close the posterior esophageal opening by suture and to make a plastic operation to cover the defect in the patient's back with skin by the use of sliding flaps. A few days after this final procedure liquids could be swallowed without leakage and soon all wounds were healed and any soft food could be taken normally. A number of drawings were made at the operation and are reproduced in the article. There are also roentgenograms and a photograph. Other cases in which this exposure was made are reported, but all proved inoperable. The conclusions are as follows: (1) That transpleural resection of the esophagus has a forbidding mortality. (2) That fatal infection follows the primary opening of the esophagus within the mediastinum. (3) That it is feasible to make an extrapleural exposure of the posterior mediastinum large enough to permit the operator to see clearly and to work safely with both hands. (4) That resection of the esophagus in the posterior mediastinum can be done by dividing the operation into two stages. At the first the esophagus is freed from its attachments and the mediastinum is sealed. At the second, 10 to 14 days later, the resection is performed. (5) This procedure deserves a fair trial by thoracic surgeons.

8. Ligation (Partial Occlusion) of the Abdominal Aorta for Aneurysm.—George Tully Vaughan reports a recent case and gives a résumé of previous cases. He ligated the abdominal aorta according to Halsted's principle of incomplete occlusion, using a piece of tape instead of the metal bands. The tape was carried around the vessel about 2 inches above its bifurcation and just below the origin of the inferior mesenteric artery. Two turns of one end of the tape made a surgeon's friction knot, which was drawn tighter and tighter until pulsation was no longer perceptible in the iliacs and barely so in the aorta above the ligature. The patient was kept in bed most of the time for two months, and potassium iodide administered. Five months after the operation he returned to his occupation as bricklayer. He is still alive and working, one year and four months after the operation.

21. The Surgical Removal of Pancreatic Stones.—Walter Ellis Sistrunk, in reviewing the histories of the patients operated upon for pancreatic calculi in the Mayo Clinic, finds that during eleven years this operation was performed four times. It is customary in this clinic to routinely examine the pancreas in all patients operated upon for upper abdominal disease. The fact that so few pancreatic calculi have been found during this time shows that they are extremely rare, or very difficult to recognize at operation. It is probable that such stones are often overlooked during the course of abdominal exploration, as they have been found at autopsy a number of times. Operations for the removal of pancreatic stones present difficulties only when the stones are impacted in the ducts near the ampulla, and can usually be performed safely.

Book Reviews.

DISEASES OF CHILDREN, Designed for the Use of Students and Practitioners of Medicine. By HERMAN B. SHEFFIELD, M.D., Formerly Instructor in Diseases of Children, New York Postgraduate Medical School and Hospital, and Medical Director, Beth David Hospital, Consulting Physician to the Jewish Home for Convalescents and the East Side Clinic for Children. With 238 Illustrations, Mostly Original, and Nine Colored Plates. Price, $9.00. St. Louis: C. V. Mosby Company, 1921.

Dr. SHEFFIELD has given us in this volume of nearly 800 pages a work that will surely gain recognition on its merits as among the most practical treatises on the diseases of infancy and childhood. It embraces the entire subject, beginning with chapters on the methods of prevention and control of disease, the various diagnostic tests, and the examination of the sick child. A special chapter is devoted to the mental diseases of childhood—the insanities as well as idiocy and mental deficiency. In the preface the author ventures the opinion that some cases of dislocation of the hip in infants are not congenital, but are acquired as the result of sepsis. We have not been able to find any discussion of this in the body of the work, but it would be interesting to learn the grounds upon which Dr. Sheffield bases this theory.

The illustrations are for the most part original and are well chosen; they are beautifully printed, but the comfort of the reader has been more or less sacrificed to them, for the entire book is printed on heavy calendered paper, adding to the weight and causing distress to the eyes by the reflection. In spite of this drawback, the book can be recommended to practitioners, especially the younger ones, whose work includes the care of children, for they will find between its covers much valuable advice.

GRAPHIC METHODS IN HEART DISEASE. By JOHN HAY, M.D., F.R.C.P., Honorary Physician, Liverpool Royal Infirmary; Honorary Consulting Physician, Ministry of Pensions; Late Consulting Physician in Diseases of the Heart (Western Command). With an Introduc by Sir JAMES MACKENZIE, M.D., F.R.C.P. New York: Oxford University Press, American Branch, 1921.

THIS is a book which, despite its rather technical sounding title, is one that the general practitioner will find exceedingly useful; for even if he does not make graphic records himself of his cardiac patients, he should be in a position to interpret those made for him or those illustrating articles in journals and special treatises. But especially will it be found of service as a guide to the student who seeks to acquire a knowledge of this comparatively new science—one of exceeding interest and full of promise for the future of cardiac diagnosis and therapeutics.

SQUINT: ITS CAUSES, PATHOLOGY, AND TREATMENT. By CLAUD WORTH, F.R.C.S., Consulting Surgeon to the Royal London Ophthalmic Hospital (Moorfields), Consulting Ophthalmic Surgeon to the Queen Mary's Hospital for the East End. Fifth Edition. Price $3.50. Philadelphia: P. Blakiston's Son & Co., 1921.

THE author of this book has been for years among the most prominent investigators on the subject of strabismus, and the fifth edition of his deservedly popular book on the subject will be welcomed. It is written in a clear, lucid style, and embodies the results of clinical experience extending over a period of years. In common with the more progressive ophthalmologists of the time he advocates the treatment of squint from earliest infancy, and to judge by the clinical histories he obtained good results when persistently following his line of treatment. It has been the unfortunate experience of every eye man to come across many strabismus cases whose complete or partial amblyopia was undoubtedly due to neglect of early treatment, whether by occlusion, atropinization of the sound eye, or training of the fusion sense, and one cannot but agree with the dictum of the author as expressed in the preface that of the cases of squint in which efficient treatment is carried out from the first appearance of the deviation, only a small proportion will ever need operation. While of undoubted value as a guide to the specialist, this book will be found useful to the general practitioner, who is often the first to see the squint and on whose early recognition of the trouble may depend the entire future of the child.

SLEEP WALKING AND MOON WALKING. A Medico-Literary Study. By Dr. J. SADGER, Vienna. Translated by LOUISE BRINK. Nervous and Mental Disease Monograph Series No. 31. New York and Washington: Nervous and Mental Disease Publishing Company, 1920.

FOR eons human nature has struggled along, trying to understand and to comply witih the laws of life, but ofttimes doing it in ignorance of the meaning and outcome of the struggle. Now comes along psychoanalysis, and according to recent conceptions, we are in the dawn of a new type of understanding—thrilling, gripping understanding, but not exactly pleasing.

As a ray of light bringing the dawn of psychoanalysis this monograph serves its ends, but it most assuredly is a strong yellow ray, almost a lurid ray at times. Frankness, generosity of view, and almost sanity save the writer in his handling of this subject. While it is beautifully written, showing a simplicity and a grasp that are a delight to the reader, at times these powers are all that seem to hold the subject matter from carrying out the discussed intentions—sleep walking and moon walking. One cannot figure whether the writer is right or wrong. One can only figure that, if we *must* believe the writer and other wanderers like him, human nature has certainly carried over a lot of unnecessary junk, degradedness, and childish motives in order to square this life and the great unconscious, socalled.

THE DIAGNOSIS AND TREATMENT OF INTUSSUSCEPTION. By CHARLES P. B. CLUBBE, L.R.C.P., M.R.C.S. Consulting Surgeon to the Royal Prince Alfred Hospital; Consulting Surgeon to the Coast Hospital, Sydney; Hon. Surgeon to the Royal Alexandra Hospital for Children; Late Lecturer in Clinical Surgery, University of Sydney, New South Wales. Second Edition. New York: Oxford University Press, American Branch, 1921.

THIS edition has been completely revised and is based upon the experience gained in treating 270 cases of intussusception. The author gives a concise but sufficiently detailed description of the anatomy, pathology, etiology, varieties, symptoms, diagnosis, and treatment of the condition, and a short chapter on the after-treatment. There are also two appendices; one giving a list of cases that have recovered after resection of bowel; the other a description of some cases that have recovered after irrigation, some in which there were recurrences, two of retrograde intussusception, and a number of unusual cases of various kinds.

Clubbe emphasizes one point very frequently (and it is one that cannot be emphasized too strongly); namely, that the treatment for intussusception is *laparotomy*, and that directly an intussusception has been diagnosed arrangements should be made without any delay for opening the abdomen. Irrigation he considers of value in certain circumstances and to a very limited degree—his views must be read *in toto* to be fully understood and appreciated—but he makes it perfectly clear that operation, the earlier the better, is indicated in all but a very small percentage of cases.

The book was designed to help the young practitioner and the young surgeon and should be a great help to them; but it also contains much of great interest and value to older practitioners and surgeons as well.

UEBER DISPOSITION. Ein Versuch die Pathogenese der Kontagiösen und der Infektions-Krankheiten sowie das Problem ihres Gehäuften Auftretens auf naturwissenschaftlicher Grundlage zu erklären. Von Dr. FELIX U. SZONTAGH. Berlin: S. Karger, 1918.

THIS volume comprises 347 pages, divided into 14 chapters on the following subjects: Necessity of predisposition to epidemics for their existence, volatile contagion, scarlet fever, genetic and œkological factors, law of specificity, variability of disease exciters, constitutive principles, preparation for disease, predisposition and immunity, phenomena of intoxications, the cancer problem, the milieu theory.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held March 15, 1921.

DR. SAMUEL BRADBURY IN THE CHAIR.

Duodenal Dilatation.—Dr. HAROLD BARCLAY presented this paper, in which he divided duodenal dilatation into two groups, acute and chronic. The acute dilatation, he said, was well known under the name of "acute dilatation of the stomach, following abdominal operations. The chronic dilatations of the duodenum were reclassified under two subdivisions, (1) those due to organic stenosis, (*a*) in the duodenal wall such as ulcer, or (*b*) about the duodenum, as adhesions, tumors, etc.; (2) mechanical occlusion of the duodenum, produced by traction of the root of the mesentery or constriction of congenital bands and adhesions. The writer referred to various synonyms for this condition existing in the literature and defined chronic duodenal obstruction as intermittent, incomplete constriction of the duodenum from pressure of the superior mesenteric artery and mesentery against the body of the vertebra or by bands or adhesions. After discussing various theories advanced to explain the condition, Dr. Barclay showed lantern slides illustrating the normal duodenum which was like the capital letter C and two other forms, the V and the U-shaped, each of which had pathological possibilities. Some of the causes of chronic dilatation of the duodenum in their order of frequency were: (1) ptosis of the transverse colon, particularly of the hepatic flexure, with or without gastric ptosis; (2) a small intestine which was provided with only a short mesentery; (3) a jejunum which dropped perpendicularly instead of having the normal sweep into the left inguinal fossa; (4) old duodenal ulcer which had become attached to the gallbladder or liver, producing a sharp kink; (5) two types of bands in the upper abdomen, one embryological and the other acquired. The embryonic bands were remnants of the gastrohepatic omentum which passed from the pylorus to the liver or gallbladder, and compressed the first portion of the duodenum. Acquired or developmental bands might pass from the transverse colon to the pylorus, liver, or gallbladder, constricting the duodenum between the band in front and the non-yielding vertebra behind. When prolapse of the stomach occurred to such an extent as to angulate the first portion of the duodenum, attacks of temporary obstruction might occur. The symptoms were like bilious attacks only there was more pain, paroxysmal in character, due to the intermittent obstruction. The intermittency in obstruction was produced by the changing position of the prolapsed stomach. The question of duodenal dilatation had remained more or less obscure and aroused but little general interest until within the past several years. There had been a number of reported operations, the majority with seemingly good results. There were many clinicians and surgeons who denied its existence, or if it did exist failed to see in it more than a phase of the generally accepted picture of visceroptosis. From his own experience in the study of 29 cases it appeared that different states of duodenal pathology were anything but rare, and would account for many cases heretofore regarded as simple gastric atony or neurosis. It had seemed in reviewing the evidence for and against that partial duodenal obstruction was a real clinical entity, and one that might account for the symptoms in those cases in which explorations had been undertaken for a possible ulcer, or a pathological gallbladder or appendix, and nothing abnormal found. Dr. Barclay said that from the standpoint of surgical control his experience with these cases had been limited; in two cases, however, it had been strikingly satisfactory. One of these was a young man, 25 years of age, who for five years had had hunger pains becoming progressively worse. The *x*-ray showed a prolapsed, fish-hook stomach with an eight hour 50 per cent. retention. Exploratory laparotomy failed to reveal anything. His symptoms returned within less than two weeks after he left the hospital. After losing sight of the patient for two years he returned and stated that his case had been diagnosed on the Pacific coast as duodenal obstruction and a duodenojejunostomy done with complete relief. The second case was that of a girl suffering with epigastric distress and nocturnal convulsions increasing in severity and frequency. In her case, also, the *x*-ray showed a prolapsed stomach of the fish-hook type. Duodenojejunostomy had restored this child to apparently normal health. In discussing the symptomatology the writer said it was well to remember that in many the condition was congenital. In the young adult who had not been subjected to prolonged illness or undue nervous strain, in fact any condition that caused loss of weight and overfatigue the stomach musculature amply compensated, and they were free from symptoms. As time went on as the result of pregnancy, sickness, or mental anxiety the neuromuscular tone was reduced, there was loss of weight and relaxation of the recti, with consequent sagging of the abdominal viscera. Under these conditions the first signs of a failing gastric compensation took place, and the stomach began to fail in its motor function. With this failure symptoms began. Perhaps the earliest symptom of chronic duodenal dilatation was the distress beginning in the epigastric region or more properly a little toward the right. At first this occurred three or four hours after meals, was moderately relieved by food, and began again as the stomach emptied. The onset was very similar to the symptoms usually described as gastric ulcer. As time went on the distress became more continuous, later there was belching of gas, constipation, the heart became irritable and rapid, and this irritability could not be explained by any cardiac disturbance or exophthalmic goiter. The picture was one of marked autointoxication and the general manner of the patient strongly suggested this condition. The patients might show evidence of neurasthenia, complain of headaches, and the urine might be scanty and of high specific gravity; it did not always show much indican. The anuria, subnormal temperature, etc., suggested that the secretion from the duodenum stimulated the vagus and lowered the vasomotor tone. The diagnosis of these conditions rested almost entirely with the radiologist, though there were certain conditions which the clinician might elicit. Many of these patients referred their pain to the right iliac fossa, complained of a feeling of fullness and discomfort. At times one might elicit a very definite tenderness either over the gallbladder region or again over McBurney's point, or both. In contracting their abdominal muscles and taking a deep breath, or by raising the stomach with the hand a kink seemed to be freed with a consequent gush of gas and temporary relief. A distended ptosed cecum may likewise be of some significance. Hays deep percussion test over the right rectus muscle in the area bounded by the liver to the right, by the normal transverse colon line below and the pylorus to the left, was said to give a tympanic percussion note when duodenal dilatation existed. Examination of the stomach contents furnished no definite data. Examinatin of the stools in certain cases showed definite carbohydrate indigestion, as evidenced by fermentation and an excess of free starch. The ultimate diagnosis must rest with the *x*-ray. The reason why the condition had not been recognized earlier was because *x*-ray plates had been relied upon. To make the diagnosis the upright patient should be fluoroscoped after the ingestion of the bismuth, the stomach pushed up by the right hand and the duodenum then became very evident. The medical treatment was discussed under the headings of postural training, the supporting belt, diet, and duodenal lavage.

X-Ray Diagnosis of Duodenal Dilatation.—Dr. HARRY M. IMBODEN made this contribution, which consisted of a lantern slide demonstration. He stated that his interest in this subject was aroused by seeing a relatively large number of asthenic stomachs in cases in which the symptoms were not accounted for by the ordinary manifestations of ptosis. A certain number of these patients showed retention in the duodenum. The condition and *x*-ray findings were described by Jordan eight years ago and while their knowledge of the subject had grown considerably during that time the interest of physicians and surgeons had not been centered upon

this subject. Ulcer and carcinoma were the only diseases in which they were primarily interested and he had found this true practically throughout the country. The clinical manifestations of duodenal dilatation could not be definitely relied upon; the *x*-ray findings, on the contrary, were very definite and conclusive. These were: (1) Reverse peristalsis, which was a symptom of obstruction in any part of the canal except the cecum and ascending colon. (2) Writhing and twisting. This seemed to be a supreme effort on the part of the duodenum to empty itself. The barium meal passed backward, sometimes to the pylorus and sometimes through the pylorus into the stomach. This might be repeated time and time again and finally the barium might be forced into the jejunum. Once one had seen this phenomenon he would never forget it. (3) Puddling. This was simply an accumulation of the contents in the lowest part of the duodenum and showed that the duodenum was unable to empty itself. (4) Dilatation. This was seen in advanced cases and a lengthening as well as an increase of the diameter of the gut was shown. (5) Tenderness over the angle of Treitz. This must be elicited with the patient in the standing position to be of value. Under the screen one lifted the stomach and followed it up with the finger to the angle and if it was tender you would find it out promptly without questioning the patient. The findings in less chronic cases were of course less pronounced than those delineated. It had been said that dilated duodenum was present only in ptotic patients; that was not correct because within the past two months he had found it in two typically sthenic patients. The diagnosis could not usually be made from the *x*-ray plates no matter how many were made but only from the screen examination. The only operation indicated was duodenojejunostomy.

Dr. JOHN L. KANTOR said that in listening to this presentation one question that had occurred to him was whether this condition could be regarded as a clinical entity of importance, and whether it occurred frequently. Neither of the speakers had mentioned approximately how often such a condition was to be met with. One who had not the advantage of all methods was not in a position to say whether or not this was a clinical entity and whether or not it was of clinical significance. Again we might say that all these cases might be divided into two groups, those due to organic lesions and those due to socalled functional conditions. It would be well if we could differentiate these so that we could tell whether we were dealing with a real pathological lesion or with a condition that might be due to constitutional causes. There was no question that when adhesions were present, or tuberculous nodes, or a cicatricial lesion that retention was to be expected. He did not see how the presentation was complete without a demonstration showing where the primary delay was. In some of the slides it seemed that the primary obstruction was in the jejunum and ileum, lower down in the intestinal tract. Then there had been no reports of postmortem examination. If one went back in the literature it would be found that Jordan first described the condition in 1912, but if he remembered correctly his claims were not universally accepted. He was not clear whether Dr. Barclay was describing a condition that was as rare, for example, as gastromesenteric ileus, or whether he implied that we had been overlooking a common condition. If one could see hundreds of cases without meeting a case of dilatation of the duodenum he thought it was against its being very common. Again when the duodenum was enlarged one should look for intestinal obstruction. Any stasis that went with atony here or elsewhere was quite capable of producing dilatation of the duodenum and the symptoms described, as was the stasis associated with migraine, mental symptoms, and insanity.

Dr. GEDDE A. FRIEDMAN stated that about eleven years ago he had observed two cases of acute paresis of the stomach and duodenum: in one case the condition followed an operation for appendicitis and a secondary operation proved the diagnosis; in the other case the acute paresis of both viscera was found at autopsy. A complete report of these two cases and of a third case was clinically observed, was made in the *Archiv f. Verdauungs Krankheiten*. In this paper he discussed at length on the causes of acute gastric and duodenal paresis, which as was well known, were various. Acute dilatation of the stomach and duodenum were described after indigestion, or after prolonged anesthesia, and infectious diseases. If one looked over the literature he found cases spoken of as chronic indigestion in which the duodenum was only dilated in the first portion. By *x*-ray examination the cap of the duodenum in such cases would have shown an ectatic condition, while other parts of this viscus would not be dilated. In the German and the French literature paralytic duodenums have been described as of central origin and in the article referred to he had gone into this theory. Referring to Dr. Barclay's paper, it was correct to think that some of the causes which were responsible for acute dilatation of the stomach and duodenum were also responsible for chronic dilatation, save for cases in which the dilatation was due to obstruction from adhesions. Dr. Friedman said he had the slides from a patient who developed this condition three months after a prolonged operation for gallstones, ulcer, etc. A gastroenterostomy was done and the appendix removed; the operation being difficult and lasting two hours, and about three months later the patient came back with symptoms of indigestion. The first and second portions of the duodenum were markedly dilated. This condition of chronic dilatation of the duodenum was probably what Dr. Kantor was referring to when he asked if it was considered rare or whether it was frequently overlooked. As to whether the operation was of great benefit Dr. Friedman said he knew from the literature about gastroenterostomy in acute dilatation and that it was absolutely of no avail. There were cases not due to mechanical conditions, in which there were no mesenteric adhesions only acute dilatation from a possible central cause; therefore he did not believe these cases would yield such excellent results from surgery.

Dr. MAX EINHORN said he was very much gratified to hear the readers of the papers discuss this subject in such a thorough manner. He had been present when Dr. Bloodgood read the paper mentioned by Dr. Barclay and had seen a few cases of duodenal dilatation himself. The diagnosis was rarely made clinically, though he had seen cases with symptoms of obstruction and paroxysmal vomiting at times. The thing he found most often in the fasting stomach in duodenal dilatation was bile mixed with gastric juice and some remnants of food. If the examination of the stomach and duodenal contents was to be of any diagnostic value it must be made on the fasting stomach. The last patient in whom he had made this diagnosis was one seen two years ago. In this case the *x*-ray examination did not show any distention because the pylorus was not obstructed, but he found remnants of food with bile from the duodenum in the stomach, though not much; that pointed to obstruction of the duodenum and not to obstruction of the pylorus. Many of these patients were of the visceroptotic type. Sometimes dilatation of the duodenum gave clinical symptoms but those were the cases of real obstruction in which surgery was indicated. In some of the cases of visceroptosis there was a six or eight hour retention; if the stomach emptied in a proper manner they could be cured by proper diet. Some cases of duodenal dilatation no doubt did require surgery if they did not get along with medical treatment.

Dr. DAVID BOVAIRD said it was one of the delights of medicine that one was always meeting with something new. Of this particular subject, duodenal dilatation, he knew nothing until his return from the late unpleasantness; since that time it had been brought to his attention and he had become very much interested in studying patients in whom this new knowledge might be applied. He had had three patients whom he had been following for some months and who were finally brought to operation. In one instance the condition was one of obstruction in the second portion of the duodenum; in the two others the obstruction was at the angle of Treitz. All had been observed for months and carefully studied repeatedly. In none was he able to make a satisfactory diagnosis until the *x*-ray was employed and until a screen examination was made. Under the screen one saw very readily the condition that had been described tonight, but until one had seen it under

the screen it would be more or less obscure, once seen under the screen, the reality of the clinical condition was assured. Two of the patients were completely relieved and the third partially. In all three the most striking clinical symptom was vomiting. In one instance the vomiting covered a period of three years. In a second there were recurrent attacks of vomiting; this symptom was by no means constant but might occur periodically. One of the patients was a young farmer who, in the interval between attacks, was perfectly well, but during an attack lasting about three weeks, he was so prostrated that he could not work. Since the operation he had been constantly at work. Another patient was a farmer's wife, 30 years of age, who complained of indefinite gastric distress without pain which she relieved by emptying her stomach. She had ptosis and kinking of the duodenum at the angle of Treitz. Diet and abdominal support were tried without relief. Since operation she had been perfectly well. The third patient had had chronic vomiting for three years, absolutely without pain. Operation had relieved him, but he was by no means cured. The difficulty in this instance was that probably the vomiting was established as a habit. In addition to these patients who were operated upon he had had a number of patients who were not subjected to operation. Some of these patients were relieved by the treatment used for ptosis. Dr. Bovaird said he thought they were fortunate in having this subject presented by an internist, and the point made perfectly clear that these cases were by no means all surgical, though the severer types were relieved only by surgery. In the terms used to designate the condition the least valuable had been chosen; it was really an obstruction rather than a dilatation. Chronic dilatation would be relatively unimportant if there were no obstruction; it was the obstruction that had to be relieved.

Dr. EDWARD L. KELLOGG stated that there was a duty to be performed in reminding the profession of the existence of this pathological entity for it appeared to be little understood. The papers read were timely and instructive. A review of the literature was interesting. The first mention found in the literature was a case report of chronic duodenal obstruction in 1752 by Frederic Boerner, a German, who wrote in Latin a flowery dissertation describing the symptoms and autopsy findings. He mentioned the marked dilation of the stomach and stated that a stricture was found in the duodenum so tight as to preclude the passage of "the most dilute fluid." The next mention of chronic obstruction appeared 137 years later in Glenard's report, but there were earlier descriptions of congenital obstruction and Rokitansky in 1849 referred to the mechanism of acute obstruction. Robinson in 1900 discussed the subject exhaustively after fifteen years of study. His report was the most complete and comprehensive treatise of the subject up to that time and referred to thirty odd cases of chronic obstruction. Codman, Conner, Bloodgood and Laffer had presented excellent studies of the condition. It might simulate appendicitis, duodenal ulcer or gallbladder disease but frequently the diagnosis could be made from the history and physical examination. Dr. Kellogg stated that in his experience the *x*-ray examination failed to reveal the condition in many cases. Dr. Imboden's paper made this feature of the diagnosis much clearer and he had no doubt that with the improved technic the diagnosis would now be made in the majority of cases. It was probable failure was sometime due to the fact that peristalsis had been stimulated by a preliminary cathartic or that the cause was not continuously operating. Bloodgood has described a group in which a dilated and movable cecum with prolapse of small intestine caused obstruction by the mesenteric drag upon the duodenum. The obstruction might exist only when the cecum was weighted down by its contents. Medical treatment was usually successful, but if it failed surgery was indicated. We must differentiate between obstruction in the first, second and third portions of the duodenum. Harris had made a special study of the first group. These cases might be cured by gastropexy (the Beyea operation) or by dividing adhesions and readjusting the duodenum (duodenojejunostomy was not indicated). In obstruction of the second portion, possibly caused by adhesions extending from the gallbladder, duodeno-duodenostomy had been occasionally performed or cholecystectomy. When the obstruction was below the ampulla of Vater or at the termination of the third portion of the duodenum, duodeno-jejunostomy was apt to be the operation of choice. The literature contained reports of this procedure in fifty-eight cases with no mortality. In Dr. Kellogg's series of forty-one cases the majority were markedly benefited. In only one case was there a complete failure. Some patients would obtain more relief if treated by resection of the cecum and ascending colon as advocated by Bloodgood. This method was applicable particularly when constipation was a prominent symptom, as it cured the constipation and at the same time relieved the drag on the duodenum.

Dr. SEYMOUR BASCH stated that it was important to bring out the point that we had here two conditions, a medical one and a more or less surgical one. Dr. Imboden had described the picture which had been described by Jordan in which there was a real organic obstruction. There was another type in which we did not get the classical symptoms of obstruction but rather manifestations of atony. If one made the mistake of urging operation in the atonic type one is apt to meet with disaster. Dilatation meant not necessarily obstruction, but might mean poor peristalsis and poor secretions. One should be sure that he was dealing with a real mechanical obstruction before advocating surgery. Dr. Basch emphasized the value of the *x*-ray in bringing out conditions, diverticuli, adhesions, etc., in the lower duodenum as well as in the upper portion. The whole subject of duodenal dilatation and diverticuli would have been lost had the *x*-ray not brought it to our attention.

Dr. L. T. LEWALD stated that he had seen and followed up four cases of duodenal dilatation. One was a congenital stricture between the second and third portions of the duodenum in a child. That case was operated upon by Dr. Downes, who performed a gastroenterostomy. Dr. LeWald had been present at the operation and had seen the stricture, though its exact type could not be determined, that was, whether it was an anatomical defect or an outside band. The gastroenterostomy was not efficient and a second operation had to be performed to excise the pylorus. Dr. Downes had stated that a duodeno-jejunostomy would have been preferable. In the second case there was a group of tuberculous lymph nodes obstructing the second and third portions of the duodenum. This group of glands could not be removed, but a duodeno-jejunostomy was performed with a cure. The third case was one of duodenal ulcer with adhesions. Dr. LeWald said he had examined this patient before operation and his attention was drawn to the duodenal dilatation. The ulcer was in the first portion of the duodenum and the obstruction was due to dense bands extending to the gallbladder region. The ulcer was excised and a gastrojejunostomy done. The fourth case was associated with ptosis and was operated upon successfully by duodeno-jejunostomy. He thought the cases associated with ptosis were the ones in which it was most difficult to determine whether or not medical treatment was sufficient. In this fourth case there was a water-trap stomach and a dilated duodenum associated with gastroptosis and angulation at the duodenojejunal junction. This type of case was observed in a series of cases of "Water-trap Stomach" published in 1913 by Dr. LeWald.

Dr. BARCLAY, in closing the discussion, stated that the subject was a new one and they were scarcely as yet in a position to make any definite statements as to the frequency of duodenal dilatation. He thought a large number of these cases should be treated along the general lines applied to the treatment of ptosis. If the condition was as common as he had been led to believe, the cases that required surgery were comparatively rare. He thought we should be ultraconservative before rushing blindfold into surgery.

Dr. IMBODEN, in closing the discussion, said that so far as the frequency of duodenal dilatation was concerned, the marked cases, with retention of six or eight hours were definitely less than those of gastric and duodenal ulcer. Speaking of the medical treatment, they had many cases treated medically but these he could not show because they had to be examined by the

fluoroscope in order to demonstrate the condition. The less marked cases were perhaps as frequent as ulcer but he was not sure. So far as autopsies were concerned, none of the patients had died. These cases were frequently missed unless they were studied carefully under the screen. It required time and patience to make the diagnosis and, as Dr. Kellogg had said, symptoms were not always present.

Experiences with the Lyon Test (Magnesium Sulphate Lavage of Duodenum) for Determination of Gallbladder Disease.— Dr. BURRILL B. CROHN, Dr. JOSEPH REISS, and Dr. MORRIS T. RADIN presented this communication, which was read by Dr. Crohn. They stated that the fruition of this test and its therapeutic application depended upon the successful demonstration of all the following premises: (1) Demonstration of the presence of a functioning sphincter at the mouth of the common bile duct. (2) Demonstrations that rhythm and contractions of the gallbladder walls and simultaneous relaxation of the sphincter action at the papilla were both controlled by contrary acting systems of innervation. (3) Evidence to show that magnesium salts caused relaxation of the smooth muscle of this sphincter when applied to the duodenal mucosa and thus reflexly caused contractions and emptying of the gallbladder. (4) That the fluid obtained was really gallbladder fluid and that changes in color, consistency and amount indicated disease. (5) That cytological, chemical and bacteriological examination of this fluid was both possible and feasible and led to dependable conclusions regarding gallbladder pathology. The steps in the theorem of Lyons were as follows: The magnesium sulphate solution, introduced through the duodenal tube in the fasting state, relaxed the sphincter at the mouth of the common bile duct. A flow of bile, common duct bile, or "A" bile, as Lyon called it, followed. Immediately thereafter the gallbladder contracted as a result of the application of the law of contrary innervation and the gallbladder, or "B" bile, appeared in the duodenum and was aspirated or syphoned off. There followed now in order "C" bile or bile from the hepatic ducts, and finally "D" or pure liver bile. Upon the collection of these fluids and their examination Lyon based his conclusions regarding the character of these specimens, their normality or abnormality, and upon the amount and character of the "B" bile were based his assumptions regarding the size and status of the gallbladder. Similarly he deduced the facts from observations upon the "C" and "D" bile regarding the presence of cholangitis or of intrahepatic suppuration. In discussing the first premises, the writers reviewed the work of Oddi and Henerickson, and described experiments of their own on dogs, by which they were able to demonstrate a definite sphincteric action at the mouth of the common bile duct, though not actually a certain anatomical sphincter. As regarded the second premises, physiologists were not in accord. Experiments which they had carried out with the assistance of Dr. Auster in the Laboratory of Physiology at Cornell Medical School in which the gallbladder bile was stained blue to identify it showed that cholegogues and solutions of salines and peptones had a tendency to encourage the flow of liver bile but they found no agent applied to the duodenum that caused the expulsion of the gallbladder contents. Strong faradic stimulation of the peripheral end of the right vagus caused general abdominal contractions of intestines, diaphragm, stomach, etc., and with these the expulsion of gallbladder bile, though no evidence of actual muscular contractions of the gallbladder were seen. They were led to believe from their observations that the gallbladder was a rather inactive organ which took little part in the physiological production, storage or expulsion of bile. Similarly the sphincter, while capable of contractility and closure under mechanical and faradic stimulation, acted very little normally as a sphincter. The flow of bile was continuous, not interrupted or rhythmic, and no functional use of the sphincteric muscle was observed. In investigating the third proposition, the writers discussed the work of Meltzer on the action of magnesium salts, and state that in these experiments on dogs in which the gallbladder contents were stained blue to identify them, they applied to the mucosa of fasting dogs' duodenum a concentrated solution of magnesium sulphate. In the fasting state practically no bile of any kind passed out of the papilla; the gallbladder was moderately full. No amount of magnesium sulphate caused any expulsion of the gallbladder contents. This experiment was repeated on eight dogs with the same negative results. In discussing the fourth premises, the writers stated that they had carried out magnesium sulphate lavage of the duodenum in seventy cases, the test being repeated a second and a third time in a few of the cases. These were all cases of gallbladder or bile duct disease or related conditions. Twenty of these cases were followed to the operating table and furnished criteria for an honest judgment. The technique of Lyon was simplified and adapted to hospital use. After the magnesium sulphate lavage the flow of bile was truly more profuse and abundant, usually a darker shade, varying from dark yellow or orange to a dark brown or deep greenish brown. After twenty to forty minutes the shades of bile again became lighter and within three-quarters to one hour returned to their original hue. This change took place in 65 per cent. of the cases and was accompanied by a pathological condition in 62 per cent. of these cases. In the remainder of the cases, sixty-eight in all, a definite change to darker and cloudier bile occurred, after the lavage with magnesium sulphate, yet no pathological condition was found at operation. On the other hand, seven cases were encountered in which no color change followed the lavage; of these five cases had definite pathological changes associated. Of these five cases without changes in the bile, three had at operation apparently stones in the cystic duct; in the other four cases in which no change of color scale occurred, no cause was found at operation. The writers then discussed the origin of the "B" bile and stated that even conceding the point that the "B" bile was usually gallbladder content, occasionally abnormal common duct bile could produce the same change. The proof that the "B" bile was really gallbladder bile would lie in the similarity of color, consistency and microscopic findings between this secondary bile and the contents of the gallbladder as found at the operating table. For this purpose they had asked the operating surgeon to aspirate the gallbladder immediately upon exposing it and to allow them to examine it. The bile aspirated at operation was nearly always darker, a deep dark brown shade, and more mucoid in consistency than the "B" bile of the duodenum. Microscopically no similarity could be demonstrated in the sediments of the two compared fluids. Often on the basis of finding detritus and numerous pus cells in the duodenal sediment of the secondary bile a chronic cholecystitis would be predicted, and often correctly, but upon sedimenting the fluid removed at operation by aspiration the same pus cells and characteristic sediment could not be found in the "B" bile specimen. This should not be a surprising statement for old chronic cholecystitis, with or without stones and with adhesions, was usually, at the operating table, a sterile process, at least so far as finding frank pus or viable bacteria within the gallbladder lumen. Then why expect to find them in the "B" bile even if this "B" bile was gallbladder fluid? If frank suppuration or an acute inflammation was present in this organ the first result was a swelling and occlusion of the cystic duct and then again one would be unable to find the evidence of gallbladder pathology in the duodenum. As to the significance of cholesterin crystals in the duodenal specimens, they had found numerous such crystals where no stones existed. In the sediment of the material separated from the gallbladder cholesterin crystals were not uncommonly present, apparently indicating supersaturated bile or bile stasis. In fact cholesterin crystals were often precipitated out of normal specimens of bile when the specimens were allowed to stand in the icebox. In regard to the question as to whether other salts than magnesium could produce the play of colors seen upon saline lavage, in a few instances sodium sulphate was tried with results similar to those obtained with magnesium sulphate. Einhorn had experimented with sodium sulphate, sodium phosphate, normal saline solution, etc., and attained results similar to those achieved with magnesium sulphate. The flow of bile that followed the magnesium sulphate irritation was apparently a saline action and not necessarily a specific quality of the magnesium ion.

While the writers had not been able to utilize the diagnostic test of Lyon for the identification of cases of gallbladder disease, they thought that the subject was entitled to much consideration and that every honest attempt to aid in its solution deserved their most painstaking attention.

Dr. ANTHONY BASSLER said he thought Dr. Crohn's paper represented excellent work and was worthy of much compliment. Starting out in a rather enthusiastic attitude he had used this method for a year and a half had found it rather disappointing in both a diagnostic and therapeutic way. Early in the course of his observations he had figured optimistically on the diagnostic possibilities of the A, B, C and D bile method. However, he found in a considerable number of people who had definitely, both clinically and by the *x*-ray and in each instance at operation, pathology in the gallbladder, yet there were no findings in either B or C bile definite enough to warrant the use of the method in any definite diagnostic way comparable for instance to the *x*-ray in the diagnosis of moderate states of duodenal obstruction. He found in several instances of people who had been operated upon for conditions other than disease of the gallbladder and in whom what looked like pathological B and C bile specimens had been obtained, that at operation there was no pathology demonstrable in the gallbladder or ducts. It is true that often he obtained findings in a case in which distinct pathology existed and then he would feel that the method was worthwhile, but in the next case the same findings would be obtained without any disease in the gallbladder or ducts—thus it was hard to draw definite conclusions as to the clinical value of the method. In people who had been cholecystectomized he had found this pathological B bile just as described and which was supposed to be from the gallbladder. Eight times the method was used just prior to laparotomy and then at operation in every instance the gallbladder contained considerable amounts of bile showing the method does not strip the gallbladder. Therapeutically there seemed to be some types of people having distress who were benefited by this mthod if it were persisted in long enough. They, as a class, do not seem to be cases of pathology of the gallbladder or ducts; they were represented in the cases that Dr. Barclay classed as bilious, or as migraine and various things more constitutional than local. Dr. Bassler said he had been especially interested in following four cases of infection of the liver in which there was distinct bacteriology and pus coming down all the time, probably from the hepatic cells. One of these cases was especially interesting since operation was recently performed and puncture proved the infection of the liver. It seemed to him that Dr. Lyon was a little overenthusiastic though there was something in it, but we had to do a great deal of work yet to find what that something was.

Dr. EDWARD A. ARONSON said that in order to criticise Dr. Lyon's test it must be performed as he performed it. Dr. Lyon paid attention to the bacteriology while Dr. Crohn paid no attention to it. Dr. Bassler had spoken of obtaining dark bile in cases which had been cholecystectomized, the speaker's experience had been quite the opposite. He had had six cholecystectomized cases and in none of them had the so-called "B" bile been obtained. A great deal of attention must be paid to the interpretation of results. Dr. Lyon insisted that the cytological examination be made immediately upon the withdrawal of the bile because changes took place rapidly. Then a great deal depended upon how one obtained drainage. It must not be fractional, but must be continuous. However, he would say that the more he saw of the work the more was he in a crystal maze. He was not convinced whether the bile came from the gallbladder or the liver or the liver ducts.

Dr. EINHORN said the question was simply whether Dr. Lyon's explanation that the dark bile came from the gallbladder was correct or not. He had tried experiments to see whether he was right or not, because it was a matter of great importance. A few years ago we did not think we could go so deeply into the diagnosis as to say whether the bile came from the gallbladder, the common duct or the liver. If one made the test as Dr. Lyon did, allowing the bile to flow out into a bottle and watching for the color change, and as soon as there was a change taking a new bottle, it would be observed that the change occurred very gradually. First the bile was golden, then it was a little darker for about ten minutes, then dark brown, and then it began to fade. He thought one could not take Dr. Lyon's explanation as correct, for if the change in the color of the bile was due to the opening of the gallbladder as a result of the magnesium sulphate the bile would suddenly get dark brown, but this was not the case; there were perhaps eight or nine different shades. How was it to be explained? The magnesium sulphate stimulated the liver and not only the magnesium, but the sodium sulphate did the same. Sodium did not open the sphincter, according to Meltzer. That showed that the explanation of Lyon was not correct and that point he wished to bring out. He also wished to say that if one gave the patient magnesium sulphate and then allowed the bile to run for fifty minutes and it became yellow and the gallbladder had been emptied, if you then gave magnesium again there would be a repetition of yellow, then dark brown and then yellow again. If the gallbladder had been emptied of its contents you could not repeat the procedure in ten minutes again. He had been watching the specific gravity, as magnesium sulphate increased the specific gravity; he found that the specific gravity was increased in the dark specimen after magnesium sulphate and not after peptone. Again, if giving 25 per cent. magnesium sulphate caused the gallbladder to open, a 10 per cent. solution, relaxing the gallbladder, should give the same reaction, but that was not the case, a milder solution giving a correspondingly weaker color reaction. All these things indicated that the emptying of the gallbladder was not involved in the reaction. The reaction was not as strong in people who had had their gallbladders out. Another point that was important was that in some cases in which there was no reaction at all that was due to faulty function of the liver and in cirrhosis there was hardly any reaction at all. This suggested that the test might be useful in estimating the function of the liver. It had been said that there was nothing in these examinations; he must say that he was not of that opinion. He rather thought the diagnostic value would increase the more we knew about it. If we did not get much out of the method at the present time, it was not the fault of the method, it was our fault. So far as he could see there was a great deal in it as regarded turbidity. Slight turbidity might not be of much significance, but if the bile looked like pea soup we could say that there was an abnormal condition of the gallbladder and usually there were stones. About the bacteriology of the bile, it was of great importance too how the examination was made. As for the cholesterin crystals, a few might be of no significance, but if there was a conglomeration of large crystals we could definitely say that we were dealing with a stone.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

LEHRBUCH DER UROLOGIE. By Prof. LEOPOLD CASPER. 608 pages with 225 illustrations and 2 colored plates. Price, 200 Marks. Published by Urban & Schwarzenberg, Berlin and Vienna.

EVOLUTION, GENETICS, AND EUGENICS. By HORATIO H. NEWMAN. 523 pages with illustrations. Price $3.75 net ($3.95 postpaid). Published by the University of Chicago Press, Chicago.

DISEASES OF CHILDREN. By Sir JAMES F. GOODHART. 942 pages with 60 illustrations. Price $10.00. Published by Paul B. Hoeber, New York.

DISEASES OF THE NERVOUS SYSTEM. By H. CAMPBELL THOMSON. 566 pages with 11 color and 12 black-and-white plates and 120 figures. Price $5.00. Published by Paul B. Hoeber, New York.

NEW BOOKS AND OLD.

XVIII. HENRY MORLEY'S BIOGRAPHY OF JEROME CARDAN.

By JOHN RUHRÄH, M.D.,

BALTIMORE, MD.

IF you are not familiar with the medical writings of Henry Morley it is high time that you become acquainted. Perhaps it is best to start with "Anatomy in Long Clothes," which is his short but remarkable account of the life and works of Vesalius. Then you will be ready to take up the record of that most remarkable man, Jerome Cardan, often referred to by his name in Italian as Girolamo Cardano, or in the Latinized form, Hieronymus Cardanus. Cardan has been referred to as the wisest fool and the most foolish wise man. He was so certain that he would go down in the history of science and medicine that he left much material for the biographer. Morley's life is the result of a careful study of his works of which it is stated he published one hundred and thirty-one during his life and left behind in manuscript one hundred and eleven. Cardan was the most successful scientific author of his time and his books have perhaps been reprinted oftener than those of the other writers, but unfortunately the most popular were often those containing the greatest amount of foolishness. His collected works were issued in 1663 at Paris by Charles Spon and comprised ten folio volumes.

Cardan was born to sorrow in 1501. His mother was a young widow whom his father had neglected to marry. This question of his illegitimate birth was afterwards a source of a great deal of annoyance and stood much in the way of his advancement. The boy led a sickly life and evidently had a pitiful childhood. He had a passion for mathematics and for games of chance, and was particularly proficient in those played with dice. As to how much his career was influenced by his bodily infirmities is, of course, uncertain. On this point Morley says:

> The day may come when somebody shall teach us how to estimate the sum of human kindness that proceeds from good digestion and a pure state of the blood—the disputes and jealousies that owe their rise entirely to the livers of a number of the disputants—or how much fretfulness, how many outbursts of impatience, how much quick restlessness of action, is produced by the condition of the nervous matter. Such calculations, though we cannot make them in the gross, we make, or ought to make, instinctively when we become intimate with individuals. The physical life of a man cannot be dissociated fairly from his intellectual and moral life, when we attempt to judge him by the story of his actions. In the case of Jerome Cardan, it is more than commonly essential that we know a little of the body that he carried to his work, for its unsoundness influenced his conduct and caused many a wise man to shrug his shoulders, both among contemporaries and long afterwards, and even to this day, over the question, "Had he not madness in his composition?"

Morley has given a considerable account of all the various disturbances which Cardan took pains to include here and there in his writings. He was a neurotic individual, whose dreams and imaginings would make fine material for some ambitious follower of Freud.

When he was nineteen he left his father's house and set out for Pavia where he made rapid progress particularly in mathematics. Jerome chose medicine as his profession and later journeyed to Padua where he accepted the post of Rector of the Gymnasium. This was on his part a characteristic action and a thoroughly foolish one. The Rector was the chief magistrate of the university, holding court and deciding disputes among the students and professors and overseeing the teachers. The real work was done by a pro-rector, while the rector himself, who must needs be a wealthy man, was called on only to open his purse. For many years after the time of which I write, the rectorship was universally shunned as a dignity not worth the price. That this "clever, penniless, disreputable young scholar of twenty-four," as Morley calls him, should have taken the post is almost beyond belief. He apparently had none of the honors or privileges that went with the position nor is there any record that he assumed the state and the garments, and the ornaments that were deemed fitting for so honorable an officer. He seems, however, to have spent a year during which he evidently gave the dinners which were expected of him and those were doubtless paid for by his hard-working mother who lived in Milan. Of course it is possible that his skill in gambling may have enabled him to pay for some of his entertainments.

As to his doctorat Morley gives the following account of his receiving his degree:

> He was rejected twice; but when he made his third effort, the adverse voices were reduced to nine, and he was admitted Doctor of Medicine, and received with due solemnity the open and shut book, the barette, the ring, and the kiss. The open book signified things known to him that he was authorized to teach; the closed book signified the knowledge that it yet remained for him, and was his business, to acquire. The barette was of an ecclesiastical form, and signified that he was consecrated as a priest to science, and by its name (bi-rect), twice right, some thought it also signified that teachers ought to be correct in practice as in theory. By the ring he was espoused to his profession. The kiss was the symbol of the brotherhood to which he was admitted, and the peace and harmony that should prevail among all fellow-laborers in art or science. Then in the cathedral he was ushered by the bedel formally from a seat by his presenters to a seat by the prior, further symbolizing that, as a man of learning, he was qualified to sit among the princes of the earth. So Jerome was made a doctor in the famous University of Padua. He was then twenty-five years old.

He started to practice in the small town of Sacco, some ten miles from Padua. Here he lived some seven years, fearing to return to Milan on account of the war, plague, pestilence, and famine which scourged that city. Morley gives the following account of him at this time:

> "The appearance of Cardan in his manhood well accorded with the temper of his mind. He had thin arms and unequal hands, the left hand being elegantly formed with shapely nails, the right hand clumsy and ill-shapen. His forehead was broad, and there was little hair upon his temples; in later and graver years he wore a skull cap on a shaven head. His beard was yellow and forked. His gait was clumsy, for he paid little or no heed in walking to the way that lay before him, and his pace and bearing varied with his thoughts. It was now fast, now slow, now upright, now with bowed head, as variable as the gestures of a child. In his speech he was too copious and too deficient in amenity. He was very fond of fishing. He had a taste for cats and dogs and little birds, so that he even names them with history, music, and other things that

adorn this transitory scene, placing them in his list between liberty and temperance on the one side, and on the other side the consolation of death, and the equal ebb of time over the happy and the wretched. Among his follies he numbers an inability to part with living things that have been established once under his roof. 'I retain,' he says, 'domestics that are not only useless to me, but that I am told also are a scandal to my house; I keep even animals which I have once accepted, goats, lambs, hares, rabbits, storks, so that they pollute me the whole house.'"

In 1531 he was married to the daughter of a neighbor. This event was preceded by a dream in which he saw a lovely maiden dressed in white. He dreamed that he was walking in a paradise of indescribable beauty and as he passed he saw a gateway open and standing there a girl dressed in white. He went to her, put his arms about her neck and kissed her. Then came the gardener who shut the gate, so Jerome hung on the damsel's neck outside the locked door of his paradise. Shortly after the house of his neighbor took fire. Thus he met the owner, a captain, and the captain's daughter, whom he saw at the window dressed in white, the image of her of whom he had recently dreamed. According to all accounts the gate of paradise continued to be locked against this unlucky couple and after many years of hard labor and privation, his wife died, just before Jerome's fame led to opulence. Shortly after his marriage in 1532, he removed to Milan and from there they went to a small town named Gallarate, because at Milan the college physicians would have nothing to do with him, giving as a reason his illegitimate birth. At Gallarate there was little medical work, and a period that bordered upon destitution began. Not only did Cardan have to struggle with the physical discomforts, but he was tormented by morbid fancies, believing that every sensation was a secret omen. In 1534 his condition had become such that he returned with his wife and child to Milan and applied for shelter at what corresponded to the workhouse, an establishment maintained for the sick and needy, and a home of strangers. Through the good offices of Fillippo Archinto, he obtained an office that carried with it a small fee, that of lecturer on geometry, arithmetic, and astronomy. In spite of the fact that he was forbidden to practise by the College of Physicians, Cardan did so whenever patients came to him.

The next five years were spent in more or less misery. Jerome, suffering with bodily infirmities, harassed by his enemies and ground down by poverty, solaced himself as best he could with music, dice, and incessant writing. This was also a period of study of the philosophers, poets, and mathematicians. His love of dice he excuses by saying, "Philosophers may play, but wise men are as kings enjoying higher pleasures." His studies in mathematics, for which he was noted, interfered somewhat with his practice as a physician, as Morley says:

> A physician even in our own day cannot acquire reputation in any branch of literature or science that does not bear directly upon tongues and pulses, without forfeiting a portion of the practice that he might have gained with ease if he had been a duller man, or if he had but hidden some part of his light under a bushel.

Up until he was thirty-five Cardan had never had anything of his printed, but his friend, Ottaviano Scoto, having become the master of a printing house through the death of his father, Cardan's hopes were at last fulfilled and the manuscript which he had written some time before about the "Bad Method of Practice among Physicians" was printed at Venice in 1536 with the title, "*De Malo Medendi Usu.*" In the dedication of this he comments on the life of a physician as follows:

> The things which give most authority to a physician in these times, are habits, attendants, carriages, character of clothes, cunning, suppleness, a sort of artificial, nambypamby way; nothing seems to depend on learning or experience. It would be well if this criticism had quite ceased to be applicable. It did not lose its force for at least two hundreds and fifty years, and is in our own day only beginning to grow obsolete.

Morley says that this is a clever book denouncing seventy-two errors in practice, one of which we can recommend to the prohibitionists. This was the error of the total denial of wine to the sick. "He taught that to do nothing with physic was much better than to do too much." The same statement afterwards was used by Locke who said, "It is better to do nothing than to do amiss."

Cardan attained great prominence as a mathematician and he was very proud of his skill in algebra. Space prevents going into the almost needless disputes he had with other mathematicians. They were jealous of him and he suspicious of them. About this time, through the kindly offices of several friends, he was at last enrolled among the members of the College of Physicians of Milan. As Morley says, he had at last attained the long-sought paradise of print and there followed rapidly various works printed in the various printing centers. His books must have sold well for they were in large demand by the various publishers.

Garrison says that his best book is "De Subtilitate Rerum," which contains among many other things a device for teaching the blind to read and write not very different from that devised by Braille. He also considered teaching the deaf by signs.

The next few years were spent in study, in writing, and in gaming. He was improvident, spent much of his time in bad company, and sank again into great poverty, having neglected legitimate sources of income. In 1544 he removed to Pavia where he was given a salary of two hundred and forty gold crowns for lecturing on mathematics. Morley gives at considerable length the account of his mathematical quarrels and says of his book, "*Ars Magna,*" the Great Art—Algebra, that it is, "A volume so especially important and begotten in so quaint a way that whether I wished this narrative to be read chiefly for information or amusement, it would equally be fit that it should therein be put prominently forward." In commenting on the connection between algebra and physics, he also says:

> A more striking illustration of the intimate connexion that existed formerly between these sciences, is to be found in that part of Don Quixote which relates how the bachelor Samson Carrasco, being thrown from his horse by the knight, and having his ribs broken, sent—it is said quite naturally—for an algebrist to heal his bruises. Keeping in mind this old association of ideas, we find that there was nothing exceptional in the position of Cardan as teacher of mathematics and practitioner in physic, nothing odd in his combination of the callings of an almanac maker, an algebrist, and a physician.

In 1543 two tracts were published by Joannes Petreius at Nuremberg. They were on astronomy and astrology and contained various horoscopes chiefly of noted persons. Cardan started a life of Galen, but apparently never finished it, and he also wrote a treatise on Example in Love. He believed in writing for the fire as well as for the press, believing that by so doing he purged his mind of much foolishness. In this present day it is a great pity that many authors do not patronize the fire more. His printed works were carefully written and revised and often rewritten, for he said, "They who write without digestion are like men who eat crude things: for a slight and temporary satisfaction they inflict upon themselves a grave and lasting harm."

Along with the others of his time he went in for what Morley calls the attractive and delusive pseudo-sciences on ghosts, dreams, portents, palmistry, signs in the heavens, and wonders upon earth. We probably know more about Cardan than almost any other writer of his time, for he left the most intimate accounts of his likes and dislikes and what he did and how he lived, so that it is easy to reconstruct his days with comparative accuracy. He had two flattering offers both of which he refused. One was to go to Rome to become physician to the Pope, the other to become physician to Christian III, King of Denmark. Now followed a period of successes, both as a medical teacher and as a practitioner, and in 1547 his professorship was increased to four hundred gold crowns. As his children were growing up he wrote a work of precepts for them.

Cardan made a remarkable journey to Scotland to examine and prescribe for the Archbishop Hamilton. He journeyed to Paris where he met with a warm reception and from there he journeyed with Cassanate, Hamilton's physician, to Scotland. While in Paris he dined with Jean Fernel and Jacques de la Boë. The latter, a professor of anatomy in Paris, Jerome describes as a merry little old man of seventy, quite bald, quite little and full of jokes, a somewhat different picture than is usually drawn of this testy old anatomist. Cardan's study, analysis, and therapy in the case of the Archbishop is quite curious and makes interesting reading, but I shall have to pass this over as taking us too far afield.

While in Edinburgh some thirty-five days the Scottish noblemen flocked to him for advice and paid him liberally for it. He was asked to stop in Paris on his return where there were a remarkable number of people who wished to consult him, one Prince offering a thousand gold crowns, but conditions in France made travelling so precarious that he determined to travel home through the low countries rather than take the risk. Hamilton paid him eighteen hundred gold crowns, of which fourteen hundred went to Cardan himself and the rest to his attendants, and he was also presented with a gold chain and other gifts. While in London he visited the King, Edward VI, who was in poor health, and he calculated the horoscope giving him a long life, but the King died soon after. As a matter of fact Cardan did not wish to give any opinion at all. He felt the danger of predicting the King's death, for he knew the fate of others who had attempted it with other monarchs before him. Cardan was offered a post of physician with the King of France, and Charles V, who was at that time besieging Metz, also was desirous of securing his services. Both of these offers were declined. Cardan went home by the way of Brussels, Louvain, Basle, and into Italy through Berne and Zurich.

His son, Giambatista, now caused him great trouble. He married a girl of bad reputation and subsequently poisoned her, for which he was arrested, tried, condemned to death, and executed. Cardan pleaded for his son before the Senate, made every possible attempt to have the death sentence changed into exile, but without avail. This was a heavy blow. He had spent his money very freely to aid his son; the calamity destroyed his local reputation, and he was made thoroughly wretched.

In 1562 Jerome resigned his professorship and went to Milan. He subsequently removed to Bologna where he began a professorship which he held for the next eight years. He was never very enthusiastic about the practice of medicine, but regarded it much in the light of the Frenchman who said that it was "La plus noble des professions et le plus triste des metiers," which Cabot has paraphrased to, "The study of medicine is heaven, and practice of it hell." Cardan says, "If I had money to earn, I could earn it as a doctor, and in no other way. But that calling of all others (except the glory that attends it) is completely servile, full of toil, and (to confess the truth) unworthy of a high-spirited man, so that I do not at all marvel that the art used to be peculiar to slaves."

In 1570, when nearly seventy years of age, Cardan was arrested and thrown into prison. Just why is not clear, but apparently he was accused of some impiety, but he was well treated and released some eleven days later. He was then in prison in his own house for eighty-six days and forbidden to publish any more books. Acting on the advice of his friends he resigned his chair and left in 1571 for Rome where the Pope had provided him with a pension. During the last few years of his life he was busily engaged revising his works and during this period he burned no less than one hundred and seventy, but left behind him one hundred and thirty-one works printed and one hundred and eleven in manuscript, of which Morley says, "Not twenty have seen the light." His advice to friends was, "publish no crude books, they disarm you and pass over to the enemy." He died at Rome on September 20, 1576, at the age of seventy-five years. A famous scholar and physician, his life is full of interest and contains many useful lessons.

Epidemic Hiccough.—In a recently published thesis of Strasbourg, Kritter dissociates this condition from banal hiccough. It is seen only in seasonal influenza, when it is motivated by a special gastropathy characterized by dilatation and reflex irritation of the terminals of the phrenics. The author separates it entirely from hiccough of encephalitis lethargica, which is due to disturbance of central innervation.—*Le Progrès Médical.*

Bronchial Biliary Fistula.—This excessively rare condition is described by Oliani. The patient, a woman of forty-eight years, expectorated from 300 to 500 c.c. of bile daily. She was so weak that she maintained at all times the horizontal decubitus. There were practised on her several acts of surgical intervention, and the last was successful—the closure of a communication between the common duct and a large bronchiectasic cavity.—*La Riforma Medica.*

A PNEUMONIA STUDY.

BY CARTER S. COLE, M.D.

NEW YORK.

I. PITCH AND TIMBRE.

THE flood of physical examinations for the army, and the great number of those who were taken ill after entering the army, would seem to justify a review of some of the facts relating to the diagnosis in certain lung conditions; moreover, the place occupied by the *x*-ray to-day compels something more than guesswork or supposition on the part of the examining physician. And yet we believe that nature has endowed man with organs that make it possible for him to check even this instrument of precision devised by man. That all men are not capable of making accurate findings we know full well; but have the physicians recognized the limitations that nature has herself placed upon them? A man who cannot tell the difference in quality between the note of a trombone and xlyophone, a flute and a fiddle, or any two instruments that give a different timbre in tone, or who cannot recognize the difference in pitch of a quarter or half tone, cannot be expected to become an expert in physical diagnosis; indeed, it would be just as reasonable to expect a man who is color-blind to be a great painter, or one who is tone-deaf to be a great musician.

During this recent epidemic of pneumonia in the camps, the fact was demonstrated again and again that the ear can detect a patch of infection quite as early as the *x*-ray—indeed, sometimes before there was enough organization to give the shadow, and it can be accepted as a maxim that any infiltration in the lung that will cast a shadow will give quite as certainly a change in sound—making the detection possible by physical examination. Once in a great while we have a patient who can produce no voice, either on account of paralysis of the cords or because of unconsciousness, in whom we are unable to make a diagnosis of pneumonia until it has reached a much later stage of development—a stage in which breathing, râles, and percussion must be our dependence; on the other hand, in the very early stage of pneumonia, none of these is of any special value, whereas the spoken and whispered voice, on account of the change in pitch and timbre, gives us absolute knowledge of even a small area of invasion. In fact, it is our fixed belief that if we could see every case of lobar pneumonia at the very outset, we would find the seat of infection to be a very small area, and quite as definitely determinable as when we find later a large part of the lobe involved; and the evidence to the ear in lobar pneumonia is a voice, metallic (wire string) and high-pitched, quite different from the pitch and timbre in the surrounding area. In bronchopneumonia we find we can just as certainly locate the area of invasion, although the quality of sound is more like that of a gut string and the pitch is not so high. When, however, the patches of infection run together, producing the interstitial form in one or more lobes, the pitch and timbre are practically the same as in lobar pneumonia. These facts obtain for the whisper, as well as for the voice, except that in lobar pneumonia at the very outset the whisper is very distinct, exaggerated, seems hurried, and has a tongue to its sound.

The phases of the later stages, when even a stone-deaf person, one who makes no pretention at a physical examination, can make a diagnosis, we will not touch upon; there are, however, some facts about fluid conditions upon which we may speak. First of all, if the fluid is limited by a pleural adhesion and compresses the lung and, still more distinctly, if it lies over a consolidated area, the voice is carried with as much or, at times, even more intensity than over a simple consolidated area, and it is well to get that "muffled sound" idea as a universal proposition out of our minds.

It is true that thickened pleura and free fluid both change the quality of the spoken voice, rendering it more dull—but this is not so when the lung beneath is compressed or consolidated. Whoever has tried the experiment of listening to the knocking of two stones together under the water, at a distance, will appreciate how the water can conduct sound. There is one condition in which the tactile sense is of great value, viz., when there is fluid, percussion gives a doughy feeling, besides the flatness characteristic of both fluid and consolidation. There is on percussion very little perceptible change in the quality of the sound or in the pitch between fluid and consolidation.

To complete this note, then, let us remember:

1. That the pitch and timbre of the spoken voice and whisper will always be changed in infiltration and consolidation.

2. That the diagnosis of pneumonia can be easily made by the voice and whisper just as early as it can be made by an *x*-ray plate.

3. That the metallic timbre of the voice of consolidation can carry through fluid with even an increased intensity.

4. That in the early recognition of pneumonic

infection, before there is an appreciable change in the respiratory or percussion sound, the voice and whisper will give us definite information as to the site or sites of invasion by reason of the marked change in pitch and timbre.

5. That lung tissue compressed by a new growth gives a change well marked in pitch and timbre of both voice and whisper.

II. BELLSCOPE PNEUMONIA.

If an apology be needed for the imposition of a new term in the nomenclature of such an old and familiar disease it will be found in the fact that in its definition—the space covered by the bell of the stethoscope—it emphasizes a clinical fact of paramount importance, the recognition of which means more to the physician and patient than anything connected with specific forms of treatment. Let me ask what is the general idea about a pneumonic infection? Is it wrong to say that the profession as a whole do not make a diagnosis of pneumonia—especially lobar—until a large part of the lobe is involved and the various râles, tubular breathing, flatness, and what not are present; whereas, the absolute facts are that the case has already, at that time, been a pneumonia, perhaps for several days; the patient has not been kept at absolute rest, and naturally a considerable area is involved. On the other hand, even a slight chill, or a small elevation of temperature that is persistent, without any symptoms suggestive of a lung involvement, would justify a careful auscultation of every inch of lung surface and this would frequently be rewarded by finding the spot of initial infection, from which we can make as absolute a diagnosis as if the whole lobe were invaded; and this obtains whether or not a cough, or râles, or bloody sputum, or tubular breathing are present or absent.

The variety of pneumonia is determined by the character and pitch of the voice and whisper and by whether there is a single spot in an individual lobe, or several spots in one or more lobes. At a later stage in interstitial bronchopneumonia, these several spots may coalesce, making the physical signs of the two varieties almost identical; but the history, the conditions in other lobes, the sputum, the temperature curve, the *x*-ray, etc., etc., will assist in making the differentiation; and, yet, even on autopsy, macroscopic examination is, at times, insufficient to enable us to say that a particular area is an interstitial and not a lobar pneumonia. Moreover, we must recall the fact that we may have either or both kinds of pneumonia in the same or in different lobes, as postmortem examinations constantly demonstrate. We have seen lobar, lobular, and interstitial bronchopneumonia at the same time in a patient; it is rare to see bronchopneumonia and lobar pneumonia in the same lobe at the same time, and not at all uncommon to find bronchopneumonia and interstitial bronchopneumonia under such conditions; on the other hand, we frequently have a lobar pneumonia in one lobe and a bronchopneumonia in other lobes, or interstitial bronchopneumonia in another lobe. The natural distribution is not an admixture of types: but we must be prepared for such an event.

It is unnecessary to rehearse the ordinary and well-known symptoms of pneumonia—a chill, single and severe, headache intense, pain, often far removed from the focus of infection and in no way associated with respiration, or when so associated, frequently on the opposite side to the one involved, râles and bloody sputum, both or either absent in the very early stages—in fact the sputum is sometimes never present, temperature, the one fairly constant and persistent factor, which when otherwise unexplained demands a careful search for a pneumonic infection, despite the absence of any other suggestive symptom. It is not, we repeat, necessary to restate these, because we would be looking for a pneumonia under such conditions; it is when we have only a severe chill, followed by sustained temperature, without any apparent indication of lung involvement, when gastric disturbances or suggestions of an appendicitis—and appendiceal infection may be the source from which a pneumonic infection obtained—are apt to direct our attention away from the lung condition, that the obligation for a meticulous search of every inch of lung surface is imperative. This is critically necessary in appendicitis, actual or apparent, as it is almost equivalent to signing the patient's death warrant to operate under an anesthetic for appendicitis when a pneumonia is already in progress.

The voice and whisper make it perfectly feasible to find the spot or spots and without the corroborative findings of râles, tubular breathing, sputum, or even subjective symptoms, except, perhaps, increased frequency in respiration, to make an absolute and unequivocal diagnosis of pneumonia. Naturally, at this early stage, the area is too small to get any information from percussion, although it is not long before we may find a difference in the resonance of our percussion note over the area involved, especially if the infection extends with fair rapidity: later, we may get absolute flatness, especially when a considerable portion or the whole lobe is invaded and consolidated.

We will amplify the character of the voice of which we are speaking: in lobar pneumonia, it is high pitched, very metallic, like the twang of a wire string, exaggerated, and easily differentiated from the immediate neighborhood not similarly affected; it is a single spot in a single lobe—thus differing from the condition in bronchopneumonia: the whisper is hurried, increased, very clear, and absolutely different from the whisper over healthy lung structure. We must not lose sight of the fact that we may have a lobar pneumonia in one or more lobes—but we only have this one spot which we have described in each lobe invaded.

Let us see the conditions in bronchopneumonia: the voice is higher pitched than in the neighboring areas, but it has a gut-string quality, it is not so intense and is consequently not carried to the ear with such apparent haste: the same is true of the whisper—not so hurried, not so intense, not so prolonged.

Under any conditions, the *x*-ray is our most valuable corroborative aid and should go hand and hand with our physical examinations from

the very outset. The trained ear and that instrument of precision work much better together and run a close race in the early diagnosis of pneumonia.

In regard to differential diagnosis: In bronchopneumonia the antecedent bronchitis, the sputum, the usual physical findings, etc., make a mistake unlikely; but this is far from true in the insidious, rapidly fatal cases so frequent as a sequela of influenza in the late epidemic; but, even in these, the areas of invasion were easily demonstrable by the voice method of examination before there were any special indications of respiratory involvement, and long before there was an embarrassment in respiration; and, yet, we know that most of the deaths were due in this epidemic, not to the bacillus of influenza, but to secondary infections causing a rapidly obliterative pneumonic exudate: however, the early recognition of this condition made it possible to materially diminish the death rate.

There is another fairly frequent condition in which the high pitched, gut-string quality of voice obtains, viz., unresolved pneumonia; but the history, the absence of fever, the character of the cough, if there be any at all, and the whole clinical picture, make the diagnosis simple.

Let us then restate these salient features of our theme:

1. Pneumonia begins in a limited area or in limited areas, according to the variety, in one or more lobes, probably present with the initial chill.

2. These places can be detected when they are no larger than the bell of an ordinary stethoscope, by the simple method of voice and whisper; percussion at this very early stage is of no value practically.

3. The pitch and timbre of the voice signs are our guides in differentiation, to which we may add that in lobar pneumonia, we have practically never found more than one area in an individual lobe.

4. Both kinds of pneumonia may occur in the same or in different lobes at the same time; but a single spot in an individual lobe absolutely means a lobar pneumonia.

5. The diagnosis by voice and whisper is comparatively easy and within the reach of everybody; but it is also very illuminating, if not obligatory, where possible, to have frequent corroborative *x*-ray examinations.

6. This absolute diagnosis may be made when the area involved may be covered by the bell of an ordinary stethoscope, often before we have sputum, râles or even a cough, and this is the reason we have coined the term—"Bellscope" Pneumonia.

II. TYPES AND TREATMENT.

Types.—1. Lobar.

2. Bronchopneumonia: (a) Lobular. (b) Interstitial—including the rapid exudative type seen in the late influenza epidemic. (c) Ether pneumonia —almost immediate resolution.

Etiological factors: (a) Pneumococci—four groups recognized and isolated, of which group I is supposed to be materially influenced by serum. (b) Streptococci—of which there are many unclassified varieties. (c) Staphylococci. (d) Bacilli—influenza, Friedlaender, etc. (e) Combinations of one or more of the above.

It must also be remembered that in the same or in different lobes we may find each kind of pneumonia, although the usual thing is to find only lobar in the lobe in which lobar occurs.

Treatment.—Lobar: Absolute quiet and rest from the moment the diagnosis is made. Abundant air and water. Stimulation directed to the actual need of the heart—usually tincture of digitalis (digipuratum if available in the severe cases), alternating with strychnine (the dosage of each to be suited to the actual condition of the heart and to be varied as the conditions demand). Hot sponge (alcohol) baths to control temperature and facilitate elimination by the skin of toxic products. Liquid nutrition until after the crisis and even later in unresolved cases. In pleural invasion, fixation of the chest wall by zinc oxide plaster. Iodide of potassium (gr. 5 to 10 by mouth every six hours). If possible avoid puncture (diagnostic) or aspiration during the stage of acute consolidation. Free catharsis at the outset and bowels to be kept open. For cough, ammonium chloride (gr. 5 to 10) every 3 to 6 hours, in individual cases adding heroin or codeine if absolutely necessary, but never morphine in the stage of active consolidation. For sedatives, the bromides freely. For hypnotics, veronal, trional, etc. In unresolved cases iodide of potash as above.

Bronchopneumonias: Our best results were obtained by the routine treatment of ammonium chloride, gr. 5 every 3 hours, iodide potassium, gr. 5 every 6 hours; in all cases free catharsis: in the influenzal cases, the throat and nares were frequently sprayed in the early part of the illness with some hot antiseptic solution; hot sponge baths were used night and morning and more frequently if the temperature demanded it: stimulation as in lobar pneumonia, when necessary; sedatives—codeine and heroin—if absolutely necessary: veronal in occasional cases, when necessary. We may add that two women, pregnant six months, one of whom was unconscious for four days, recovered, without miscarriage, and have since given birth to fine boys.

III. OBSERVATIONS ON POST-INFLUENZAL PNEUMONIA.

After the seizure due to influenza infection, in which one or another symptom may be emphasized, even when the bronchial irritation seems to be comparatively negligible, we are apt to notice that the temperature which has almost or completely returned to normal, begins to make a slight rise, which is apt to continue with an accretion daily until 102° F. or a higher point is reached and maintained. At this time, there is apt to be some coughing, and there may be some bloody sputum—we have seen in some cases practically pure blood—and yet the patient has absolutely no respiratory distress, his rate of respiration being maybe as low as 18; he may complain of no pain anywhere in his chest. A careful stethoscopic examination—aside from voice—may give no indication of any pulmonary involvement, but

the spoken voice will, without fail, indicate the areas in which we have an exudate, even before it is sufficiently dense or organized to give a shadow on the *x*-ray plate; and we know that we have a veritable pneumonia, which in many instances, has progressed rapidly to a point where oxidation has been seriously impaired, the lungs, as it were, flooded, and a fatal result made unavoidable. Just why one case will follow this course, while another never reaches a dangerous point, we have been unable to determine; but we feel quite sure that if we recognize and treat these conditions at the very outset as pneumonias, we seem to be able to limit the process in many instances. We may safely say that the influenza bacillus is seldom, by itself, the cause of a fatal pneumonia; and that the pneumococcus, streptococcus, and other organisms, individually, or in combination, have very often supplanted the influenza bacillus—or, if you choose, followed his path of preparation, and induced the later condition that has proved so fatal.

The character of the pathological lesions, on autopsy, also emphasizes these facts, as it is not unusual to see bronchopneumonia, interstitial pneumonia, and lobar pneumonia, all present in different lobes; in fact, the first two named are very frequently associated. In another paper we have emphasized the fact that the physical findings in life, in later stages of interstitial bronchopneumonia are indistinguishable from those of ordinary lobar pneumonia; it is in the early stages when we have a gut-string note from the spoken voice, areas in the same lobes that have not coalesced, or, perhaps, better, before the spaces in which we can hear normal voice in a lobe have been occupied by the lobular and interstitial invasions causing the obliteration of the breathing space over a considerable part of the lobe, that we are able to determine definitely the character of the pneumonia. It may be worth while to add that the signs of an extensive bronchitis, so generally characteristic in ordinary bronchopneumonia, are usually absent in these pneumonias following influenza. In the stage of convalescence it is not at all unusual to find a considerable pulmonary edema over the invaded pneumonic area; and this frequently makes the determination of fluid by physical examination much more difficult, more especially where there is only a thin layer. Fortunately the presence of a thin layer of fluid is not of grave import, unless it be streptococcic; and even then it does not seem to be fraught with the same danger that the condition exhibited when the cases had suffered, as they did in the pneumonia scourge of the army camps in the winter of 1917-18; in fact, many of them, after diagnostic puncture, got well without being operated on for empyema. It may also be worth while to emphasize the fact that the voice from a consolidated lobe travels through fluid, especially a thin layer, with increased, rather than diminished volume. The boggy flatness on percussion is the best physical evidence of fluid; and the *x*-ray is absolutely dependable for confirmation and for picking up interlobar or other pockets that are apt to escape detection even by a most careful physical examination. Going back then to the very outset of the pneumonia in these influenza cases, when the spoken voice and the *x*-ray shadow are our only—but entirely sufficient—means of making the diagnosis, what means have we of limiting the exudative process? If we eliminate the cases of blood-stream infection, which all observers agree are comparatively rare in these influenza cases, we can positively state that iodide of potassium has been our sheet-anchor. In all cases with any bronchial irritation we have given ammonium chloride (5 gr.) every three hours; and in addition, in the cases with exudate, from the very outset, we have given 5 grains of iodide of potassium (in saturated solution) every six hours, increasing the dose in extensive invasions 1 grain at a time until 10 grains were reached. So the medication was, in the pneumonia cases, ammonium chloride 5 grains (occasionally a 10-grain dose in severe cases) every three hours; iodide of potassium 5 grains—increased gradually to 10—every six hours. Severe coughing can be lessened by the addition, when necessary, of heroin, gr. 1/12, restlessness by bromides, codeine, and anything but morphine, unless morphine is absolutely unavoidable, as it seems to be in some of the fatal and hopeless cases. The temperature seldom remains high for a long time and hot sponge baths take care of it. The bowels should be kept well open and high saline irrigations are often of value.

The cases in which gastric irritation was a factor were only occasional. The use of mixed vaccines intravenously was started after the first week or so of the epidemic, and the terminal results have yet to be given by the men who employed them; at least, there seemed to be a striking diminution in the mortality after their use had been introduced; although, the same fact was observed in cases in which no vaccines were given; in fact, the virulence of the disease was, apparently, considerably abated after the first two weeks.

The use of cardiac stimulants was often unnecessary; indeed, a characteristic feature of many of the cases was the slow and sufficient heart action. In the severe cases, digitalis alternating with strychnine in doses of 15 minims and 1/60 grain respectively—every six hours, was usually sufficient: occasionally, a double quantity of each was employed for a short while.

The low leucocyte count was very common, and when it did not rise with an increase in the pneumonic exudate, the outlook was grave.

With a high leucocyte count the prospects are better, even with considerable lung involvement. The prognosis in a given case may not be easy to determine from physical signs; but an extensive infiltration, even when there may be comparatively little discomfort or disturbance of the respiration—we have seen three lobes invaded with a respiration of 26, a temperature of 101° F., and a pulse of 88—a condition which is beautifully delineated on the *x*-ray plate, does not hold out much promise of recovery, more especially because the involvement of an additional new area, though limited, will determine quickly a fatal ending; and the pulse, temperature and respiration will make their upward leap almost instantly.

In the blood-stream infections the vaccines and serums hold out some hope of influencing the result, although the pericardium, peritoneum, and kidneys are apt to be rapidly invaded by infection and the outlook is far from promising.

Having registered our objection to morphine, it may be well to add our reasons: in most cases, disturbed conditions of stomach and intestines immediately supervene, vomiting being the usual thing, and diminished peristalsis—in some cases a definite intestinal paresis—are natural, we had almost said, necessary sequelæ of its use. The same stasis obtains in the lungs themselves, encouraging certainly in this variety of pneumonia an increased "flooding" of the interstices at points already involved; and, we may add, that the mortality, in cases that we have seen that were given morphine, was maximum. Of course, it may be said by those in favor of morphine that we employed it only in the hopeless cases—which is nearly the fact; but we have seen a number of cases that were not, apparently, necessarily fatal, in which the use of morphine was followed by a fatal result.

Our observation of the so-called "cat" method of digitalization in quite a number of these influenza pneumonia cases—indeed, for a time it was "routine" as soon as the diagnosis was established—has not encouraged us to employ it in any of our own cases: we emphasize "observation," because, on theoretical grounds we have been unable to see a single reason to use it in pneumonia, while we can see many reasons why it is absolutely unjustifiable; and we believe that it will be only a short while before its most earnest advocates must abandon its employment in such cases as we are now considering, and most likely in any case of pneumonia. This does not mean that we do not use digitalis when it is indicated and in sufficient doses in any case of pneumonia. Because a healthy cat can tolerate doses of one-half of 0.14 per cent. of its body weight in c.c. as a starter, followed by half this quantity in six hours, and half the last quantity as a regular dose every six hours until digitalization is accomplished, we have been unable to see why it is desirable, or even permissible to do this in a human being sick with pneumonia. We are prepared to believe that there are cases in which rapid digitalization may be a desideratum and that this may be the one best way to accomplish such a result rapidly; but we do not consider cases in which we have a rapid exudative process in the lungs to be in such a category. We would not say that in one series of twenty-five cases with fourteen deaths the "routine" digitalization was responsible; but it would be interesting to know what would have happened if it had not been employed. Whether the tachycardias that were not at all uncommon in the digitalized that did recover were related to the medication, we are not prepared to say: at least they seemed much more frequent than in cases in which only normal methods of cardiac stimulation were followed.

Finally, it is well to emphasize another point of difference in the management of this type of bronchopneumonia and the uncomplicated lobars or even the ordinary bronchopneumonias. In the lobars, no one therapeutic agent is of more value than air—indeed the open-air treatment was almost universal in the army camps, save for a few cases for some special reason unsuited to such care; in ordinary bronchopneumonias we use fresh warm air rather than open air; but in the influenza cases pure, warm indoor air seems to be almost a necessity.

We may add that during the invasion of influenza and throughout the pneumonic infection, the throat and whole upper air passages were sprayed frequently, with the idea of lessening the amount of reinfection from this source.

IV. REVIEW OF ONE HUNDRED AND EIGHTY-ONE CASES.

This particular series of cases came under the special care of the writer during February, March, and the first half of April, 1918, during which time hemolytic streptococcus was the prevailing factor in the fatalities and the complications that characterized all the pneumonias in nearly all the army camps and cantonments in this country. Had the "military necessity" for an autopsy in every fatal case obtained, we would not only be able to give more interesting details, but we might have gotten some invaluable facts to guide us in the management of a similar condition in the future. However, we had a fair number of autopsies; and from these we could definitely conclude that the cases that were diagnosed early seldom died from their pneumonia alone. Among the possibilities of the future are vaccines to lessen the fatal complications resulting from the Streptococcus hemolyticus and its equally unwelcome playmates, staphylococci, influenza bacilli, etc.

It is not necessary to state that this series was in no way selected but included all the cases—the obviously fatal or actually moribund on admission, as well as those that were diagnosed in the bellscope stage, i.e. when the consolidation involved an area that could be completely covered by the bell of the stethoscope (see Section II of this article); and, in these cases, recovery was the rule, in spite of an occasional complicating suppurative pleuritis—regardless of type and streptococcic affiliations.

In the interstitial form of bronchopneumonia, in which the areas have run into each other—as they do in the advanced stages—the history must be our guide in differentiation from other forms of lobular as well as from lobar pneumonia.

The mortality is, without doubt, materially related to the amount of lung tissue involved, and our ability to control this, at least in a measure, by making an early diagnosis, when a very small area is involved, must be an important factor in reducing our death rate, no matter what line of treatment we employ.

In this series, serum was used in but two cases, both Type I, and both complicated by Streptococcus hemolyticus. One was infected in both lower lobes, and in all the cases, of whatever type, the mortality was high under these conditions; the other was discovered in the bellscope stage, the infection being at the lower outer edge of the left lower lobe. Both gave high temperature reactions after each intravenous injection, and in

the milder case there was an apparent rapid extension of the area involved after the first dose of serum, but no special change thereafter. The former patient died, the latter recovered. However, it is not our intention to go into any discussion of specific forms of treatment, but to record the methods used, which may be characterized, perhaps, as the use of horse sense instead of horse serum.

For those who went through the epidemics of pneumonia later in this same year, it is unnecessary to speak of the differences in the kind of lung involvement, the rarity of empyema, the unusual occurrence of lobar pneumonia, the much less common complication by hemolytic streptococcus in these epidemic cases.

We have already stated that the mortality in cases of two-lobe involvement was high, and it is unnecessary to state that it was still higher in the three and four-lobe cases. One of the last-named made a good recovery, but was only normal a few days when he contracted measles, which was followed by bronchopneumonia, double empyema, and death.

In the early detection of fluids, especially empyema, the value of frequent white blood examinations both during the height of the invasion and during convalescence, the careful observation of the temperature curve, and frequent *x*-ray and physical examinations cannot be overestimated. When we are prepared to go ahead with the surgical care of the patient, we may use, under the strictest asepsis, the exploratory needle, but the indiscriminate use of the needle for diagnosis is unnecessary and undesirable. The exploratory puncture of the lung itself could only be justified under most exceptional conditions and for some most imperative reasons; as a routine measure for type determination, it comes near being a criminal procedure, in our opinion.

A discussion of the management of the fluid cases must be left for another occasion; but, from both a medical and a surgical standpoint, it is one of the most vital subjects, and it is a long way from solution. Just at this time, there is a fair unanimity of opinion in the belief that open operations on cases while they have an acute consolidation do not promote the longevity of the patient.

In regard to treatment, we may say, without hesitation, that the cases discovered in the very early stages required little or no treatment, no matter what type they chanced to be, except absolute rest in bed, proper care of the bowels, abundant fresh air (but not open air for the negroes), liquid nutrition and stimulation adjusted to the demands of the individual case by the condition of the heart. The originator of the serum urges its early use, pushed to the limit by one who has familiarized himself with its correct employment, otherwise a great injustice will be committed in estimating its efficiency, but he only advises its employment in Type I cases and condemns its indiscriminate use.

The plan we followed was an effort to assist and imitate nature in her care of such cases and was characterized by the systematization, simplicity, and possibility of application under almost any and all conditions. During the acute febrile stage of the lobar pneumonias, except in the negroes, the cases were kept in the open air, unless they complained of the cold, when they were returned to the ward. We did not find that the bronchopneumonias did well in the open air. In the lobars, the patient was kept as nearly at absolute rest as possible, not being allowed to turn over in bed without assistance or to sit up until the crisis had passed and resolution was well under way. The bronchopneumonias were allowed more latitude in moving around the bed, or being moved ,if they were very weak. Water was forced upon all of them frequently, if they did not ask for it.

Delayed resolution was treated by iodide of potassium in 5-grain doses three times a day, the amount increased a grain each day, if there was no trouble from it, until 10 grains were given; and it was always administered in a half tumbler of water.

All patients got their morning and night tepid sponge bath; and for temperature above 104° F. a hot sponge every four hours; over 105° F. the same every three hours.

Stimulation was based on the quality and rapidity of the pulse, the general principle being that no stimulation was required when the pulse was of fair quality and under 100. Above this point we began with strychnine, 1/60 grain, and tincture of digitalis, 15 minims, alternating every eight hours; calling this eight-hour stimulation. If the pulse got above 110 we would shorten this interval to six hours, keeping the same dosage. Above 120 we kept the same interval but doubled the dosage, that is, used digitalis 30 m. alternating with strychnine 1/30 grain. Above 130 pulse rate the dosage remained the same, but the interval was shortened to three or even, in desperate cases, to two hours; and in such cases we would introduce a new stimulant such as adrenalin, camphor, caffeine, whiskey, etc. We used digipuratum, when available, for digitalis, in cases in which the pulse rate had risen above 120. The increase in restlessness and delirium made whiskey undesirable, if it could be avoided, although in a very few cases it seemed to be of benefit.

The bowels were always at the outset cleaned out by a full dose of castor oil; after this enemata and salines were used when necessary.

In the wildly delirious, a strait-jacket was a valuable adjunct to bromides and baths. Ordinarily, sodium bromide, 30 grain doses, was efficient.

Stimulation was withdrawn as soon as it could be—as indicated by the pulse rate, following the reverse order, often jumping over one or two steps, the guiding thought being not to give what was not needed.

Writing, reading, conversation (prolonged) were all interdicted during the early stages and until the crisis had been safely passed. Morphine was strictly forbidden in acute stages, except under most unusual circumstances—in spite of which two of the fatal cases were given morphine, contrary to orders. For pain, strapping, hot-water bags, flaxseed poultices were usually sufficient. After the acute stages, morphine was used, when necessary, but was seldom necessary.

In bronchopneumonia of the ordinary type, the infusion of wild cherry with chloride of ammonium (½ ounce to 8 ounces, tablespoonful dose every three to six hours)—with heroin grain 1/12 added in obstinate cough—gave complete satisfaction.

The incidence of empyema and the mortality in these cases deserve separate mention, because of the thirty-nine deaths, fifteen were directly due to this cause, most of the patients having recovered from their pneumonias for quite a while. This would leave us only twenty-four deaths from pneumonia, including eight cases moribund on admission, two cases of diphtheria, and one case of acute cardiac dilatation complicating the pneumonic infection; in fact, only thirteen deaths in the series were due to the pneumonia. Both cases of diphtheria also had a severe nephritis.

A mortality of 15 in 87 cases of empyema is most distressing; but of this number the following facts may be noted:

Not-Typed	*Typed*
1. Diphtheria, abscess lung.	1. Hemolytic streptococcus.
2. Hemorrhage into pleural cavity.	2. Staphylococcus; two lobes.
3. Moribund on admission.	3. Hemolytic streptococcus, two lobes.
4. Had a pneumonia of three lobes and a necrotic area in one of these.	4. Hemolytic streptococcus, four lobes.
5. Have not heard cause; a simple circumscribed case.	5. Hemolytic streptococcus.
	6. Nonhemolytic streptococcus.
	7. Hemolytic streptococcus, type III, two lobes.
	8. Hemolytic streptococcus, type IV, two lobes.
	9. Interstitial bronchopneumonia following measles.
	10. Streptococcic septicemia, type I.

It is not possible to expect a brilliant outcome in these cases under any method of treatment.

Lobar Distribution of Cases

One lobe	115
Two lobes	44
Three lobes	5
Four lobes	2
Bronchopneumonia	15
Total	181
Right lower, middle and upper	12
Right middle and upper	4
Right middle and lower	4
Right upper and lower	9
Right upper	7
Right lower	49
Total	75
Left upper and lower	8
Left upper	9
Left lower	49
Total	65
Right and left lower	14
Right and left upper	3
Total	17
Right upper and left lower	2
Right lower and left upper	2
Both uppers and both lowers	2
Right upper and lower; left lower	1
Right upper and middle; left lower	1
Right upper and left upper and lower	1
Total	9
Bronchopneumonia and interstitial	1
Interstitial bronchopneumonia	2
Bronchopneumonia	12
Total	15

Types

	Type I	Type II	Type III	Type IV
	10	7	6	9
	7	3	3	12*
	2		2	
Total	19	10	13	21

Total 63

*With hemolytic streptococcus; with nonhemolytic streptococcus; with streptococcus and staphylococcus.

Hemolytic streptococcus	29
Nonhemolytic streptococcus	14
Staphylococcus and streptococcus	1
Pneumococcus and streptococcus	1
Pneumococcus not I, II, or III	1
Pneumococcus precipitated in I and II	1
Staphylococcus	1
Interstitial bronchopneumonia	4
Bronchopneumonia	4
Moribund and not determined	6
Total	66
Cases not typed	7
I, II, III, and IV	6
Miscellaneous types	8
Total	87

Analysis of Fatal Cases

Not Typed: Total	7
Died	12

Of these, only two died of their pneumonia alone and both were two lobe cases. The remaining cases were:

Scarlet fever	1
Acute heart failure	1
Peritonitis	1
Moribund on admission	2
Empyema	5
Total	10
Typed: Total	128
Died	27

Of these, only nine died of their pneumonia and one of these, by his deliberate disregard of orders—repeatedly sitting up—was practically a suicide. The remaining cases were:

Diphtheria and nephritis	1
Moribund or hopeless on admission	5
Acute cardiac dilatation	1
Empyema; Nonhemolytic streptococcus	1
Empyema; Hemolytic streptococcus	9
Total	18

Of this total of eighteen, eight were straight hemolytic streptococcus infections and it is not unlikely that systemic infection was the rule in all.

	Type I	Type II	Type III	Type IV
	1	2	0	1*
	2	1	2	4‡
			1	
Total	3	3	3	5

Total 14

*Straight.
‡With hemolytic streptococcus, diphtheria and nephritis.

The bacteriology of the remaining thirteen cases was as follows:

Not I, II, or III:	
With staphylococcus gram positive, bile insoluble	1
Diplococcus gram positive, bile insoluble	1
Nonhemolytic streptococcus	1
Hemolytic streptococcus	1
Interstitial broncopneumonia; hemolytic streptococcus following measles	1
Probably hemolytic streptococcus; admitted dying	2
Hemolytic streptococcus	5
Total	13
	Total 13
	27

Grand total of deaths from all causes 39, in which hemolytic streptococci were definitely demonstrated in all but four of the typed cases and were probably present in as large a proportion of the 12 deaths not bacteriologically studied. We would welcome, therefore, any vaccine or other method that may be found to control this kind of infection. Even in these cases, their frequent recovery when discovered and treated in the bell-scope stage, made this necessity stand out as the one of transcendent importance in all varieties of

pneumonia—the earliest possible recognition of its existence; the great probability that it is already present when the chill occurs, and the possibility of making the diagnosis both by physical examination and by *x*-ray, make it obligatory not to overlook its existence in this stage.

573 Seventh Avenue.

LEUCOPENIC LEUCEMIA.*

By NATHAN E. BRILL, M.D.,

NEW YORK.

THERE are many aspects of the subject presented in Dr. Rosenthal's paper that could be discussed, but I feel that the allotted time will permit me to direct attention only to one of the most important phases of the subject, therefore I shall have to be content to restrict myself to a clarification of the confusion which I find generally in the minds of medical men concerning leucemia, partly due to the multiplicity of terms used by most authors who have written on this subject. I think this clarification will ensue if you follow the history of the evolutional development of the literature of the disease.

No doubt you will remember that the first description of the disease came from a Scotch clinician, Hughes Bennett, who, in 1845, recorded the case of a patient in whom he found an enlargement of the spleen and of the liver, and whose blood on examination showed what he called a "suppuration of the blood." One month later Virchow gave an account under the title of "white blood" of a similar condition in a patient in whom he likewise noted enlargement of the spleen, epistaxis, and unusual increase of the white blood cells in the blood. It was at autopsy in both these patients that the important changes in the organs were found. Subsequently Bennett called the condition leucocythemia, and Virchow gave it the name of leucemia, the latter name now being generally used.

Not very long after his first case Virchow reported another case with a similar condition of increase in the white cells of the blood which, however, was associated with an enlargement of almost all of the lymphatic glands and very little increase in the size of the spleen. In still later papers he distinguished between the form associated with splenic enlargement, in which organ he believed the excess of lymphocytes was formed—splenic anemia—and the form attended by enlarged lymphatic glands in which bodies he thought the increase of the white cells occurred—lymphatic leucemia—and he called attention to the smaller size of the leucocytes in the latter form as compared with their size in the former.

You will also remember that the man who first called attention to the presence of nucleated red cells in normal bone marrow, Neumann, found the marrow often profoundly changed in cases of leucemia, and he attributed to changes in the bone marrow the resulting disease. His communication, in 1870, gave rise to considerable discussion among medical men, and it became finally agreed that there was also a spleno-medullary form of leucemia. The acceptation of this last form did not add to the clarity concerning leucemia but, on the contrary, created confusion, because it soon became known from experience that enlarged lymphatic glands occurred in cases associated also with enlargement of the spleen, changes in the bone marrow, and increase in the number of white cells in the blood, hence another, the mixed form of leucemia, had to be added. During these years, then, leucemia was supposed to be a disease characterized by white blood, associated with anemia, by large spleen in some cases, in others by large lymphatic glands, and in still others by both enlarged spleen and enlarged lymphatic glands.

It was Ehrlich's epoch-making researches in the chemical reaction of acid and non-acid dyes on the white blood cells which finally culminated in the discovery by him of entirely distinctive differences in the white cells of the blood, enabling him to establish the normal presence of cells peculiarly belonging to myeloid tissue—chiefly the polymorphonuclears and granular myelocytes—and those arising in lymphoid tissue, the lymphocytes. He created, therefore, on a histological basis, two types of leucemia, namely, myelogenous (myeloid is a better name) and lymphatic (lymphoid is possibly preferable) leucemias. Since Ehrlich's time very little has been added to our knowledge of the histology and pathology of the blood cells, the chief gain in our knowledge being in clinical variations of leucemia depending on the types of each group of cells, and a wider recognition under the microscope of the embryonic or premature forms of these two cell groups. Clinically it soon became established that in certain infections such as pneumonia there was a large increase in the blood of polynuclear cells, which, however, did not constitute a leucemic state, and that in other somatic conditions there could be a relative and absolute increase in the lymphocytes of the blood without it being significant of lymphoid leucemia.

In teaching my classes I am accustomed to tell them that to gain an adequate conception of leucemia one has to conceive of a general distribution throughout the body of two distinctive systems of cellular tissues, namely, the myeloid and lymphoid systems of cells. The former is commonly found in all the hemopoietic organs, namely, bone marrow, spleen, liver, less frequently in the kidney, lymph nodes, periosteum, lungs, and skin; the latter is less commonly distributed in the lymph nodes of the body, less extensively in the lymphoid tissues of the spleen and bone marrow, and still less extensively in the lungs, kidneys, the other viscera, the periosteum, and the skin. Under certain influences the nature of which is unknown a hyperplasia of these tissues can occur, giving rise to increase in the size of the organs affected and causing cells to invade the blood stream, commonly in large numbers. Thus, if myeloid hyperplasia results we are dealing chiefly with enlargement of the spleen, liver, and myeloid changes in the bone marrow with myeloid elements in the blood, usually in large numbers, hence a myeloid leucemia. These myeloid infiltrations or hyperplasias less commonly involve the kidneys and other viscera, and even less the skin, showing in the last varying sized infiltrations—the myeloid dermatosis. When they occur in the periosteum and subperiosteal tissues they

*Presented as part of the discussion on leucopenic leucemia at a meeting of the Section on Medicine of the N. Y. Acad. of Medicine, May 17, 1921. (See page 914.)

produce myeloid collections of cells giving the appearance of bony growths to which the name of chloroma has been given. Some authors believe that chloroma is a distinct special disease, but in the writer's opinion chloroma is nothing but a special localization of a leucemic process in the periosteum of bones, particularly the flat bones, which can be formed of myeloid cells on the one hand, hence a myelogenous chloroma, or, on the other hand, from a lymphoid hyperplasia constituting a lymphoid chloroma. In other words, chloroma is an uncommon clinical variety of either myeloid or lymphoid leucemia. Sometimes, though not always, these chloromatous so-called tumors are green in color, hence the name chloroma, due to the presence of a peculiar chromogenic compound whose nature is unknown. All chloromatous tumors, however, are not green in color.

Similarly, under other unknown conditions an analogaus change may occur in the lymphoid tissues, creating a hyperplasia of the lymphoid elements of the body with a large increase in their numbers in the circulating blood. This would commonly be associated with enlargement of the lymph nodes of the body, with but relatively little enlargement of the spleen and with lymphoid changes in the bone marrow—lymphoid leucemia. In a few instances the skin may be the seat of lymphoid infiltrations—lymphoid leucemic dermatoses—as may also the periosteum, as mentioned, giving rise to lymphoid leucemic chloroma, and there may be collections of lymphoid infiltrations in the lungs or in the other viscera.

These unknown causative conditions of hyperplasia usually produce changes in the normal histological blood picture on account of their influences on the hemopoietic tissues, particularly the bone marrow, giving rise to a high degree of anemia which may even be associated with hemorrhages in the skin and from the mucosa, due perhaps to the disease process affecting the blood platelet formation.

It may be accepted as a general rule that whenever any pathological agent affects the bone marrow, it may affect therein more than one group of cellular activities, so that when the bone marrow is much involved in leucemia the noxious agent may induce hyperplasia in erythroblastic tissue as well as in the myeloid, with the result that there may be an invasion of the blood by premature red blood cells, normoblasts and megaloblasts, together with changes in the blood, particularly the presence of embryonic red blood cells. It was this condition of marked anemia, with high color index and embryonic red cells, occasionally found in the very severe form of myeloid leucemia, that induced von Leube to classify this condition as a distinct disease, which he called leucemia. This term ought to be cast aside, because it does not describe a particular entity, but only a phase in the course and progress chiefly of myeloid leucemia.

The speaker has for years insisted on the analogy which antithetically exists between pernicious hemolytic anemia and the leucemias. Just as the unknown etiological agent in the latter may cause the irritative process in the myeloid (or lymphoid) tissues of the bone-marrow to overrun into the erythroblastic tissue and produce hyperplasia in the latter, so may the toxic agent in pernicious anemia affect not only the erythroblastic elements in the bone marrow but the leucoblastic (white cell producing) tissue as well; hence one not uncommonly sees in advanced and in fulminating cases of pernicious anemia premature myeloid cells in the blood such as myelogones, myeloblasts and myelocytes, together with the characteristic changes in the red blood cells.

Take it also as a general rule that the more acute and fulminating the leucemic process is the more likely is the blood to contain the premature embryonic types of the myeloid or lymphoid cells. Hence in acute myeloid leucemia, the myelogones, the myeloblasts and the myelocytes may be the dominating cells in the blood, and in the acute lymphoid leucemia the lymphoblasts and small lymphocytes may be the significant blood factors.

Just as in the course of a pernicious anemia the bone marrow may become exhausted and be unable to restore the needed red blood cells, in other words, becomes aplastic, so in the course of the leucemias an analogous condition may obtain and the white blood cells become markedly diminished even to the extent of being reduced from 100,000 per cubic millimeter to 15,000 and less, resembling normal figures. This reduction may be also the result of treatment or of a remission in the course of the leucemia, which not uncommonly occurs to delude the physician to believe that the disease may disappear.

These remissions, as you know, not infrequently occur in the course of a pernicious anemia, strengthening the conception of analogy. During a remission of this kind in leucemia it may be difficult to make a diagnosis, because the somatic symptoms likewise improve, the spleen diminishes in size, the lymph nodes become markedly diminished in size, and the anemia may disappear as may the hemorrhagic spots in the skin. A careful examination of the blood, however, usually shows abnormal white cells, particularly characterized by qualitative changes, either a few premature cells or an inversion in the proportion of the myeloid cells on the one hand and of the lymphoid derived white blood cells on the other. In these remissions the number of white blood cells may become even lower than normal and may show a definite leucopenia, the number being 3,500 white blood cells to the cubic millimeter or less. We prefer, however, to restrict the term leucopenic leucemia (also known in the literature as aleucemic leucemia, because the small number of white blood cells in the blood contradicts the conception of an increase of white blood cells which was once thought to be an essential for the conception of leucemia, hence the term, aleucemia) to those cases of the acute leucemias, either myeloid or lymphoid, which begin with all the signs usually indicative of an acute infectious disease, such as chill, high fever, rapid loss of strength and weight, hemorrhages from the mucous surfaces and also into the skin, rapid infiltrations of leucemic hyperplasia, particularly in the tonsils where they may produce a speedy necrosis.

When the tonsils are so involved they almost invariably become the seat of secondary invasion by the Vincent's spirillum which may readily

be distinguished by smears taken from the tonsils. The most of these acute cases affecting the tonsils are accompanied by a very nasty, foul-smelling stomatitis, and are wrongfully diagnosed by practitioners as diphtheria or Vincent's angina. A microscopical examination of the blood usually reveals the secret that the necrotic mouth and pharyngeal condition are due to an acute leucemia. Be on your guard, therefore, in such cases to examine the blood carefully for premature myeloid or lymphoid cells.

These acute cases go on rapidly to the production of an intense anemia with many skin hemorrhages. They may begin, and frequently do, with none of the somatic signs such as enlarged spleen or enlarged lymph nodes, but the blood reveals the condition not in an increase of the number of white cells as much as in the presence of premature embryonic forms such as Dr. Rosenthal described with such clearness as myelogones and myeloblasts in the acute myeloid leucemia and as lymphoblasts in the acute lymphoid form of the disease. These are the cases which may show in the first days a marked diminution below the normal number of white blood cells in the blood and to which the name of leucopenic leucemia (acute aleucemic leucemia) ought to be reserved.

The leucopenia gives away after a short time to a more or less rapid increase in the number of white blood cells to even 150,000 or more per cubic millimeter before death, or the acute stage may, more rarely, turn into a subacute or still more commonly into the chronic form of the disease. It was once thought that most of the acute forms of leucemia belonged to the lymphoid variety. It is only in the past few years that better tinctorial reagents and the discovery by Schultz of an oxidase reaction (the indol synthesis) in certain cells that what were once considered to be lymphoid cells have shown them really to belong to the myeloid group; hence acute myeloid leucemia is now regarded as very much more common, while the acute lymphoid leucemia is rare.

Under treatment by *x*-ray and by radium the chronic leucemias may improve both as to the objective signs of the disease and as to the diminution of the number of white blood cells. In fact, a leocopenic condition may result. This does not indicate any more than the occasional spontaneous remissions as, in my experience, all the leucemias are fatal.

From what has been said, then, it may be seen that from the original conception of pus blood being the sign of leucemia, the involvement of the hemopoietic organs particularly became the significant factor in the conception of the disease; that there are two types of cells distributed in part throughout the body which become involved in the hyperplasia of leucemia, causing the more or less extensive infiltration of the various organs and tissues with myeloid and lymphoid cells respectively; that in this process the red-blood-cell producing tissues may be stimulated to activity causing the picture of so-called leucanemia, which term ought to be discarded; that the disease leucemia may exist in an acute or chronic state, and that it is almost invariably fatal.

48 West Seventy-sixth Street.

THE FUNCTIONAL AND DEVELOPMENTAL RELATIONS OF THE NERVOUS MECHANISM.

By Donald A. Laird,

Iowa City,

Instructor University of Iowa; recently Research Assistant, Iowa Child Welfare Research Station; formerly Examiner, Psychiatric Unit, Great Lakes Naval Station.

One who is classified among the so-called human beings of the vertebrate phylum and has his own inner ruminations as well as the behavior of his fellowmen to observe cannot but be forcibly impressed by the importance of the neural mechanism in the economy of daily life. When one gives the matter only casual attention he is quite likely to be led to assume that the neural aspects of the organism are prepotent above all others. Superficially such a deduction is inevitable in consideration of the rôle of consciousness in determining largely the overt behavior of the organism. And consciousness is more or less tacitly assumed by all concerned to be an immediate correlate of the nervous mechanism.

Clinical evidence, also, would lead one to an emphasis of the neural characters in the animal organism. The numerous recent clinical studies in vegetative neurology especially furnish a weighty line of evidence tending to force the balance still higher in the favor of the neural organization. Certain it is that as vertebrate development has taken place the nervous system now occupies an intimate and fundamental relationship to the organism as a whole.

There is a very grave likelihood, however, that the part taken by the nervous system in the economy of vertebrate animals, and *pari passu* in the developmental origin of animals, will be much overrated. Through stereotyped thinking it is very easy to give the nervous system a priority of development which finer and more pertinent facts do not warrant. The man-in-the-street and the cloistered, introspective psychologist and philosopher deal with certain facts and assume certain attitudes which enhance the functions assumed by the neural organization, especially as it bears upon conscious states and volitions.

Then there is the theological thinker—and we are all more or less theological—who somewhat unconsciously identifies mind and spirit and arrives at a valuation of the character of the neural constituents of the animal that shamefully ignore or berate the other aspects of the organism. Muscles and glands are considered the animal parts of the body. The nervous system is looked upon as contributing the traits that are essentially human and in the likeness of the Creator.

This attitude toward the fundamental relationships of the nervous system is not limited to those who make a rather subjective approach to the question of the place occupied by the nervous system in the animal economy. Practitioners of medicine and even students of neurology are dealing with certain objective facts which in themselves would reinforce the point of view which is being indicated. Unless these objective facts are viewed in their proper perspective they will only reinforce the sub-

jective convictions regarding the omnipresence and omnipotence of the nervous system.

The fact that it is only through musculature that the nervous system becomes functional and is of any use to the organism is quite likely to be overlooked or passed over with an "of course." The give and take between the muscular, glandular and neural mechanisms is very probably ignored most shamefully.

Admittedly the overt functions and even to a considerable extent the vegetative functions of the higher vertebrates are largely attuned through the neural mechanism. This prominence of the nervous system in the life and behavior of the vertebrate organism encourages a point of view respecting its primitive development and origin which is not only unwarranted but against the current of fact.

Superficially it is quite the logical thing to look upon the nervous system as being of great evolutionary age in comparison to other bodily tissues and a sine qua non without which animal life is impossible. This has been the attitude of the leading scientists at times. For example, Linnæus, the great Swedish scientist of the eighteenth century, distinguished plants from animals solely by the fact that the latter were sentient. We now know

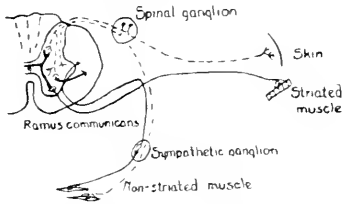

FIG. 1.—The complete neuromuscular mechanism as found in a higher vertebrate. The receptor division is indicated by the broken lines, the effector by the solid lines and includes the striated and non-striated musculature. The associational or intermediary division is within the spinal cord and is represented by the heavy lines.

that many organisms truly classified as animals are non-sentient, but the differentiation of so profound a thinker as Linnæus is significant in this connection when what might be termed the common-sense point of view is being indicated.

What is superficially most prominent in the higher organisms, however, is seldom of fundamental significance for the total range of animal life. Such is the case with the nervous system. In this paper a review will be attempted of the data from animal biology and behavior as they bear upon the developmental origin of the fundamental nervous structures. No attempt will be made to introduce new observations. The point of view to be presented is distinctly an American achievement, having been originated and masterfully championed by Professor G. H. Parker of Harvard University. It is the only satisfactory account of the developmental relations of the nervous system, unifying the diverse threads of evidence in a manner unattained by any other statement of this genesis.

The point of departure taken by this account is functional rather than solely morphological. Like the account itself this functional, physiological attitude is the result of the work of American investigators.

Three functional aspects are to be differentiated in the fully developed nervous mechanism. First in order of excitation are the *receptors* which are highly specialized in the more advanced vertebrates. In the lower forms of animal life these receptors may be nothing more than a free nervous termination resembling the cut end of a thread and reacting uniformly to all types of stimulation. When present, either in generalized or specialized form these receptors or sensory structures function to convey nervous impulses to other parts of the body upon stimulation by light rays, pressure, chemicals, and other agents to which it is essential for the organism to adjust itself.

The next functional division to be distinguished is the *associational* or *intermediary* parts of the neural organization. These function to bring the various receptive structures into active relationship with the parts of the organism by which a response to the stimulation is effected. This brings us to the third functional sector of the nervous mechanism, the *effectors*. The effectors proper are the muscles and glands through which the spatial orientation of the organism is accomplished. It is by means of the afferent neurones that the other parts of the nervous system are brought into physiological relationship with the effector structures.

From functional considerations the nervous system is thus seen to comprise certain morphological structures that are not in the strict sense nervous elements. Hence it has been deemed advisable to designate this physiologically functional system the neuromuscular mechanism. The nervous system alone and isolated is of little biological value. It is only of value as it becomes functionally active when related to certain structures which are capable of modifying the relations of the animal to its environments. Moreover, function is quite as significant as structure in determining the course of primitive development of the organism.

This complete, three-phase, functional mechanism is found in its entirety only in animals of a rather complex organization. Among the less differentiated multicellular animals these functional aspects of the neuromuscular mechanism are found in varying degrees of relationship. Accordingly we will now turn our attention to those animals with representative degrees of functional development, studying them alike in morphology and behavior.

Irritability is a common property of all living organic matter, both plant and animal. This characteristic of living protoplasm has root in the unstable molecular structure of organic matter in the living cells. This property of irritability provides the basis for behavior. In its simplest forms behavior is an organized irritability occasioned immediately and directly under the influence of certain environmental forces. In its more complicated forms behavior is an indirect and less immediate and less constantly organized irritability. The simpler forms of behavior are spoken of as tropisms.

Tropic behavior is present in plants as well as simple unicellular animals. Certain of the plants turn their open flowers toward the source of light. Among the protozoa we find that the Euglenæ also invariably seek the light. The tropisms are directly adaptive in their service to the organism. Thus in the Euglenæ, as in all protozoans, certain negative

chemotropisms keep the organism away from noxious chemical influences, while other tropisms impell these microscopic animals into contact with food particles which are enveloped and digested.

These lowly protozoans are devoid of all nervous

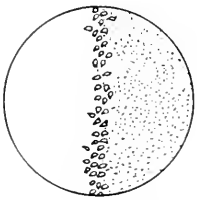

Fig. 2.—Demonstration of a light tropism in euglenæ. The left half of the experimental field is lighted, the right half shaded. The euglenæ seek the intermediate region. This behavior takes place in a single celled animal devoid of all nervous structures. (Adapted from Famintzin.)

structures in the morphological sense of the term, but still we find them living a rather rational existence, as it were. They are selective in their reactions or tropisms, being stimulated positively by certain environmental influences and negatively by others. Normal protozoans are not subject to the vicissitudes of appetite as is man, but uniformly reject or accept food particles. A rather monotonous existence these tiny single-celled animals live, but on the whole a very well regulated life.

Among the lowest multicellular animals we also find this machine-like behavior. Differentiation of function as well as structure is taking place in these primitive metazoans, but still among the lowest—as in the sponges—no nervous tissue has yet been discovered.

The chief activity of the sponges consists in causing a flow of water through the central cavity of the animal. This water enters through the numerous lateral pores found along the sides of the animal. It is these pores which give it the characteristic spongelike construction. Numerous flagellated cells, the choanocysts, located in these lateral

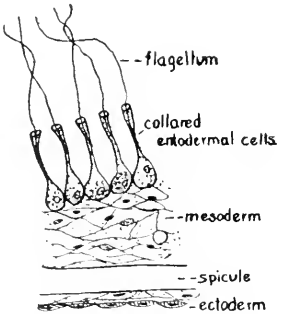

Fig. 3.—Section of a sponge showing flagella which line the canals. No trace of nervous tissue is to be found. (After Shull.)

pores and around the central cavity, produce a flow of water through the lateral pores, into the central cavity, and finally out at the apex through the mouth-like osculum. These flagellated cells lash their flagella continuously, keeping up a steady flow of water through the porous system of the organism.

Although the sponges are free from any nervous mechanism primitive muscular cells, the myocytes, have been differentiated. These specialized con-

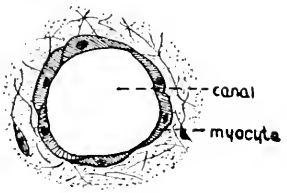

Fig. 4.—Section at right angles to axis of a canal in a sponge, taken near the aperture. Primitive muscle cells prominent. This is the first step in the development of the neuromuscular mechanism.

tractile structures are situated as ringlike structures around the pores and osculum of the sponge. Now if the inner surface of one of the lateral pores or the osculum is punctured by a needle these primitive muscle cells contract, closing the pores of the body wall with remarkable quickness for so sluggish an animal.

Thus we find in the sponge an extremely simple yet effective and somewhat specialized mechanism which is more reflex-like than tropic. And still this mechanism functions independently of all nervous structures. It is functionally complete in the myocyst. In the developmental relations of the neuromuscular system effectors in the form of contractile tissues are thus seen to precede the nervous structures. Moreover, in the more primitive condition the effectors are functionally complete in themselves.

As a rudimentary condition of the functional independence of musculature in man the only morphological structure yet demonstrated to have this status is the sphincter pupillæ of the eye. When all neural connections with this muscle are removed the muscle will still contract when stimulated even by a small amount of light. The heart of vertebrate embryos also begins active functioning before neural connections have been established with it by the rapid developing nervous system.

The first phase in the development of the primitive neuromuscular mechanism was the formation of musculature (effector) which was functionally sufficient in itself to meet the demands of the organism it served. Ascending the metazoa we find

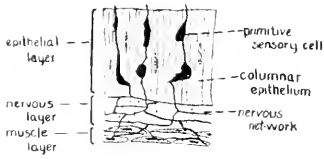

Fig. 5.—Diagram of the ectoderm of a sea-anemone showing a simple effector-receptor system with the nerve-net type of connection.

the cœlenterates more specialized in structure and function than the sponges. These animals, of which the sea anemone and jelly fish are typical, have distributed throughout the ectoderm specialized cells which function as sense cells or receptors. One

is therefore not at all astonished to find the sea anemone very responsive to external stimulation. Simple mechanical stimulation causes an immediate contraction of the entire organism.

While the neuromuscular organization of the sea anemone is primitive and rather diffuse and general, there is a specialization of sensory function present in the receptive nervous cells. The mouth and lips of the animal are responsive only to the contact of food particles and not to ordinary mechanical stimulation. The general epithelium, however, is sensitive to mechanical stimulation, but not to particles of food.

There is no evidence, either anatomical or behavioristic, of a central nervous organ in the cœlenterates. Anatomically the primitive nervous layer forms a continuous system in which the cellular processes are fused into a net-work. This nervous layer lies immediately against the layer of muscle fibers and probably stimulates the muscles directly and diffusely.

The behavior of the sea anemone is also such as to lead to the conclusion that its nervous organization is diffuse and unspecialized. For example, if bits of meat and blotting paper soaked in meat extracts are placed alternately on the tentacle of one of these cœlenterates these morsels will be carried to the mouth without hesitation and without discrimination. After several repetitions of this deception, however, the animal becomes aware, as it were, of the trick which is being played. After a dozen or more feedings on the meat and meat-soaked blotting paper, it will begin rejecting the camouflaged food morsels while meat is still greedily accepted by the tentacles and carried to the mouth.

Now after one group of tentacles has been educated, so to speak, to distinguish the real from the spurious food, the experiment can be performed with another group of tentacles which are unpractised in overcoming this deception. When this is done it is found that they unhesitatingly accept both the meat and the paper and convey them to the mouth of the animal. There is thus no generalizing of the experience as would be observed if the organism possessed even a primitive centralization of its nervous structures.

The first phase in the developmental relations of the neuro-muscular mechanism was found to be the formation of contractile effectors. As the animal scale is ascended more or less specialized receptive cells of primitive but true nervous tissue are found. In the lower cœlenterates, as the sea anemone, this receptor system is rather diffuse, although somewhat specialized. As an example of the higher cœlenterates we may consider the jelly fishes. In these very sensitive and specialized sense organs are to be distinguished. There is still no evidence from the microscopic anatomy or the behavior of these more specialized cœlenterates of a centralization of organs or the existence of intermediary or associative nervous structures.

The first morphological nervous tissue was chiefly sensory or receptive and in immediate contact with the effectors. Parallel if not identical structures of a diffuse nerve-net character are found in the intestinal walls of man. There minor plexuses from the sympathetic system and the nerve processes from these plexuses lie in immediate contact with the contractile layers of tissue which they stimulate. The movements of the intestinal walls in churning the food and in peristalsis are ordinarily thought to be under the control of the vagus and the splanchnic nerves. Experimentation has demonstrated, however, that when these nerves from the central nervous system are completely removed from all contact with the intestine its behavior remains characteristic and functionally sufficient. In man, therefore, we find that this primitive effector-receptor functional mechanism is present in certain portions of the sympathetic nervous structures and is functionally adequate in itself.

Above the cœlenterates the truly intermediary neurones make their appearance. Centralization of the nervous structure also begins to take place. The further development of the neuromuscular mechanism consists in the elaboration and organization of these intermediary structures. It is beyond the scope of the present paper to discuss the development of the structural organization.

To summarize: In considering the developmental relations of the nervous system a functional point of view is necessary. Functionally the unit is a neuromuscular mechanism rather than simply the nervous system.

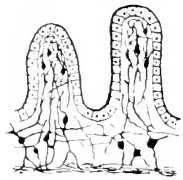

Fig. 6.—Villi of human small intestine with Meissner's plexus and the primitive type of nerve-net connections in the nerve supply which is derived from the cœliac division of the solar plexus.

Irritability is a property common to all protoplasm, as is also conductivity and contractility. Nerve cells have the properties of irritability and conductivity emphasized in their specialization. In muscle cells contractility is emphasized. Single-celled animals in which all the protoplasmic properties are unspecialized can react to and adapt themselves successfully to their environment without the aid of any nervous structures at all. The most primitive multicellular animals have no nervous structures, but some of the cells have the property of contractility developed in advance of the others and these contractile, primitive muscle cells are the first parts of the neuromuscular mechanism to develop. The next part of this functional system to develop is the rudimentary sense cells which are morphologically nervous in character as well as in function. Later the so-called motor neurones and the associational or intermediary neurones have developed. The developmental relations of these latest parts of the functional mechanism are not traced in the present paper, but they consist in a centralization of structure and organization of relationship of increasing complexity with increase in complexity of behavior and position in the animal scale.

Embryological development of the higher vertebrates and man repeats in a modified way the essential steps of this relationship. In the adult man

structures are also found which functionally demonstrate the stages in the developmental origin of the nervous system. These stages of development in the order of their occurrence are: effectors, receptors, intermediaries.

ANEURYSM OF THE VERTEBRAL ARTERIES.

By J. FLOYD MORROW, B.S.,

MORGANTOWN, W. VA.

ASSISTANT IN THE DEPARTMENT OF ANATOMY, WEST VIRGINIA UNIVERSITY MEDICAL SCHOOL.

ANEURYSM of the larger arteries of the brain according to Finely[1], is a rare condition, occurring nineteen times in 9000 autopsies collected from Gray's Hospital by Pitt, and seven times in 501 cases of aneurysm, according to Crisp's figures. They seldom attain a size larger than a walnut and frequently lead to fatal rupture when no larger than a pea. The middle cerebrals and the basilar are more often affected than the other vessels. The other cerebral arteries, the vertebrals and the communicating arteries occasionally suffer.

Aneurysms of the larger cerebral vessels, as stated by Stewart[2], are of an acquired spontaneous origin usually following a chronic arteritis together with an increase in the blood pressure. Inflammation with softening of the arterial wall from the lodgement of emboli in the cerebral vessels is a lesser evil in the production of aneurysmal dilatation. Chronic arteritis of syphilitic origin is said to be the main etiological factor. Alcoholism, excesses, and certain pathological conditions, producing in the last mentioned an increase in blood pressure, are contributory in a varying degree to the initiation of or to the acceleration of the process.

Aneurysms occurring within the cranium are usually of the fusiform type producing a dilatation and elongation of a section of an artery. The seriousness of such a tumor mass depends upon its location, size, rate of growth and secondary changes which it may undergo. When a vertebral artery is affected we can expect a great variety of disorders to follow. The most vital part of the nervous system, the medulla oblongata, is subjected to a severe pressure test. The organ may become distorted in both form and position. The pressure may extend to the pons and produce a large notch on its exposed surface.

With the advent of the tumor mass certain recognized degenerative changes are initiated within the medulla. Mayer[3] states that these changes manifest themselves in the form of a compression bulbar paralysis of a varying intensity. The development of the disease is generally a protracted one; and the bulbar symptom-complex does not as a rule come on suddenly, but step-like, or it may suddenly become acute. Seizures appear repeatedly during the malady, characterized by incoherent speech, deglutitory paralysis, dyspnea, acceleration of the pulse and cardiac arrhythmia, and occasionally a considerable rise in temperature. The bulbar symptoms gradually disappear, to come on again with a new attack. In the intervals also, phenomena remain which are due to an irritative or paralytic condition of one or several bulbar nerves, or to softening of the pons or medulla. Rhythmical twitchings of the facial muscles and of the velum palati have been observed, more frequently paralysis of the facial, trigeminal, vagus, accessory, cochlear, etc. The alternating character of these paralyses is very characteristic. The paralysis may be a simple or an atrophic one. A paralysis of the extremities in the form of a general paraplegia, hemiplegia alternans, or a paresis of the legs is almost always present to some extent.

Last November the body of a white man, aged about 50, was received by the Department of Anatomy of the West Virginia University Medical School. Unfortunately it was impossible to get any previous history of the case. The general physical appearance of the body was indicative of the man having died very suddenly from acute cardiac or respiratory disturbances while in apparently good health. There were no signs of emaciation of atrophy. In fact, the development of the musculature and body contour was considerably better than that of the average robust individual.

In removing the brain a large solid tumor mass was encountered in the region ventral to the medulla. Examination revealed a spontaneously cured fusiform aneurysm of the right vertebral artery. The aneurysmal dilatation began 1.5 c.m. from the bifurcation of the basilar artery and increased abruptly to its greatest diameter of 2.5 c.m. This extreme dilatation was continued for a distance of 3 c.m. downward and the artery again very abruptly assumed its normal diameter. Section of the aneurysm showed a channel of approximately normal size on the side proximal to the medulla, while the mass of the tumor was of a grayish lamellar and incompressible consistency resembling cartilage somewhat but not staining to show any cellular elements. The arterial wall covering the aneurysm was 2 mm. in thickness and very hard from the deposition of salts, except that portion immediately over the blood channel which appeared to be normal. The other vertebral artery was crowded laterally and showed a dilatation for about 2.5 c.m. of its course, with a diameter of nearly one centimeter at its greatest development. This artery was very sclerotic. The basilar artery was in a position considerably to the left of the midline and was very torturous. The circle of Willis had several small areas of sclerosis.

The medulla oblongata was pressed into an unrecognizable mass by the aneurysm. The pyramids, pyramidal decussation, olives, anterior fissure, lateral sulci, etc., were obliterated. The anterior surface of the medulla was concave with a depth of 0.4 c.m. and 1.7 c.m. transverse and vertical measurements respectively. The distance anteroposterior through the organ was less than half that of the normal, while transversely it was one-third wider than that of a normal medulla. The position with respect to the midline was fairly well maintained. At the deepest part of the concavity the medulla was pushed backward 2 c.m. so that it occupied a position between the cerebellar lobes. The pressure had been greatest on the right side and gave to the medulla the appearance of having tried to rotate out of its normal axis in a clock-wise direction. The deformity of the medulla shows that its substance was not only compressed but pushed out of its normal relationship of parts in a dorsal and in lateral directions. There was no gross evidence of any softening of the organ.

The pons was pressed slightly upward on the left side obliterating the inferior portion of the midline, and presented a notch 9 mm. wide, 12 mm. long, and 3 mm. deep. Other findings were a gorged right auricle and an embolus in the femoral artery just below Poupart's ligament.

A section of cervical cord stained by Marchi's method showed a great number of degenerated fibers scattered throughout the fiber tracts of the cord. The degenerated fibers were more abundant in the large sensory and motor tracts, the fasciculi gracilis and cuneautus, dorsal spinocerebellar and crossed pyramidal tracts showing the greatest degree of involvement.

Such an impairment of the cord suggests the liability to motor and sensory disturbances as was stated above. But in the case described we see a most remarkable disfigurement of the medulla without the atropic or simple paralysis which may follow a pressure upon the organ. The findings indicate that if there were manifestations of a compression bulbar paralysis they were of a mild transient type, and that death probably resulted from a sudden acute involvement of the respiratory and cardiac centers in the medulla.

The location of a vertebral aneurysm, situated as it is on the most vital center of the nervous mechanisms, offers a very interesting study. It is a well-recognized fact that the medulla will not withstand any sudden injury without serious or even fatal consequences. When we see a medulla reduced by a pressure to less than one-half of its normal diameter and a cord showing motor and sensory degeneration, the question of how much and how long can the medulla withstand this continuous increasing pressure naturally arises. Here, the rate of formation of the aneurysm is apparently the main factor. As the tumor mass encroaches upon the medulla, the latter attempts to functionally accommodate itself to a change of form and the attendant pressure.

In the case reported it is evident that such an attempt of accommodation was relatively successful. When the tumor mass has reached the size of a walnut together with the pronounced disfigurement of the medulla it is suggestive that a relatively long period of time was necessary for its development. The gravity of the situation it appears would be the inverse of the rate of formation, while the actual size of the tumor mass should be considered as secondary in importance; otherwise there could not have been produced such a deformity of the medulla. While the normal functioning of the medulla becomes impaired, it is only when a vital center or a fiber tract is suddenly blotted out can a fatal termination be expected. Here, the factor of a softening of the medulla is of first importance, while a fatal hemorrhage, which is rare in this location, is secondary in consideration. Even though a spontaneous cure of the aneurysm may be affected, as happened in the case described, the tumor mass will persist as a foreign body, and the degeneration of the medulla must continue.

The diagnosis of cerebral aneurysm Finley states is seldom, if ever, made with certainty. In Beadles 555 cases apoplexy was the first symptom in 46.3 per cent. of the cases. Here the aneurysms are chiefly of the miliary type and are confined to the smaller vessels of the brain. The characteristic murmur indicating an aneurysm of one of the larger arteries is seldom heard. Diagnosis based upon a murmur, according to Beadles, has been proven correct in only two instances by post-mortem findings.

It would seem therefore that the chief point upon which to base a diagnosis is a pressure manifested by the symptoms it produces. With an aneurysmal dilatation of either of the vertebral arteries the possibilities of hearing the characteristic murmur would be greater because of their more superficial position than when the other arteries of the brain are similarly affected. The disappearance of the murmur by pressure on the vertebrals where they pass through the foramina of the lateral processes of the sixth cervical vertebra would be of value in making the diagnosis. When the aneurysm has undergone a spontaneous cure even this means of a diagnosis must disappear. Unfortunately the seriousness of the condition may be recognized too late, after perhaps irreparable damage has been done, in which event any surgical interference would be of little or no value. Even with a grave prognosis the institution of proper medical treatment and certain hygienic measures may temporarily alleviate the patient's condition. Hence, the earlier the recognition of the presence of a vertebral aneurysm the greater will be the chances for a prolongation of the patient's life or perhaps even a cure.

Let it be suggested that the possibility of a cure of a vertebral aneurysm by ligation of the artery presents itself. The point of choice for its ligation is through the sub-occipital triangle of the neck. In 36 ligations of the vertebral artery there were three deaths (Jos. D. Bryant[5]).

Summary.—1. Aneurysmal dilatation of the vertebral arteries is a very rare condition.

2. The medulla oblongata and many of the cranial nerves are damaged by the aneurysm as is manifested by the resulting compression bulbar paralysis.

3. A correct diagnosis of vertebral aneurysm is difficult to make and it is likely to be made late in the progress of the disease.

4. The treatment before the aneurysm has undergone a spontaneous cure is surgical, and symptomatic in the later stages of bulbar paralysis.

5. The earlier the diagnosis of vertebral aneurysm is made, the more favorable will be the prognosis. In any event the prognosis must be considered grave.

PROPOSED LEGISLATION CONCERNING HEALTH CENTERS.*

By JOHN H. BARRY, M.D.,
NEW YORK.
ASSISTANT SANITARY SUPERINTENDENT, DEPARTMENT OF HEALTH OF THE CITY OF NEW YORK.

My temerity is strained to the breaking point in accepting this invitation to discuss—if it means to debate—the illuminating views of our gifted Commissioner on this subject upon which he is so singularly well informed. I can only explain the honor of being chosen by the fact that our Borough of Queens has had more experience with the health

*Part of a discussion on an address of State Commissioner of Health, Hermann M. Biggs, at the Sea View Hospital, Staten Island, May 19, 1921.

center plan than any other part of Greater New York, based upon the argument which justifies it best — a large geographical area with relative sparsity of population.

As in all large new problems of its kind, the exact truth may lie in the mean between the extremes of unprogressive medicine on the one hand, and, on the other hand, the highly progressive standards of new medicine at which the present day is aiming. It is only too true that the day of the unprogressive, shiftless, careless practitioner who wilfully shuts his eyes upon new thought and modern ideas is passing or passed. And it is perhaps equally true that highly refined specialism and group medicine are prone to look with too harsh and severe disdain upon the clinical judgment, the relatively crude diagnostic skill, and the high-minded devotion to an almost sacred calling entirely bereft of commercialism (not at all so true of to-day) which have been responsible for very many substantial results and glorious triumphs in pre-laboratory and *x*-ray days.

We of Queens have been under a modified health district administration for five years. I say modified advisedly, for it was soon learned that the overhead costs of full-time health officers and clerical administration forces were unjustifiably heavy. Then, too, the complexity of service as represented by the *lay* pursuits of sanitary and food problems on the one hand and the *medical* service as expressed in infant and child welfare and communicable disease control on the other hand seemed to offer a more ready and efficient solution at the hands of men specially qualified by knowledge and experience, each in his own sphere, on these widely divergent functions.

The budgets, as I view them, in a State-wide health district plan to carry on all specialized forms of treatment and to make the service comprehend every possible requirement are appalling. Let me say to our Commissioner and to you my dear ladies and gentlemen, that one of the reactions which has come out of our experience from needful economy of city funds has been rather not so much "group medicine," but as we might call it, "group nursing," which has followed economic and, we think, reasonably efficient lines. We are working under an *amalgamated* and not a *special* system of nursing. We find that, in applying these workers, at least those who follow instructed lines, to all the functions in common of an intelligent nurse's life that we can give them more enthusiasm, interest, and variety in their work, that we can keep them intensely occupied and that, treating the *family* as the unit, we can avoid multiple overlapping and duplication. Fancy the loss of time and efficiency involved in sending one nurse to long distances on welfare and school follow-up work, while, in striking distance of said visit, another must be sent on the quarantine of an infectious case or the investigation of, and advice to a tuberculous patient.

We have pursued all the identities of *nursing* and, to a great extent, *medical* service enumerated in health center plans with forces made elastic and preferential (by amalgamated and group system) to the exigencies of seasonal, school-period, or epidemic needs.

There would seem to be three avenues of approach to the coordinated study of the needs, the rights and privileges, and the different viewpoints of all interested and concerned in any improved system of medicine: (1) The community. (2) The Medical profession at large. (3) Public health administrators and workers.

The Community.—Has the economic condition of very recent times been the most outstanding in its need of clinical, free, or charitable aid to the community at large? Have we not just passed through a period, despite some present clouds of unemployment, which lends itself least to the need of community helpfulness and charity to the masses? Has there ever been less dependence, less abject poverty, more affluence? Has there ever been higher wage, scarcer labor, or a higher appreciation put upon its value, while scientific or educational service stood still or even depreciated?

And if wage loss through numerous strikes and profligacy of expense or extravagance during prosperous times defeats the reasonable financial independence of the working masses today, shall it be called the community's moral fault or should it be its chief concern? Individualism, self-respect, and independence are not best fostered by proffers of gratuitous and charitable aid. Some there will be in all ages too ready to accept needless free help.

The Medical Profession.—The marvellously lessened output of recent graduates from our medical colleges must be read in the light of a profession discouraged and dismayed over the lack of recompense and reward attending its heroic and faithful service. A disheartened profession viewing its work ill-requited, giving its generous quota of war service unstintedly and with heroic sacrifice, men, alone of all professions who are expected to, and do defeat their own personal interests through high-minded devotion to the principles of preventive medicine, cannot well be asked to view with complaisance any plans which may circumscribe their narrowed and ever-narrowing field of just emolument and recompense for worthy, altruistic effort.

We have no quarrel with the specialist's fees—we feel that in so invaluable a service as the preservation of life and the conservation of health, that he should receive recompense commensurate with and proportionate to earnest endeavor in all the other learned professions. But we deplore the disparity and disproportion between his and the general practitioner's or family physician's recompense, the latter bearing all the burdens, sharing all the anxieties and worries of the family, forced to accept most of the blame and censure in unfortunate outcomes, and obscured by the specialist in the glories of fortunate and satisfactory results.

In harboring ill-will, however, against many health department functions and withholding much of its cooperation, we must feel that the medical profession has a distorted vision, for many undesirable burdens are lifted from their shoulders; much service which we render would not be sought from the private physician for pay, and many opportunities for emolument such as physical defect corrections are referred to them without their being embraced.

Public Health Administrators and Workers.—I hope it may not be too true, but I fear it is at least half so that we who have learned to live on public

salaries (modest though they be, yet assuring us a livelihood) are prone to absorb to ourselves in departmental channels some of the paying service justly belonging to the profession at large.

Much public health service, like public welfare work, directed along free and clinical lines, belongs only to the needy and the poor. We must not encroach unfairly upon the field of the private physician in his just relation with the patient able and willing to pay for service. If we err in this particular, we must react against it, because only in rendering him this exact justice can we hope to obtain that sincere and heartfelt cooperation upon which rest the security and effectiveness in such large measure of our public health service.

I have not made any very positive statements nor challenged many of the Commissioner's arguments. Perhaps many of them are unanswerable.

I would conclude with two queries.

1. Why recruit the country forces from State aid? Why not rather attempt to make private professional life again appealing and reasonably remunerative so that to the charms of country life might be added the security of reasonable reward.

2. Why impose upon the cities—already fortified and equipped by city appropriations and generous private endowments—a tax for country service in which they have no common interest save that of human sympathy? By all means if the country must be served on hospital laboratory and clinical lines to a proportionate degree with that of the cities, let the *counties* pay for the service and not the *State*.

Jamaica, Queens Borough.

GONORRHEAL INFECTION FROM A BATH TUB.

By J. Henry Dowd, M.D.,

Buffalo, N. Y.

Genitourinary Surgeon to the Sisters of Mercy, and Contagious Hospitals.

The following case report is worthy of record, even though the bath tub could not be produced, nor was it possible to find gonococci in the female.

H. S., being sent for treatment, was examined and found to have a profuse urethral discharge of two or three days' duration; the microscope showed the condition to be gonorrheal.

Close questioning brought the information that he had never had venereal disease, and had had no sexual relations in two years until ten days previous when he was married.

The condition being fully described to the young man, it was suggested he send his wife at once for examination. She gave the following information: In January, 1921, as a delegate, accompanied by another young woman, she visited a nearby city (previous to marriage her home was in the country), remaining a week. About five days or so after her arrival she noticed a quite large stain, yellowish in character, on her night robe, but no pain or inconvenience on walking. Communicating this to her friend, the latter also stated that she had found a similar stain; neither had ever noticed any discharge on their underclothing before; her friend complained of painful urination. Knowing nothing of venereal disease, and thinking the condition due to a weakness of some sort, no attention was paid to the condition, which gradually disappeared. The woman absolutely denied sexual intercourse, and there was no doubt of the truthfulness of her statements. But she did admit that on account of financial reasons they had chosen a cheap hotel, and had taken a bath in a tub used by all the guests on the floor they occupied; this was taken on the day they arrived. In the latter part of February she was taken suddenly ill with very severe pain in the chest and back (over the scapula). This was diagnosed as pleurisy, although she informed me she had no difficulty in breathing, nor was any fluid taken from the chest.

Examination showed no inflammatory action at the vulva; no pus could be expressed from the urethra. The speculum, which caused a great deal of pain on being passed, showed an inflamed cervix, eroded, and containing a plug of mucopus. Microscopical examination did not reveal gonococci (we all realize the difficulty in finding gonococci in women, even when we are positively certain infection is present), but there was an entire absence of Doederlein bacilli—as strong evidence that gonococci or some other infectious bacteria were present as though they are found.

The young woman informed me that during the month of March her friend was seriously ill with severe pain in the lower abdomen (pelvic region), and since then she has had more or less pain at the menstrual period, something that had never occurred previously. I am unable to state the diagnosis in this case, but it is very probable it was due to involvement of the pelvic contents: ovaries, tubes, etc., and of gonorrheal origin.

It is assuming a great deal to disagree in the diagnosis of a case that you do not see, but there is no doubt from the history of the condition this young woman suffered from gonorrheal thecitis and not from pleurisy.

Assuming that these young women used their own towel, what other mode of infection was possible, other than that some one, male or female, having gonorrhea had taken a bath previously and infectious material adhered to the tub, thus infecting these two young women, possibly others, I cannot say.

427 Franklin Street.

Scopolamine in Parkinsonism.—Paulian and Bagdasar, Rumanians, comprise under the latter term not only paralysis agitans *per se* but the almost identical syndrome which follows encephalitis. In the former condition, the use of henbane, hyoscyamine, and hyoscine is established, a fact which may not have been known to the authors, who cite several cases in which hydrobromate of scopolamine gave good results in the post-encephalitic syndrome.—*La Presse Médicale.*

The Pressure of the Biliary Secretion in Man.—Robitschek and Turoli have measured this pressure in several cases of biliary drainage following operations on the common duct. There is no mention of a manometer, but the bile was allowed to accumulate in a vertical tube. The pressure sent the bile column up to as high as 270 mm. in a tube 5.5 mm. wide. The opportunity for testing cholagogues was utilized and while physostigmine was positive and pilocarpine was much more so, papaverine was decidedly negative and lowered the pressure. The latter is not due solely to vis a tergo or secretory pressure, for the muscular coats of the ducts and even the intraabdominal pressure are factors.—*La Presse Médicale.*

New York, November 19, 1921.

SOME PROBLEMS OF COMPARATIVE PSYCHIATRY.

SOME thirty years ago a series of anthropological studies were begun on the insane of New York State, at the State Pathological Institute, before its early decease, and several thousand cases were studied. Unfortunately, when the institute succumbed to politics these records were scattered, never, perhaps, to become available for scientific purposes. So far as we know, there has been no similar attempt since that time on anything like the same scale and yet it is doubtless true that psychiatry would benefit immensely by such comparative studies, inaugurated as these were in a spirit of scientific zeal, and carried on by many earnest and qualified workers.

A few scattered and not altogether profitless investigations in comparative psychiatry have been made from time to time. By means of them we have learned, for example, that insanity was rare among the aboriginal Australians and has been frequent since the coming of the white settler; that paresis is extremely rare among the Chinese in the interior, but common along the coast, while syphilis is frequent in both places; that both syphilis and paresis are common in Japan, a maritime nation; that the native Africans do not exhibit true manic-depressive psychoses or paranoias to any extent; that the American Indian is free from paresis and paranoia; that there are psychoses in other countries unknown in America, such as a hashish psychosis in India, one associated with leprosy in Asia, and "running amok" in Malaysia; that the Hebrew race shows a small percentage of alcohol and drug psychoses and a large percentage of precox and imbecilities; that the native Irish show a high percentage of insanity and the Irish in America a high percentage of alcoholic psychoses. We know these things in a general way as the result of what few studies have been made already, but there is room for much more work.

We might investigate, for example, the statement often made that the immigrant is a menace, with its apparent support in figures tending to show that the incoming aliens during a certain period showed a higher incidence of insanity than the native population during the same period. This is, however, misleading when we consider that this alien group is made up very largely of young adult males, in other words, of the class which ordinarily furnishes the greatest part of admissions to asylums, while it is contrasted in such pessimistic reports with a group containing a large admixture of children. Why is insanity more frequent in rural districts in spite of the greater stress of urban life? What is the incidence of insanity in those whose parents were born in a foreign country? Of those whose grandparents were so born? Of those who have three generations of American ancestors? Or four, or five? Is there a difference in the liability to insanity of those who live in the mountains and those who live in the lowlands? Is insanity more frequent in the mulatto than in the negro? And so on.

The difficulties, of course, are many. Those best qualified for such statistical studies, that is, psychiatrists, are usually in institutions where they are overburdened with work. It is not possible to pay for work of this kind: the only reward is the ultimate good attained, and this is long in realization. A man who is already weighted down with routine duties does not readily take to long, arduous statistical studies where he is only a cog in the machine; he is attracted to research work, if at all, by some local problem which he can complete in a reasonable time and publish under his own name.

It may be some day, however, that a Federal board will be created, or a private endowment furnished, by means of which a continuous study of the above and many other problems may be carried on over a term of years with an almost certain benefit to psychiatry directly and the human race generally.

THE CHARACTERS OF CUTANEOUS TUBERCULOSIS FOLLOWING MEASLES.

FOLLOWING measles various forms of cutaneous tuberculosis may develop, such as gumma, lupus, or lichen scrofulosorum, either combined or separately, which latter is more common. Lupus is the most frequent of all and deserves mention because of the special characters it presents. Although not absolute, they impart a special aspect to this cutaneous lesion following rubeola. In lupus vulgaris, the process ordinarily begins by a small nodule which slowly enlarges and after a number of years attains a large size. Postubeolic lupus, on the contrary, has a sudden onset and usually several spots develop at the same time on different parts of the body like a true exanthema, occasionally resembling varicella. Successive eruptions are not common, the elements rapidly reaching their final dimensions. The process, therefore, is striking by reason of its wide dissemination. Patches are met with on all parts of the body and limbs, but rarely on the face; these lesions frequently assume the verru-

cous type. The elements composing the patches are usually small, varying from the size of a millet seed to that of a hemp seed, rarely reaching a centimeter in diameter; the smallest are formed by a single nodule, the larger by five or six agminate nodules. The patches are numerous, frequently as many as fifty, or less often there may be only five or six or less. These forms of lupus have a relatively benign evolution; the patches very rarely ulcerate and usually do not give rise to the great destruction of tissue met with in the ordinary forms of the disease. When once developed the eruptive elements often remain stationary and occasionally disappear spontaneously, sometimes leaving cicatrices or sometimes without trace. A slight pigmentation may be the only evidence of their former presence. Mild local treatment, such as the application of guaiacol, may result in a cure, and although the lesions do not usually give in to such simple therapeutic measures, they are, on the whole, easily cured by total excision, cauterization, or scraping, and do not relapse. A benign evolution of the process is the rule, but in some few instances the lesions undergo an evolution similar to that of lupus vulgaris. Generally speaking, it would appear that when the lesions are few in number they rarely have a tendency to spontaneous retrogression, but they nevertheless differ from ordinary lupus in that they can be easily cured by appropriate treatment. This benignity of postrubeolic lupic lesions might, at first sight, lead one to doubt the tuberculous nature of the process, but in every case in which histological examinations and inoculations have been carried out, the diagnosis has been unquestionably confirmed. For that matter, the tubercle bacillus is more easily demonstrated in these lesions than in ordinary lupus, the lesions sometimes being alive with bacilli. This occurs particularly in the very acute processes, manifested by an external generalized granulia.

Tuberculosis of the lymphnodes is less rare and in a number of cases it coincides with or precedes the cutaneous lesions. Joint tuberculosis is also met with after rubeola, but usually the lungs escape infection. In one or two recorded cases tuberculous meningitis caused death.

Briefly stated, ordinary lupus and postrubeolic lupus resemble each other only in the elementary lupic nodule and their histological characters, but differ profoundly by the number and distribution of the lesions and the evolution of the cutaneous changes. Ordinary lupus forms a single patch, postrubeolic lupus occurs in multiple patches; the former has a tendency to ulcerate and destroy the tissues, the latter to become fixed or with a tendency to retrogress. Ordinary lupus resists treatment, the postrubeolic form is hastened to recovery by treatment and, although the latter may not merit being regarded as a special morbid entity, it is, from its very peculiar clinical aspect, a lesion quite distinct from lupus vulgaris.

Among the other postrubeolic cutaneous tuberculoses it is to be remarked that verrucous tuberculosis from the viewpoint of development and distribution of the lesions offers the same characters as ordinary lupus, but histologically it presents the structure of an anatomical tubercle. Tuberculous cutaneous gummata rarely present such a vast dissemination or so rapid a development, only a few elements of lichen scrofulosorum being met with among the gummata. But as a rule the different forms of cutaneous tuberculosis rarely occur singly and may be simultaneously met with in the same subject with a more or less marked predominance of one or the other. Nevertheless, whatever may be the variations in their grouping, they preserve the remarkable characteristics already referred to and consequently should occupy a special place in cutaneous pathology.

IS FOLLICULAR TONSILLITIS A GENERAL MALADY?

THE common medical belief regarding this disease has been that it is a local malady, any constitutional symptom attending an attack being caused by the absorbed toxins, subsiding as soon as the toxins cease to be formed. Salzmann (MEDICAL RECORD, 1920, 3) and others have recently questioned the correctness of this, and now Guisez writes in the *Gazette des Hôpitaux*, July 19-21, 1921, xciv, 57, expressing the same doubt. He says that for the past dozen years his attention has been drawn to the possibility of the constitutional nature of chronic tonsillitis. The type of tonsillitis referred to is chronic, catarrhal, and follicular, the crypts being at times wholly or partly obliterated with retention of the contents. With benign flora thus retained nothing may happen, but when, as often occurs, virulent germs are retained a phlegmon may form, or there may be a general infection. The local symptoms may be insignificant so far as the patient himself is concerned, but careful examination will bring out the existence of a disease focus. In addition there are periods in which the patient complains of something wrong, such as pressure sensations or vague pains. There may be induced tenderness on external pressure over the tonsil. Of great clinical value is the redness of the free border of the anterior pillar. Owing to the fact that the tonsils tend to shrink in size after puberty these cases are most apt to appear in late childhood and the prepuberal or early adolescent periods. The condition once established may persist well into the adult period, say beyond the age of 30. The constitutional malady to be outlined is more common in young women.

The disease as studied by the author appears to have very little in common with the focal infection of tonsillar origin which figures so largely in American literature. In the latter, one organ or tissue usually bears the brunt—notably the articular system, and the seat of the focus is not

an essential factor in the picture, for this may be the teeth, nasal sinuses, middle ear, prostate, etc. The affection described by Guisez is limited strictly to the tonsil and he barely alludes to other primary foci. The young woman is apparently in inferior general condition, looks tired, has no appetite, and becomes fatigued, especially toward evening. She complains of various pains, in the limbs or back chiefly, and these are made worse on standing. She seldom eats before the middle of the day and by 4 or 5 o'clock in the afternoon is "all in." The thermometer, if used at this time, will show a slight elevation of temperature. This fact is evidence enough of a mild infection. Failure to improve with change of scene, tonics, and other reconstituents excludes neurasthenia, anemia, primary debility, and such diagnoses. Recovery following morcellation of the tonsil clinches the diagnosis. Of all the symptoms of slight chronic infection loss of appetite is the most valuable; and after operation the appetite returns and is keen. Among local conditions secondary to these infected tonsils the author notes especially orthostatic albuminuria, cardiac functional disturbances, including pseudoangina pectoris, which will be found described in the works of J. Mackenzie, and certain dermatoses. The author does not speak of the participation of the joints and with the exception of orthostatic albuminuria does not allude to implication of the kidneys. His disease picture could hardly avoid overlapping the picture of tonsillar focal infection in some minor details, but the autonomy of each is evident. The distinction may be made as follows: the picture drawn by Guisez is apparently a pure toxemia, while in cases of focal infection the condition is a mixture of toxic and metastatic manifestations. Again Guisez is silent on lesions which follow *acute* tonsillitis, and it is in this condition that we most commonly fear the appearance of endocarditis, nephritis, and some of the worst joint affections.

THE TREATMENT OF BEGINNING OF COXA VARA.

SINCE coxa vara is frequently due to rickets or tuberculous infection, medical and hygienic treatment of the patient must never be overlooked, and it is important to determine the time when treatment of this affection should be begun, otherwise much harm may be wrought. It is the osteitis which leads to softening of the bone and it is the osteitis which permits an essay at reduction. To appreciate the degree of the osteitis is no easy matter, but nevertheless it is absolutely necessary. The state of the skeleton cannot be easily judged under the thick layer of soft structures so that the periarticular lesions must form the basis of the estimation of the bone lesion; for the inflammation does not remain limited to the neck of the femur, but, extending beyond the joint, it involves the muscles, tendons, perivascular sheaths, cellular tissue, and even the skin, and here, as in all inflammatory processes, the lymphatics play a preponderant rôle. The reaction of organic defense is shown by the afflux of the lymph and its inevitable transudation and to this the effects of blood stasis are added. The edema resulting from the dilatation of the vessels in proximity to the focus of osteitis, with the consequent slow circulation, explains this state of affairs which must be dealt with. The infiltration of all the soft structures explains the imperfect nutrition resulting from a defective circulation of the blood and lymph in the parts. The muscles degenerate and the tendons undergo the same process, so that a coxa vara—at its onset a disease of the femoral neck—becomes a lesion of the entire articular and periarticular region. This is one of the chief causes of the difficulty in exploring the parts and is likewise a cause of failure in treatment when these lesions are overlooked. Therefore, before undertaking any direct treatment of the neck of the femur a preparatory treatment by massage is essential. Its effect is both beneficial and immediate, quite as much so as in fracture where methodical and mild massage reduces the hematoma and infiltration of the traumatized parts.

In coxa vara, massage fulfills two indications. In the first place it is a diagnostic measure because, after reducing the infiltration, the tumefied neck of the femur can be palpated. Therapeutically, it eases up the circulation by dispersing the extravasated fluids and rids the muscles of their morbid products. The diseased joint is in a rigid state of defense common to all arthropathies, assuming the most favorable position for this purpose in which all the muscles and other soft structures surrounding the joint take part in order to maintain the limb in this position. By proper massage the muscles relax and the surgeon should profit by this resolution, but to attain the desired end all depends upon the position of the patient. He should lie on the back and the limb should be held strongly in extension by an assistant grasping the foot so that the leg is in forced adduction with outward rotation of the foot. The femoral neck is thus, so to speak, offered to the frictions of massage which should be made in the direction of the inguinal fold. After this, the patient will be ready for the second phase of the treatment, namely the maneuvers of reduction.

For the purpose of carrying out these manual orthopedic maneuvers the muscular contraction must be overcome in order to avoid pain. This can be accomplished when the patient is at perfect rest lying on the back and sufficient time is allowed for muscular relaxation. The reduction is accomplished in two phases, the first of which prepares the second. This is why extension should be combined with adduction and external rotation which exaggerates the pathological position of the limb. The second phase is a sudden jar made as forcibly as possible, which pushes the limb with force in the opposite direction to the pathological position, that is to say toward abduction. A simultaneous effort

at internal rotation should be made. The difficulties in realizing this are numerous. The patient should be fixed on the table by the two hands of an assistant strongly applied on the two iliac crests and the hand on the diseased side may at the same time exercise a direct pressure on the anterior part of the neck of the femur. A single attempt only should be made at each séance at reduction on account of the pain, due to the osteitis. But no matter how severe the pain may be, it subsides quickly so that another attempt at reduction can be made on the following day and so on, until it is a *fait accompli*.

This treatment is not always completely successful, although it will generally improve the condition; but when the deformity has become permanent this treatment is dangerous and surgical interference becomes obligatory.

Pfeifferian Meningitis.

Recently there have appeared some isolated reports on the existence of a purulent meningitis due to Pfeiffer's bacillus. Cases were reported during and after the pandemic of influenza which appeared to stand in no relation whatever to the movement of the latter or of post-pandemic cases. This fact was used at times as evidence for excluding the organism in question as the cause of influenza. Four cases of this affection are reported in the *Acta Medica Scandinavica* for June 17, 1921, by Christiansen and Kristensen, one of whom represents the Blegdams Hospital and the other the Danish Serotherapeutic Institute, Copenhagen. In each instance the lumbar punctate contained the hemoglobinophile bacilli in pure culture. Of the 3 cases one ended in recovery. This was in a boy aged 2 years who was ill with the disease 5 weeks. Clinically the case was a typical one of uncomplicated meningitis. In the three fatal cases the duration of the disease was from 9 to 15 days. In the recovered case over a pint of cerebrospinal fluid was withdrawn during the illness. The bacteriological study is complete and leaves no doubt as to the nature of the causal organism. This was at first regarded as the meningococcus and the treatment was based on that supposition. After the change in diagnosis there was no standard treatment to prescribe, owing to the infrequency of the infection. There was no evidence of any connection between the four cases which were in all respects sporadic, and there had been no cases of grippe in the community at the time when these meningeal cases occurred.

Mumps-Pancreatitis and Diabetes.

The theory that the fatal diabetes of childhood might be due to metastatic pancreatitis complicating mumps, while attractive, has, so far as known, never been substantiated. Even if shown to be due to pancreatitis it would be difficult to impute the latter to antecedent mumps, and, on the other hand, clinical pancreatitis during the course of the latter, which has repeatedly been seen, is not known to be followed by diabetes of a progressive and fatal character. But there is a series of cases of transitory diabetes presumably due to mumps-pancreatitis, and in 1912 Cheinisse collected the case material. Of the total number, but one answers all of the requirements of medical science. The child complained of pain in the pancreatic area and vomited, while the stools showed steatorrhea and there were polyuria and glycosuria. No case has been reported since Cheinisse's summary which can pass muster and this author recently calls attention to a report by Belgian physicians (*La Presse Médicale*, September 10, 1921, xxix, 73) which does not measure up to the standard. A boy of 18 had gone through an attack of mumps 18 months before, but with no data pointing to clinical pancreatitis. He presented evidences of beginning diabetes, the urine containing enough sugar to cause balanitis. The condition promptly vanished under the proper diet. There is no mention of the condition of the stools, but some alleged symptoms of hepatic insufficiency sufficed to throw doubt on the pancreatic origin of the glycosuria.

News of the Week.

Maternity Bill Reported by the House Committee.—The Sheppard-Towner bill for protection of maternity and infancy, already passed by the Senate, was favorably reported on Nov. 7 by the House Interstate Commerce Committee. As approved by the committee the bill would limit to a period of five years the annual appropriation of $1,000,000 for use by the State and the Federal Government in the effort to protect infants and mothers. The appropriation of $450,000 for starting work under the bill was retained. Efforts will be made by the committee to have the bill considered by the House this month.

Public Health Service Not Subject to Military Rules.—Attorney-General Daugherty has handed down a decision stating that "the personnel of the United States Public Health Service is not a part of the military forces of the United States and therefore not entitled to certain exemptions allowed to members of the military and naval forces under the revenue laws." This decision was brought about as a result of confusion over the status of Public Health employees arising from executive orders issued by former President Wilson soon after the outbreak of the war which declared that the members of this branch of the Government service constituted a part of the military forces in times of threatened or actual war. Congress did not create the health service to perform military or naval duties, nor to be subject to military or naval rules, Mr. Daugherty said.

Cholera in Erivan.—Cholera in virulent form is raging in Erivan, capital of Armenia, according to a report from a party of investigators of the Near East Relief. The report states that the dead wagon makes daily rounds and tells the story of dire want and starvation that we have heard so often from the Near East.

Tuberculosis in Poland.—In a recent report from Dr. Charles Phillips, statistician of the American Red Cross Commission to Poland, it is shown that, in spite of the enormous spread of tuberculosis during the war, the number of cases is now actually less than in 1914, and the percentage of cases among the Jewish population is about

one-half that among the non-Jewish population. The average proportion of the difference is figured by Dr. Ganc as 100 to 180, although in some years it runs as high as 100 to 214. Dr. Ganc states that it is not only Jews of the rich and well-nourished classes who resist the disease, but also the Jews of the so-called "Lumpen-proletariat"—the poorest dwellers of the Ghetto. He asserts that the latter class of Jewish population is less subject to tuberculosis than the richest and most comfortable class of non-Jewish population. In a memorandum read before the Social Medicine Association of Warsaw on Oct. 13, 1921, Dr. Ganc stated: "The same rule works also among the Jewish population of London, New York, Budapest and Vienna, although perhaps less markedly than in Warsaw. The non-Jewish population of England, supposedly the healthiest of all nationalities, is still more subject to tuberculosis than the poorest Jews of the London Ghetto. In New York the average city adult death rate is 12.93 per thousand of population, but the Ghetto rate is below 10; the city's infant mortality rate is 85 per thousand, while the Ghetto rate is only 52, although this figure applies to a district so congested that the population averages 3,000 people to a city block. Dr. Ganc thinks one explanation is that the Jewish population has succeeded in developing a considerable resistance to certain diseases, particularly those associated with city life. Dr. Wadysaw Szmajch of the Charles and Mary Hospital declares that Jews resist tuberculosis better than other nationalities because they give more attention to their health than others.'

Flying Hospital Shown at Aviation Exhibit.—According to a report from a New York *Herald* correspondent, many new wonders are displayed at the aviation exhibit being held in the Grand Palais, Paris. Among them one of the most marvelous is a flying hospital, equipped with stretchers and able to carry a doctor and an assistant to perform regular operations in the air. There is an operating table, a full medical equipment and two patients can be carried on the stretchers. The machine is equipped with stabilizing appliances which will enable the doctors to work just as if they were in a city hospital. This is a Breguet biplane capable of developing a speed of 100 miles an hour.

Infant Mortality Among Colored Population of New York.—The Bureau of Child Hygiene of the New York City Department of Health has been conducting a special campaign against infant mortality among the colored population of the city. This work began in 1915, when the statistics of the Health Department showed that the infant mortality rate in the Columbus Hill District, which harbors a large colored population, was 314 per thousand births, while the infant mortality rate of an adjoining district, largely a white population, was 147.7. The statistics for 1920 show that the infant death rates of these districts have been reduced to 116.5 and 103.8 respectively. The infant mortality rate among the white population alone and among the colored population alone shows that for the city as a whole the infant mortality rate for the former in 1915 was 96.2 and for the latter 202 per thousand births; in 1920 the infant death rate was 83 for the white population and 164 for the colored population. The decrease in infant mortality for the period 1915-1920 was 13 per cent. for the white population, while for the colored population during the same period it was 18 per cent. This reduction in the infant death rate among the colored population is directly attributable to the energetic efforts of the Bureau of Child Hygiene of the Health Department, but it is also a sign of awakening on the part of the colored population to the importance of life-saving measures among its children.

The "Journal of Orthopædic Surgery," the official organ of the American Orthopedic Association and of the British Orthopædic Association, announces that in January it will change from a monthly to a quarterly publication. In issuing the *Journal* every three months it is planned to provide the readers with fully as much, or even more, reading matter than under the present arrangement, and it is hoped that the *Journal* may be made more valuable and interesting. The *Journal* will continue to be published in Boston under the existing management.

Ex-President Eliot's Opinion of Physicians.—In an address before the Twentieth Century Club of Boston, a couple of weeks ago, one-time president of Harvard University, Charles W. Eliot, remarking with disapproval that many "physicians now base their charges on the supposed income of the patient," said: "Physicians are constantly invited by patients of their own and by outsiders to prescribe alcohol. If that appeal is made to men in the habit of basing their charges on the income of the patient you see what a temptation is presented to the physician. Multitudes of physicians are yielding to that temptation." Dr. Eliot is as intemperate of speech as ever and as indifferent to facts as when he was younger.

Harlem Health Center Opened.—Nov. 10 Governor Nathan L. Miller, Mayor John F. Hylan, and Health Commissioner Royal S. Copeland formally opened East Harlem Health Center, 345 East 116th Street, a demonstration planned and financed by the New York County Chapter Red Cross to show the increased efficiency of housing all health and welfare agencies in a given district under one roof. Twenty-one health, nursing, welfare, and community organizations are combining in East Harlem Health Center. Dr. James Alexander Miller presided at the opening exercises and addresses were made by Governor Nathan L. Miller, Miss Lillian D. Wald, representing the Henry Street Visiting Nurse Service; Robert W. de Forest of the National Red Cross, Homer Folk of the State Charities Aid Association and the local Red Cross, and Dr. Herman M. Biggs, State Commissioner of Health.

Promotion in the Public Health Service.—Past Assistant Surgeons W. H. Slaughter, James G. Townsend, and Walter M. Jones have been promoted to the grade of surgeon, Public Health Service.

Dr. William C. Sandy, psychiatrist of the New York State Commission of Mental Defectives, has been appointed Chief of the Division of Mental Health of the new Department of Public Welfare of Pennsylvania.

Dr. John J. Moorhead of New York was recently decorated on Governors Island by General Robert Lee Bullard with the Distinguished Service Medal for his services as commanding officer of an evacuation hospital in France. Dr. Moorhead has hitherto received the Croix de Guerre, the Medaille d'Honneur, and the United States Army citation.

Hospital Notes.—A drive for a fund of $500,000 with which to build an extension to the Mt. Sinai Hospital, Chicago, is being conducted.

The United States Public Health Service has established a hospital for the treatment of trachoma at Russellville, Ark. The establishment of the hospital was contingent upon the county's placing the building, which has been donated by the Russellville Chamber of Commerce, in condition to receive patients. A fund for this purpose has been appropriated.

The new addition to St. Anthony's Hospital, Pendleton, Ore., erected at a cost of $200,000, is about completed. This addition will bring the capacity of the hospital up to 160 beds.

Dallas, Texas, is to have a new $1,000,000 hospital, erected under the auspices of the Methodist Episcopal Church.

The Board of Directors of the Babylon (Long Island) Hospital have voted to proceed with the erection of a building to cost $50,000 on a new site recently acquired in Bayshore. About $10,000 has already been subscribed toward the building fund.

Post-Graduate Hospital Dedicates Memorial Tablet.—The Post-Graduate Hospital, on Nov. 12, unveiled a memorial tablet dedicated to the nurses and doctors who served in the war while attached to the Post-Graduate Hospital unit at Savenay, France. Addresses were made by Col. Samuel L. Lloyd, director of a Base Hospital Unit, and Miss Amy Patmore, who served as the unit's chief nurse. The tablet contains the names of the 380 doctors and nurses who made up the staff of the base hospital. Five names are distinguished from the others by gold stars.

Methods Proposed for Better Care of the Insane in Ohio.—The Institute for Public Efficiency of Ohio has made recommendations to the Governor looking to the more efficient care and treatment of the insane in that State. Two of the seven State hospitals for the insane, the one at Athens and the one at Dayton, have shown a steady decline in the average daily population since 1915, while the others are filled to capacity. The report sent to the Governor recommends the redistricting of the State for insane hospital purposes; a proper classification and segregation of patients; the development of consulting staffs; the establishment of mental clinics, and the development of field work. It is felt that these measures would result in a material decrease in the number of those requiring institutional care.

Pediatric Societies to Hold Joint Meeting.—The New England Pediatric Society, the Philadelphia Pediatric Society, and the Section on Pediatrics of the New York Academy of Medicine will hold a joint meeting in New York City on Dec. 3. The day will be spent in visiting clinics at various hospitals in the city and there will be a dinner at the Hotel Pennsylvania in the evening. Information in reference to the meeting may be had by addressing Dr. Marshall C. Pease, Jr., New York Academy of Medicine.

Obituary Notes.—Dr. AUSTIN WILKENSON HOLLIS of New York died suddenly of cerebral hemorrhage in Watertown, Conn., on Nov. 6, at the age of fifty-three years. He was graduated from the College of Physicians and Surgeons of Columbia University in 1890, and was formerly professor of clinical medicine there. He was a member of the American College of Physicians, the American Medical Association, and the New York Academy of Medicine. Dr. Hollis was for many years visiting physician to St. Luke's Hospital and physician-in-chief of the New York Dispensary in Spring Street.

Dr. CHARLES N. SMITH of Toledo, Ohio, died on Oct. 25, at the age of sixty-one years. He was graduated from Bellevue Hospital Medical College, New York, in 1882, and served on the staff of several local hospitals. He was a member of the American Medican Association and of the American Association of Obstetricians and Gynecologists, of which he was elected president in 1913.

Dr. CHARLES ELIHU QUIMBY died suddenly of apoplexy at his home in New York City on Nov. 6, at the age of sixty-eight years. He was a graduate of the New York University Medical School in 1878, a member of the American Medical Association, the American Climatological Society, and the New York Academy of Medicine. He was visiting physician to the City Hospital since 1895 and consulting physician to the Manhattan State and Jamaica hospitals.

Dr. JAMES SYMINGTON of Tarrytown, a retired physician, died of cancer in the New York Hospital on Nov. 5, at the age of fifty-eight years.

Dr. JAMES P. BOYD, formerly of Akron, Ohio, died suddenly in Larchmont, Conn., on Nov. 10, at the age of seventy-one years. He was graduated from the Long Island College Hospital in 1875.

Dr. JOSEPH M. RATLIFF, a graduate of the Cincinnati College of Medicine and Surgery in 1878, died suddenly at his home at the Grand View Sanatorium, an institution for the care of the insane which he had conducted for many years, on Nov. 5, at the age of seventy-three years.

Dr. MARY VINCENT of Chicago, a graduate of the University of Michigan Medical School in 1875, at one time physician to the Sarah Hackett Stevenson Home, died of heart disease on Nov. 1, at the age of eighty-two years.

Dr. THOMAS C. THORNTON of Lewisburg, Pa., a graduate of the University of Vermont College of Medicine in 1862, died suddenly on Oct. 21, at the age of eighty-two years.

Dr. J. ANSON SMITH, superintendent of the County Asylum for the Insance at Blackwood, N. J., died following an operation for appendicitis on Oct. 29, at the age of fifty years. He was graduated from Jefferson Medical College in 1897.

Dr. JAMES CAMPBELL ANDREWS, a graduate of the Eclectic Medical College, Cincinnati, in 1868, died at his home in Philadelphia, Pa., on Nov. 2, at the age of eighty-four years.

Dr. THOMAS B. ROCHE, a graduate of the University of California Medical School in 1898, died at his home in Sacramento as the result of injuries received in an automobile accident while in gov-

ernment service at Fort McDowell, on Oct. 27, at the age of fifty years. Dr. Roche formerly served as a member of the San Francisco Board of Health and was at one time superintendent of the City and County Hospital.

Dr. GEORGE W. BRADLEY of Waverly, Ill., a graduate of the Louisville Medical College in 1871, died on Nov. 2, at the age of eighty-three years.

Dr. WILLIAM A. DICKEY of Toledo, Ohio, a graduate of the Louisville Medical College in 1877, died on Nov. 3, at the age of sixty-seven years. He was president of the Toledo Academy of Medicine and surgeon to the police and fire departments of the city.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, October 28, 1921.

Meeting of the British Association for the Advancement of Radiology and Physiotherapy.—This association held its annual general meeting on September 30 last. Dr. Robert Knox, the president, in reviewing the work which the Association had accomplished since its foundation, pointed out that the first steps toward the institution of the Cambridge Diploma in medical radiology and electrology had been taken by the Association which approached the senate of the university on the subject. Since those early days the University of Cambridge had consistently sought the advice of the B. A. R. P., and had recognized the course of instruction organized by it in London as qualifying for admission to the diploma examination. In addition to its educational activities, Dr. Knox went on to say, the B. A. R. P. had recently initiated the policy of issuing authoritative statements on medical subjects to the daily papers. There were certain objections to the frequent appearance of individual names in the public press, yet at times the need of enlightening the public on technical matters was urgent. The issue of manifestos approved by the council of the association appeared to him to fulfill the joint requirements of being authoritative and at the same time free from any suggestion of personal bias. Dr. Knox hoped some day to see in London an institute of radiology housed in a building worthy of the extent and importance of these subjects, having its own museum and library and perhaps having its own clinic, so that every possible facility for teaching and research in radiology and allied subjects might exist in the capital of the Empire. He called attention to the fact that these ideals could only be realized if the B. A. R. P. were supported by all medical men throughout the whole country who were interested in electrical subjects, no matter whether they exclusively specialized in them or not.

The Increase of Criminal Abortion.—Dr. Gordon Ley addressed recently a meeting of the infant welfare workers, teachers and mothers, arranged by the National Association for the Prevention of Infant Mortality at Morley Hall, Hanover Square, London. Dr. Ley dealt with the dangers of unintentional poisoning during pregnancy. As regarded the criminal aspect of the subject, he said that he feared that criminal operations were on the increase. There were parts of London where he felt sure such operations took place in hundreds every week, and were performed by doctors, midwives, and persons with no knowledge of obstetrics.

Panel Practitioners.—The panel practitioners of this country have given in to the terms laid down for them by Sir Alfred Mond, the new Minister of Health, that is a reduction of the annual fee of eleven shillings, agreed to about a year ago, to nine shillings and sixpence. The panel practitioners asked for thirteen shillings when the terms of a year ago were being discussed, and they expressed themselves as both dissatisfied and aggrieved at the fee being fixed at eleven shillings. At a conference of panel practitioners, held last week at the Central Hall, Westminster, which was attended in large numbers by such medical men from all parts of the country, the question was dealt with in private. A statement was given out that after mature consideration a decision had been come to to accept a reduction, not because it was deemed that a reduction was justified, but wholly from patriotic motives. It was proposed by the conference and adopted that a deputation should meet Sir Alfred Mond and suggest that the fee settled on should be ten shillings. In accordance with this proposition the Minister of Health was visited and the proposal passed made to him. However, when the meeting took place Sir Alfred Mond declared that no advance on nine shillings and sixpence could be offered. On being made acquainted with the ultimatum the conference decided to accept the first proposal without any further demur. The sole concession made by the minister was that the sum of nine and sixpence agreed upon should be guaranteed for a period of two years.

Hospital Crisis Still Urgent in London.—Sir Alan Anderson, speaking in London on Oct. 25 last to the members of the Charity Organization Society, gave fresh figures showing the serious situation of the voluntary hospitals in London. Speaking as one of the honorary secretaries of King Edward's Hospital Fund, Sir Alan Anderson said that they had during the summer to find out how the London hospitals stood in their own estimates. These figures were now in, and they showed a total estimated deficiency for the current year of £500,000. Expenditure would exceed total receipts by this amount. The sum available for distribution by the Hospitals Commission for the whole country was £500,000, so that the King Edward's Fund Committee had to see which of the hospitals were really on the rocks. It was recognized that the least solvent hospitals would be obliged to shut down or not pay their tradesmen's bills. London hospitals which appeared to be in this position of greatest need had an estimated deficiency of about £230,000 this year, which meant they were running into debt at the rate of about £20,000 a month. The fund had reported this to the Hospitals Commission, and "the ball was now with them" (a football term signifying in American vernacular that it "was now up to them"). There was sufficient evidence of a grave

and instant crisis. Unless some marked change should come over the whole picture of hospital finance a large number of beds would have to be closed. Very much the same thing was happening all over the country, except that in some towns difficulties had already been grappled with and either wholly or in large measure met. In 1913, before the war, hospital expenditure in London was £1,188,000. In 1920 the expenditure had risen to £2,841,000. In the same period the income of the hospitals rose from £1,478,000 to £2,447,000. The charity income had risen from £1,370,000 to £1,868,000, while payments by users or potential users had increased from £97,000. The Government grant in aid of the hospitals would cover only a short period of the emergency. In six months' time new schemes must be in working order. The deficiency had to be faced at once, and this was the point King Edward's Fund had reached. Sir Alan Anderson went on to deal with the proposals of Lord Cave's Committee that the hospitals should ask more from the classes which used them, and discussed the question of weekly contributions. King Edward's Fund, he said, did not actually agree that the users of the hospitals should pay more, but that they ought to impress on the people who used the hospitals that they should pay if they could afford the money. He hoped for a greater use of the Hospital Saturday Fund as a means of collecting fresh contributions. In conclusion he made it clear that no system of weekly payments by potential users could do away with charity. If such payments were to prevent the public from giving to the hospitals Sir Alan said, then the whole voluntary system would necessarily break down.

Perils of the Cinema.—At a conference of women social workers, held by the National Organization of Girls' Clubs recently, at the Mary Ward Settlement, Tavistock Place, London, Miss Neville, warden of the Mary Ward Settlement, maintained that in its present state the cinema stimulated wrong emotions. She said that the cinema showed us at our worst. We see sordid scenes, morbid scenes, and too much lack of self-control and drunkenness shown, on the one hand, and, on the other, too much luxury, motorcars, powdered servants, and so forth. Serious subjects are treated lightly, and there is a tendency to jeer at married life, and to treat immorality as a matter of course. She went on to say that experience had taught her that it was the easiest thing in the world to stimulate good taste in people and to teach them to be disgusted at bad films. It was remarkable what natural good taste even small children had, although a great effort was made nowadays to destroy it. It had been shown time and again that children preferred a beautiful and faithful film of bird or animal life even to thrilling adventure stories. Educationally the cinema had a great work before it. She had found that films showing beautiful swimming or dancing were invaluable in developing in young girls a sense of the dignity of the human figure, which was badly needed nowadays to combat objectionable dress and lack of self-control. The true function of the cinema, however, would always be to entertain, and it was the duty of the nation to see that such an important recreation was clean and artistic.

There is much truth in the contention that films do the young harm from the mental, moral, and physical standpoints. There is altogether too great an appeal to the animal side and the lower instincts of the human being and too little to the spiritual side and higher mental faculties. Films might be and should be of the greatest educational value to children. There are few better ways of teaching the young certain things, as, for instance, geography, natural history, entomology, zoology, and so on, than by the agency of films. Some physical injury is done to children by picture shows. The eyes are, in some cases, hurt to some extent, while in this country, at any rate, some of the halls in which films are exhibited are stuffy, not too well ventilated places, in which the vitality of the young tends to be decreased. In short, in a variety of ways these places of amusement and instruction could be immensely improved, and, instead of being a source of danger, might be rendered potent means of imparting useful knowledge and of providing healthful amusement for young and grown-up people alike.

Operations for the Removal of Tonsils.—There has been quite a lively controversy recently in the *Times* with regard to operations on school children, and especially with respect to the removal of tonsils. It has long been held by some in this country, and doubtless in America also, that tonsils are removed from school children on occasions somewhat indiscriminately and without due cause for the operation. But no one would perhaps go so far as Lieut.-Col. Kynaston, who declared in a letter to the *Times* a week or so ago that enlarged and even septic tonsils could be cured by internal medical treatment. The paper controversy at length resolved itself into a duel between Colonel Kynaston and one of the chief nose and throat authorities of London, Dr. Irwin Moore. In the last letter that Dr. Moore contributed he said that he had written a private letter to the army medical man, challenging him in the interests of medical science and of public health to discuss and go into the subject more fully with him. As the writer pointed out, Colonel Kynaston will then have the opportunity of giving the names of acknowledged authorities who support his view that the chronic enlarged and septic tonsils can be successfully treated by internal remedies. The subject requires free and wide ventilation and it would be instructive to learn the views of nose and throat specialists in America on this very important matter. Of course, it has been discussed frequently in your country, but it would be valuable to know on this side of the Atlantic the opinions of some of your leading authorities.

Professorship of Chemistry at Middlesex Hospital School.—Dr. W. B. Tuck has been appointed University Professor of Chemistry at Middlesex Hospital Medical School. He was a student at University College from 1902 to 1906 and took his degree in medicine in 1910, when he became teacher of chemistry to medical students at University College. He has, since 1919, been lecturing at Middlesex Hospital Medical School.

2. **Ether Day Address, October 18, 1921.**—Dr. Frederick C. Shattuck, in this address, delivered on the centennial anniversary of the Massachusetts General Hospital and the diamond jubilee of anesthesia, states that the records of the hospital show that the first patient was admitted September 3, 1821. Up to January 1, 1922, there were 18 admissions, 122 during the year 1822. There were probably 60 beds in 1822. In 1823, when the wings were finished, there were 93 beds. Admissions to the wards in 1920 were 6185, 25,302 to the Out-Patient Department. The Out-Patient Service was started October 16, 1846, the same day that the first operation was done under ether. Speaking of the debt the hospital owed to those who had served it as trustees, Dr. Shattuck pays tribute to James Jackson, who with John C. Warren, was cofounder of the hospital. He first, in 1822, described "alcoholic neuritis," in 1855, "painful tumor near the cecum," now known as appendicitis, and in the same year published the medical "Letters to a Young Physician." Walter Channing, in 1843, published "Notes on Anhæmia," in special connection with the puerperal state. Therein are described cases of that form of grave anemia now called pernicious anemia. John Barnard Sweet Jackson was Curator of the Cabinet of the Boston Society for Medical Improvement, and also of the Warren Museum. His catalogue of the former cabinet, published in 1847, was characterized by a distinguished Philadelphia professor as "the most valuable contribution to pathological anatomy made up to that date in this country." Jacob Bigelow, a pupil of Benjamin Rush, whose Essay on Self-Limited Diseases, dealt a staggering blow to the heroic treatment of the day, to the holy trinity—bleeding, purging, and puking. Of this oration, Dr. Holmes said, "This remarkable essay has probably had more influence on medical practice in America than any similar brief treatise, we might say, than any work ever published in this country." Oliver Wendell Holmes, high as he ranks as poet and wit, ranks still higher for his clarion call on puerperal fever. It is noteworthy that Channing's paper on Anhæmia, Jacob Bigelow's on Self-Limited Disease, and Holmes' on Puerperal Fever were all published in the *New England Quarterly Journal of Medicine and Surgery*, and in the same year, 1842. Henry Ingersoll Bowditch, in conjunction with Morrill Wyman, was a pioneer in the treatment of pleural effusions by tapping. He was the first chairman of the State Board of Health of Massachusetts. Calvin Ellis played a conspicuous part in the advance in medical education inaugurated by the Harvard School, and, dying, left his whole property to the school. Other trustees of the Massachusetts General Hospital nearer our own time, to whom Dr. Shattuck pays tribute, are Henry K. Oliver, James C. White, Reginald H. Fitz, and Walter James Dodd, roentgenologist to the hospital, who, not knowing the danger from *x*-ray burns, was soon severely burned. He underwent fifty operations, suffered grievous pain, and died a martyr to science. His story should be widely known, and its lesson laid to heart. Richard C. Cabot, Father of Hospital Social Service, is happily still with us, and has seen his child grow rapidly to maturity and travel around the world. Dr. Shattuck said that if he were asked to name the three most conspicuous services which had been rendered to humanity through the medium of the Massachusetts General Hospital, he would unhesitatingly select Anesthesia, Appendicitis, and Social Service.

2. A Method of Preserving the Antigenic Properties of Gonococcal Proteins in Glycerol.—Ralph Oakley Clock and Stanley D. Beard, having successfully devised a method of preparing a stable pollen antigen, whereby the antigenic properties of the pollen protein are preserved by glycerol for a period of at least two years, attempted to find out whether glycerol would also preserve bacterial protein. They point out that saline vaccines do not represent the full immunizing properties of the bacteria. The gonococcus, even in living cultures, shows evidence of rapid destruction by autolysis. Gonococcus saline vaccines have not yielded uniformly satisfactory results, probably because they contain a considerable amount of nonspecific products of autolysis and too small and variable an amount of gonococcal proteins. The gonococcus glycerol vaccine is free from autolytic products. Glycerol being hygroscopic, prevents hydrolytic autolysis of the bacterial proteins, and the intigenic power is thus preserved. Gonococcus glycerol vaccine possesses many times more immunizing power than a corresponding saline vaccine, because the glycerol vaccine contains the bacterial proteins in a relatively unaltered and stable form. The glycerol vaccine does not readily deteriorate. It is not heated, thereby eliminating the possibility of protein changes due to partial heat coagulation. The gonococcus glycerol vaccine is prepared in concentrated form and is kept under the preservative action of glycerol until immediately before its administration, when it is diluted with physiological salt solution. The dosage begins with one hundred million and progressively increases by that amount at each subsequent dose up to one thousand five hundred million. For refractory cases the dosage may be continued up to two thousand million. The types of cases in which the gonococcus glycerol vaccine has been used in clinical trials with encouraging results are the acute complications of gonorrheal infection, including arthritis, epididymitis, vesiculitis, and prostatitis. The gonococcus glycerol vaccine is prepared as follows: The ten so-called Torrey strains of the gonococcus are grown on the surface of nutrient agar in Blake bottles. The sixteen hour bacterial growth is washed in normal saline by centrifugalization to free it from autolytic products formed during the growth of the bacteria. The bacterial mass, washed free of autolytic products, is immediately suspended in 66 2/3 per cent. glycerol to prevent any further autolysis or deterioration of the bacterial protein. The vaccine is not heated. The suspension is standardized and tested on white mice.

14. A Contribution to the Mercurial Therapeusis of Syphilis.—L. G. Hadiopoulos, Reginald Burbank, and L. P. Kyrides, in 1917, started experimental work on a new synthetic organic mercurial (mercurosal) prepared by one of them. Mercurosal, the disodium salt of mercury salicylacetic acid, has a percentage of mercury

averaging between forty-two and forty-three. It has certain attractive features in that it is soluble in water and has a relatively low toxicity, rendering it adaptable for intravenous administration. It was therefore decided to give it a trial in the treatment of syphilis. Beginning in 1917, they gradually introduced mercurosal in a 2 per cent. aqueous solution, first as intramuscular injections of 1 or 2 c.c., and later as intravenous injections of 4 to 8 c.c. Before the end of the same year the clinical and serological behavior of their cases encouraged them to abandon all other mercurials in favor of mercurosal. From a study of their primary cases the following conclusions are drawn: The abortive treatment of syphilis at the stage of chancre is no longer a possibility but a probability. It cannot, however, be stated with any certainty that mercurosal or any other mercurial can succeed alone without salvarsan. Cases are tabulated in which active mercurial treatment at this stage did not prevent the appearance of secondaries. The immediate effect of mercurosal in particular, and probably of all other mercurials, in early cutaneous and mucous syphilides is questionable. On the other hand, as marvelous a drug as salvarsan is in clearing cutaneous and mucous lesions, it often fails in completing a symptomatic, and more so a serological cure, when it is used alone without or with insufficient mercury. The place of mercurials as an adjuvant to arsenical treatment in secondary syphilis is of great significance because results obtained by mixed treatment are more lasting than by salvarsan alone. The value of mercurosal in contrast to other mercurials in secondary syphilis is incontestable. When mercurosal in conjunction with salvarsan treatment is persisted in long enough there will be very few cases that will not ultimately come under therapeutic control.

2. Alcoholism in Relation to Mental Depression.—Pierre Janet argues that alcoholism is not an intoxication of an accidental nature, which will disappear and leave no traces if alcohol is suppressed. In dealing with alcoholism we are dealing with an alteration of the mind—a mental disease—antecedent to the present absorption of alcohol and in one sense independent of alcohol. In the majority of cases the impulse to drink alcoholics began on a certain date that was connected in some way with some particular event in the person's life. It is easy to show that alcoholism begins under the same conditions as various forms of mental depression. Persons fall into the habit of alcoholism just as they sink into a state of mental depression, as the result of physical or mental overwork, a change of surroundings, a change of position as the result of a rupture, disappointment in a love affair, etc. This is the general rule, and there are fewer exceptions than we imagine. Diminution of alcoholism is primarily the work of the hygienist and the mental specialist. Those who have devoted themselves to the work of supplying workmen's cottages; who are seeking to give families healthful places of abode, with plenty of fresh air in their rooms, are doing more than one would at first imagine for the care of mental depression and of alcoholism. Those who have endeavored to assure workingmen, and more especially working women, a good, substantial diet at a reasonable price, have made an important contribution toward the suppression of alcoholism. But in addition to the physical side, shall we not some day study into the mental hygiene of our people? If we could make the social struggle less severe; if we could check the desire to attain social position too rapidly, and if we could discourage dangerous ambitions, could we not unite what now seem irreconcilable: Freedom of thought and tranquillity of beliefs? The physician should not concern himself chiefly with the disintoxication of the patient. He should take active interest in the disorder of depression which called forth the craving for the poison before the intoxication took place and which will bring back the same craving after disintoxication, no matter how complete it may be, has taken place.

3. Physical Characters and Enzymatic Activities of Duodenal Contents: Findings During Gastric Digestion in Normal Young Men.—C. W. McClure, A. S. Wetmore, and Lawrence Reynolds conducted this study at the Peter Bent Brigham Hospital. The subjects were fed on five types of meals. These meals consisted of: (1) 300 c.c. of a mixture of milk, water, and cottage cheese; (2) 300 c.c. of 20 per cent. cream; (3) 300 c.c. of 0.5 per cent. cooked cornstarch solution in which were dissolved 15 grams of lactose; (4) 300 c.c. of tap water. To each meal was added 40 grams of barium sulphate. A fifth type of meal consisted of 40 c.c. of 20 per cent. cream and 10 grams of barium sulphate. The barium in the meals permitted observation by means of the fluoroscope. The duodenal contents collected after feeding these meals all contained bile, showed rather characteristic degrees of viscosity, varied in color, and were usually very largely liquid, containing but a very small amount of the food originally fed. The finding of the differences in viscosity and color suggests that the character of the fluids entering the duodenum is in some way dependent upon the kind of food ingested. Before beginning the study of enzymatic activity the writers devised methods which would conform to the basic principles of the physical chemistry of enzyme action. Tabulated figures show that in the hourly specimens of duodenal contents derived from the milk and cottage cheese and the cream meals there were sufficiently uniform degrees of enzymatic activities to permit the estimation of average figures for the degree of each type of enzyme action. Duodenal contents derived from the fasting duodenum or from the water meals, and in specimens collected over periods of only 15 minutes, showed degrees of enzyme activities considerably below this standard. Similar results were also obtained occasionally in duodenal contents derived from the starch and lactose meals. These findings suggest the existence of some relation between kind of food eaten and the degree of enzyme action in duodenal contents. The hydrogen ion concentration of the duodenal contents derived from the various types of meals was determined by means of a potentiometer. The hydrogen ion concentrations were found to vary between 5 and 7.5, with, however, an occasional exception between 4 and 5. These findings are similar to those of McClendon and his co-workers. No relation was found between the degree of enzyme activities and the hydrogen ion concentrations. This observation, together with the finding of variations in the degree of enzymatic activities in relation to the types of materials ingested, suggests that food plays a more important rôle in the production of enzyme action in the duodenum than does the degree of acidity. This finding supports Pawlow's contention in contradistinction to that of the "secretin" theory of Bayliss and Starling. Enzyme activities were determined in the hourly specimens of duodenal contents derived from fifteen normal young men, after the ingestion of milk and cottage cheese, or one of the cream meals. On the basis of these observations, the normal minimum for enzymatic activity, as determined under these experimental conditions, is considered to be, for proteolytic activity, 2 mg. of nonprotein nitrogen; for lipolytic activity, 1 c.c. of tenth normal sodium hydroxide, and for amylolytic activity in the neighborhood of 1 mg. of glucose.

5. Fractional Analysis of the Duodenal Contents in Normal Individuals.—Julius Friedenwald and Joseph Sindler made fractional analyses of the duodenal contents of ten normal individuals according to the method of Einhorn with his special agar tubes. From these observations they feel justified in concluding that this method of examination presents a simple means of determining quantitatively the degree of alkalinity as well as the quantity of ferments present for several hours after the stimulation of the duodenal contents by means of a test meal. The degree of alkalinity is usually highest in the fasting state, and falls immediately after the test meal is given, and then gradually rises; it bears no relation to the curve of gastric acidity. A similar effect is observed usually in regard to the ferments, the strength of one ferment being wholly independent of the other. Finally these findings, obtained under normal conditions, appear sufficiently definite to serve as a basis for further studies of pathologic changes in the duodenal contents.

6. Foci of Infection in Cases of Pyelonephritis. Study II.—Hermon C. Bumpus, Jr., and John G. Meisser recall that in a recent study they attempted to show that pyelonephritis may often be due to focal infections, and that the colon bacillus, which is usually found in the urine and believed to be the cause, is a secondary infection. They now report a second series of cases which, with the six cases previously reported, shows that 82 rabbits were injected with strains of a green-producing streptococcus obtained from the teeth, tonsils, urine, and blood of patients suffering from pyelonephritis, and that in 63 of the animals lesions of the kidney were found. This, they believe, is evidence for concluding that pyelonephritis may often be due to focal infections harboring streptococci which have a selective affinity for the urinary tract, and that the colon bacillus, which is commonly found, and has been generally believed to be the cause, is of purely secondary importance.

10. Injurious Combined Effect of Roentgen Rays or Radium and Topical Remedies.—George M. McKee and George C. Andrews call attention to the fact that small doses of roentgen rays or radium, combined with topical irritants in strength, may result in severe injury. Any drug, chemical, remedy, or agent that is capable of effecting an inflammatory reaction in the skin may make the latter more susceptible to irradiation. Chrysarobin, scarlet R medicinal, iodine, mercury, pyrogallic acid, cantharides, resorcin, betanaphthol, tar, iodoform, sulphur, salicylic acid, and remedies of this kind effect hypersensitiveness of the skin. They cause least trouble when used as powders; they are more potent in solution, and most potent in the form of ointments. Caustics, such as sodium hydroxide, or potassium hydroxide, acid nitrate of mercury, zinc chloride, trichloracetic acid, nitric acid, silver nitrate, etc., all may enhance irradiation effects. Ultraviolet light, especially if applied at the point of visible reaction, may enhance the effect of roentgen rays and radium. Carbon dioxide snow must be used with great caution on irradiated skin. The writers have seen deep, slowly healing ulcers follow a five-second application of carbon dioxide snow with firm pressure in skin that had been permanently injured by roentgen rays two years previously. Prolonged applications of heat or cold, and friction, especially if combined with liniments, may enhance irradiation effects.

11. Magnesium Sulphate as an Aid to Anesthesia.—Arthur H. Curtis reports a case in which the injection of 310 c.c. of 4 per cent. chemically pure magnesium sulphate solution administered by hypodermoclysis resulted in the death of the patient. Post mortem examination demonstrated a marked jaundice, marked acute fatty changes of the liver, cloudy swellings of the parenchymatous organs, and multiple petechial hemorrhages of the pleura. He concludes (1) that preliminary hypodermoclysis of magnesium sulphate solution usually lessens the requisite amount of other general anesthetic and greatly relieves post-operative distress, and (2) that study of the fatal case herein reported, together with evidence from previous experimentation on animals, indicates that magnesium sulphate solution sometimes produces profound changes in the liver and cannot be considered a safe anesthetic for general use.

3. Hair-Balls or Hair Casts of the Stomach or Gastro-intestinal Tract—A Report of Two Cases of Hair Cast of the Stomach with an Abstract of 108 Cases.—Ivor J. Davies thinks it not improbable that unreported cases of this condition occur not infrequently in the surgical practice of all large hospitals. Careful research in the literature shows the condition to be almost an entity for there is a close uniformity of feature in the reports. Moore states that the incidence of hair-balls in the human stomach may well be used as an argument in favor of evolution, as they are frequently found in animals in the season when the hair is shed, and but rarely give rise to serious symptoms, since they are frequently expelled by vomiting or passed in the feces with a thick coating of food particles. In human beings the hair-eating habit is usually confined to young females, and generally dates from childhood. There seems to be no correlation with an unstable nervous constitution as in nail-biting. The diagnosis is one mainly of differentiation of gastric tumor, and for all practical purposes lies between malignant disease and hair-mass. The early age, long history, good health, and the particular features of the tumor are almost peculiar to hair-mass. The free mobility of a hard, smooth mass apparently in a fluid sac is the most striking impression gained from the published records of hair-ball of the stomach. If one bears this fact in mind then the possibility of hair-ball will be remembered and a diagnosis can be definitely established by radiography. In one of the writer's cases the diagnosis was made before operation. In the other the hair-mass weighed 6½ pounds, the largest on record. In this case, except for occasional attacks of dyspepsia, definite disturbance of the digestion had only been present for six months prior to operation, though the huge mass of hair completely filled the stomach. In most instances the only abnormal physical signs recorded are those of an abdominal tumor, which is most commonly present in the epigastrium or extends across the hypogastrium. The tumor may take a lower position owing to gastroptosis, and when this is marked the pylorus may be in the pelvis. In the writer's case, in which the tumor weighed 6½ pounds, the position of the stomach had led to the provisional diagnoses of pregnancy and splenic anemia.

4. Treatment of Syphilis by Intravenous Injections of Mercury.—J. Ernest Lane recalls that the treatment of syphilis by intravenous injections of mercury was introduced into the Male Lock Hospital in 1895, and the following year he read a paper on it before the Third International Congress on Dermatology, held in London the following year. For various reasons he did not persevere with the treatment. In 1917 he decided to give the treatment a further trial, the results of which have been perfectly satisfactory. He has now treated 166 women in the Female Lock Hospital, 66 of whom were pregnant. The routine adopted was one injection of one of the salvarsan substitutes and five injections of cyanide of mercury solution per week; the doses of the latter varied with the tolerance of the patients, and it was found that many could stand a dosage of 40 to 50 minims. The writer is impressed with the value of intravenous injections of mercury in pregnant women and considers it infinitely superior to any other routine of treatment. It is not appropriate to the treatment of out-patients in the venereal disease clinics, but is most reliable for use in institutions where the patients can be induced to stay until the complete subsidence of all symptoms of syphilis.

7. The Accuracy of the Formalin and Sachs-Georgi

Tests for Syphilis as Compared with the Wassermann Reaction.—W. Neave Kingsbury reports the results of formalin tests carried out on 261 cases and the Sachs-Georgi reaction in 252 cases. Only 43 per cent. of the serums giving a positive Wassermann reaction showed a positive formalin test, while 9.5 per cent. of serums giving a negative Wassermann gave a positive formalin test. In the Sachs-Georgi tests the cases giving a negative Wassermann and a negative Sachs-Georgi is 97 per cent. of the total negative Wassermann reactions, but the proportion of positive results was poor. The writers claims that this investigation again proves that the formalin test is unreliable. As regards the Sachs-Georgi test the results are distinctly promising. The technique is much simpler than that of the Wassermann reaction on account of the omission of the complement and other constituents of the hemolytic system. But this is rather more than balanced by the great difficulty of determining the presence or absence of a precipitate in many instances. A strongly positive Sachs-Georgi reaction may be taken as evidence of the presence of syphilis, but a weak reaction must at present be looked upon with suspicion because of the difficulty of distinguishing the weakest positive reaction and the slight precipitation given by some negative serums. It appears possible, however, that the detection of the weakest positives may be made easier by modification of the antigen and by special methods of reading the result.

October 15, 1921, No. 3172.

1. A Lecture on Pericarditis in Childhood.—F. John Poynton, in this article, discusses more particularly the nonrheumatic forms of pericarditis. In an analysis of 100 fatal cases of suppurative pericarditis of all varieties, 84 per cent. of the patients were under 4 years of age. This form of pericarditis rarely occurs as a solitary event; there was only one such case in this series, and the author has seen one other; 54 were associated with empyemata and 31 with pleurisy or pneumonia. The difficulties of diagnosis frequently lead to delay or oversight. One great cause of difficulty is the frequent absence of pericardial friction; this sign was recorded in only two cases in this series. The development of a definite effusion is the one great assistance in diagnosis when there has been no friction. The diagnostic signs to which Poynton attaches the most value are the gradual disappearance of the heart sounds step by step with an increase in the area of cardiac dullness. A noticeable feature in pericardial effusion is the upward extension of the dull area, sometimes on both sides, but particularly on the left. This upward extension compresses the upper lobe of the left lung, with the result that there may be an impairment of the percussion note over the left clavicle, below this tubular breathing from the pulmonary collapse, and below this again the wooden dullness of the pericardial effusion. Nevertheless, these signs may be puzzling, for one has to take into account the possibility of a pneumonia in the left upper lobe. The dull area due to pericardial effusion may extend far beyond the apex beat into the left axilla, and then the possibility of a left pleural effusion suggests itself. On the right side the precordial dullness may reach the nipple line; the direction of this right line extends from above downward and outward; when the heart is dilated and there is no effusion, the outline of the dilated right auricle is generally curved and forms with the hepatic line an acute angle. Unfortunately when there is, in addition, an adherent, thickened pericardium this distinction does not hold. There are interesting signs at the back of the chest in some cases of pericardial effusion—signs which are also met with when there is great cardiac dilatation. In children these signs are very striking. A patch of intense tubular breathing appears to the left of the spine about the level of the inferior angle of the scapula; below it the breath sounds, though diminished, may be natural and above it they are unaltered. Later the note becomes dull on percussion even to the base, and the area of tubular breathing expands downward, but over this area there may be no adventitious sounds. As to the treatment, in rheumatic pericarditis the process generally subsides and in these cases the author has not seen the course of the case perceptibly altered for the better by operative interference. The pneumococcal and other suppurative infections may also quiet down in very exceptional cases of slight severity, but far more frequently they tend to remain active. As a general rule one should move slowly to paracentesis in rheumatic pericarditis. In suppurative pericarditis it is safer to trust to drainage of the pericardium than to paracentesis. In exploring the pericardium Poynton prefers the abdominal route—in the French literature often termed Margan's route. By this route the ensiform is removed and the pericardium incised from below.

2. A Study of Some Factors Controlling the Normal Sugar Content of the Blood.—P. J. Cammidge, J. A. Cairns Forsyth, and H. A. H. Howard, finding it impossible to explain satisfactorily on present theories many of the phenomena observed in the course of an experimental investigation of diabetes mellitus to which they had been led by previous work upon the changes in carbohydrate content of the blood associated with pancreatic disease, have studied the subject afresh. As a result of these newer investigations they now hold a theory which may be summarized as follows: (1) The liver contains a diastatic ferment, the action of which is reversible. 2. In the fasting state the glycogenetic activities of this ferment are very largely inhibited by (*a*) an antiferment formed by the pancreas, (*b*) the impermeability of the resting liver cells to sodium chloride, (*c*) the reaction of the fasting blood and liver cells. (3) As long as the pancreas and liver are functionally intact and a flow of blood with a normal reaction is maintained, glycogenolysis will be constant therefor and the sugar content of the blood vary within very narrow limits. This is true of all animals of similar constitution, no matter what their habitual diet may be. (4) The entrance of food into the stomach causes a flow of acid, and when this acid reaches the duodenum a formation of secretin results. (5) The secretin (*a*) stimulates the liver cells to produce bile, thus permitting the entrance of sodium chloride, which activates the diastatic ferment; (*b*) causes the pancreas to pour out its alkaline secretion into the intestine to combine with the acid gastric contents, forming acid salts and sodium chloride, which pass into the liver and increase the activity of the diastatic ferment; (*c*) interferes with the formation of the internal secretin of the pancreas, thus diminishing its inhibitory effect on glycogenolysis in the liver. (6) Carbohydrates reaching the liver from the intestine or formed from proteins in the liver are converted into glycogen by the diastatic ferment, the efficiency of the process depending upon the extent to which the glycogenolytic action of the enzyme is inhibited by the internal secretin of the pancreas. Unless the power of glycogen formation possessed by the liver is exceeded, sugar as such, or formed from starch in the intestine, does not pass into the general circulation or play any direct part in the rise of blood sugar following feeding. This theory appears to account for the constant level of the normal blood sugar content of the blood in a fasting condition, and to explain the variations produced by the ingestion of food. It also permits of a reasonable explanation of the changes occurring in disease.

2. Examination of the Blood in Diabetes Mellitus.—R. T. Williamson describes a simple blood test which he has been using for twenty-five years, and which has never given the reaction in any disease except diabetes. In carrying out the test only a small quantity of blood is required—a large drop. A test tube with a diameter of not more than a quarter of an inch is used. It is washed with water and the water jerked out of the tube, with the exception of one drop, which is allowed to remain at the bottom of the tube. The patient's finger is pricked, and 20 cubic millimeters of blood are taken up with a fine capillary tube, placed in the tube and mixed with the drop of water. Then 1 c.c. of a 1-6000 watery solution of methylene blue is added. Finally 40 c.mm. of liquor potassæ are added to the mixture. The contents of the tube are mixed by placing the finger tip at the open end of the tube and slowly inverting the tube six or eight times. The mixture has a definite blue or bluish green color. The tube is then placed in a water-bath or a wide test tube containing water at the bottom of the tube. The water is kept boiling. At the end of four minutes if the blood sugar is decidedly increased the fluid in the small test tube will have lost its blue color and have become a brownish yellow. When the blood sugar is not increased the fluid in the small test tube retains its blue or blue-green color after heating in the water bath four minutes. As a control the same procedure may be carried out with normal blood. The writer used this test for cases of diabetes when first seen, and finds it of value as an indication of the severity of the diabetes. In cases of so-called "renal diabetes" no methylene blue reaction will be obtained. This test does not preclude the necessity for making other blood tests to ascertain the exact percentage of sugar.

5. Some Uses and Doses of Hypnotics.—F. Wyatt-Smith summarizes his personal experience in the treatment of mental diseases as follows: "(1) I do not believe there is any danger of producing an addiction to hypnotic drugs by their intelligent medicinal use. (2) Opium, and its products, should never be regarded as hypnotics. (3) The bromides are of little practical use as such. (4) Bicarbonate of sodium and night-socks have a far better right to the title. (5) Chloral hydrate is, perhaps, the most generally useful of the cheaper hypnotics; and is, probably, not very dangerous even in cases of fatty heart. (6) Paraldehyde is the best mere nightcap in mild cases, and is useful in a dose up to half an ounce with the first dose of some other hypnotic, such as sulphonal, to anticipate its coming into action. (7) Sulphonal is, except for its high price, the best of our hypnotics in that it is also a decided mental sedative. It appears to be quite safe in doses up to at least a dram a day, given in divided doses of 30 grains night and morning, or, better, of 20 grains three times daily. (8) Hyoscine is our strongest agent in a hypnotic emergency, and is quite safe up to 1 50, and probably up to 1/33 of a grain, hypodermically. It should be given an extensive trial in delirium tremens.

7. Letters to a Young Physician. Alfred Kahn.

6. Functional Disturbances of Gastric Secretion, Motility and Sensibility.—W. H. Foreman asserts that contrary to our teaching, gastric digestion and gastric sensibility suffer little from disturbances of gastric secretion. On the other hand, gastric digestion and sensibility are disturbed with average gastric acidity. The secretory function of the stomach is influenced by so many factors outside the stomach that the amount and character of the secretion gives little knowledge of the pathology in the stomach. In the interpretation of gastric motility we must consider (*a*) organic disease in the stomach, (*b*) the gastrointestinal tube as a unit with its segmental irritability and tone, (*c*) derangements in other viscera, (*d*) nerve and psychic stability. Pain in the epigastrium may be: (*a*) true gastric pain in organic disease in the stomach or duodenum, (*b*) pain "referred" from other structures, (*c*) true gastric pain from organic or functional derangements in other portions of the gastrointestinal tube or in other structures, visceral or somatic, (*d*) reflex pain in epigastric somatic structures from visceral disease or visceral dysfunction. The reflex occurring over the splanchnic and spinal nerves, (*e*) pain due to hyperirritability, instability, or disease of the nerve centers.

3. A Case of Food Idiosyncrasy. James C. Carter.

2. The Study of Therapeutic Agents by County Societies.—A. G. Osterman has been advocating to county medical societies a more thorough study of drugs, their properties, chemistry, and everything that is known about them. Last year in the county society to which he belongs they selected for discussion the drug sodium citrate, for the reason that in its study they found many pathological conditions where this drug or its combination with others acted almost as specifics. Among the facts brought out about sodium citrate were its wonderful property of relieving the viscosity of the blood, and also when added to the blood outside of the body, its power to prevent its coagulation. When taken into the stomach it loses its acid radical, being excreted as a carbonate, adding to the alkalinity of the blood, diminishing the hydrogen ion, and relieving excessive acidity from whatever cause. In studying the effects of sodium citrate on infants its beneficial effect in all conditions of hyeracidity and resulting spasticity of the duodenum (colicky babies) was brought out. Sodium citrate added to milk prevents the massive coagulum of excessive acidity, the curds following its use being small, and always soluble. The acidosis of diabetes mellitus, and the intolerable itching that sometimes develops during its course around the genitalia and anus are promptly relieved by its administration. In the plethora of the last months of pregnancy, sometimes the forerunner of eclampsia, some cases can hardly be bled because of the viscosity of the blood. Here relief is obtained by the combination of citrate and calomel. In old chronic plethoric asthmatics, great eaters with high blood pressure, shortness of breath, wheezing, cough, emphysema, and the usual dilatation of the right side of the heart, the citrates in combination with the vasodilators give relief. The use of vaccines in acute infections never gives results until acidosis is relieved. The citrates are especially indicated in the Neisserian infections where the vaccines most often fail simply because this acidosis is lost sight of. The citrates of potassium may act better here than the sodium salt, on account of its effect on the kidneys. Chronic furunculosis can sometimes only be relieved by the thorough and persistent administration of sodium citrate. Irrigation with a solution consisting of 5 parts citrate of sodium, 20 parts sodium chloride, 500 parts water will close suppurating sinuses, and used as a hot moist application will sometimes abort furuncles. This agent is useful in influenza and acute lobar pneumonia, its effect being due to its remarkable property of relieving the high viscosity of the blood, taking the burden off of the heart and allowing of a freer and easier circulation through the lungs.

Nature of Bee Poison.—Flury obtained the poisonous secretion of 200,000 living bees for analysis. He found a large lipoid fraction and concludes that the active principle is a complex association of lecithin, and a basic compound which is related to two quite different animal toxins, viz.: snake-venom and cantharidin.—*Schweizerische medizinische Wochenschrift.*

Book Reviews.

CLINICAL BACTERIOLOGY AND HAEMATOLOGY FOR PRACTITIONERS. By W. D'ESTE EMERY, M.D., B.Sc., Lond. Director of the Laboratories and Lecturer on Pathology and Bacteriology, King's College Hospital, and Lecturer on General Pathology, London School of Medicine for Women. Sixth Edition. Price, $3.50 net. Philadelphia: P. Blakiston's Sons & Co., 1921.

THE new edition of Emery's familiar and excellent work will be welcomed by its large number of friends. There are but few changes to be found, chiefly in the introduction of certain new methods. The bacteriology is necessarily very brief in a book of this size, but the methods given are purely clinical. It is a work for practitioners rather than for laboratory men, although the latter may well find points of interest and value in it. The American readers will wonder why he has devoted so much space to the estimation of the opsonic power of the blood for we have come to believe it of little value. The section on cytodiagnosis is excellent.

URINARY ANALYSIS AND DIAGNOSIS by Microscopical and Chemical Examination. By LOUIS HEITZMANN, M.D. Formerly Professor of Pathology and Bacteriology, Fordham University School of Medicine, New York. Fourth Edition. Price, $4.00. New York: William Wood and Company, 1921.

IN this fourth edition of the book there have been few changes although the text has been quite thoroughly revised. There has been added a chapter on the Determination of the Functional Efficiency of the Kidneys by Walter T. Dannreuther which is fairly complete. In other respects the plan of the previous editions has been closely followed as will be recognized by all who are familiar with the book. About two-thirds of the volume is devoted to the microscopical examination which is apparently considered by the author to be rather more important than the chemical examination. He claims to have reached a degree of proficiency in the recognition of cellular elements found in the urine that has not been reached by other investigators, and discusses the criteria whereby many difficult diagnoses may be made. The book is profusely illustrated with drawings that are often excellent. The author uses the term pus-corpuscle in a very loose and confusing manner, at times apparently considering these bodies as identical with leucocytes but in other places deriving them from epithelial cells. There will be many who will dispute his claims to diagnostic ability, especially in the recognition of the origin of epithelial cells, but it must be admitted that he has probably studied this subject more thoroughly than the majority of his critics.

THE MEDICAL CLINICS OF NORTH AMERICA. Volume iv, Number 5. New York Number. March, 1921. Published Bi-monthly. Price per year, $12.00. Philadelphia and London: W. B. Saunders Company.

THIS number of the Clinics presents contributions of the clinics of nineteen authors in ten different institutions. As usual the titles exhibit a wide range of material so that the volume contains something of particular interest to nearly every medical reader. Longcope calls attention to the jaundice that occasionally follows the administration of arsphenamine, Pardee speaks on disease of the coronary arteries, and Holland on gastro-intestinal symptoms. McCann's discussion of basal metabolism and Ottenberg's of transfusion are both timely and interesting. Bullowa has an interesting contribution on scarletina but his photographs of the desquamation do not show what they are intended to show.

AIDS TO CHEMISTRY. By WILLIAM PARTRIDGE, F.I.C., Joint Public Analyst for the County of Dorset; Lecturer in Chemistry (Public Health), University of London, King's College. Price, $2.00. New York: William Wood & Company, 1921.

THIS is a new book, rather than a revision of the previous editions. It contains a large amount of information packed in a small space, and it should prove of service to medical students in following lectures in chemistry. It is too condensed to be of use to those who have not studied the subject. The volume is smaller than its predecessors, but this is an advantage. We recommend the book to the medical student who is struggling with this subject in some large textbook.

AIDS TO OPERATIVE SURGERY. By H. C. ORRIN, O.B.E., F.R.C.S., Ed., Surgeon, Ministry of Pensions Orthopedic Hospital, Newcastle-upon-Tyne; and late Civil Surgeon to the Third London General Hospital; late Surgeon to and Medical Officer-in-Charge of the Red Cross (Weir) Hospital, London, etc. Price, $1.75. New York: William Wood & Company, 1921.

THIS is a much-needed addition to a useful series. All of the "Aids" or "Compends" on Surgery which we have seen omit or minimize the subject of Operative Surgery. A student preparing for an examination has no time to go through the encyclopedic treatises labeled "Surgery"; but he can read, and refresh his memory in, some small volume such as this. All the more important operations are described quite briefly; and while only the absolute essentals are given, no step has been omitted. This volume, like others of the series, is intended a a companion to larger works. In a future edition, the addition to each section of a few lines giving the Indications for the various operations would add to the value of the book.

EINFÜHRUNG IN DIE ALLGEMEINE KONSTITUTIONS—UND VERERBUNGSPATHOLOGIE. Ein Lehrbuch für Studierende und Aerzte. Von Doctor HERMANN WERNER SIEMENS. Price 64 marks. Berlin: Julius Springer, 1921.

THE theoretical section deals with the conception of the congenital construction, of which the status arthriticus is an example, the disposition or factors which predispose to or invite disease, and the inheritance of disease. The practical section is devoted largely to the concepts of Mendelism and to the diagnosis and therapeutic management of the inherited element. The author fully covers familial diseases. The number of pages of the present volume is 229 and there are many charts showing the descent of diseases. The reader would be puzzled by the author's terminology were it not for the presence of an ample glossary. The previous literature of this subject is not large, although the author gives 67 bibliographical references, chiefly to articles in periodicals.

RÔLE DES COLLOÏDES CHEZ LES ÊTRES VIVANTS. Essai de Biocolloidologie. Nouvelles Hypothèses dans le Domaine de la Biologie et de la Médecine. Par AUGUSTE LUMIÈRE. Price 16 francs. Paris: Masson & Cie., 1921.

IN this work M. Lumière expounds a new theory regarding the origin and nature of the physiological and pathological phenomena in the living body of plant or animal. He holds that all transformations, all reactions which concern growth and nutrition have to do with matter in the colloidal state. Colloids form pseudo-solutions composed of very fine particles called by Naegeli micellæ, held in suspension in the intermicellar fluid. The micella has an inert center surrounded by active matter. It is animated by so-called Brunonian movements and undergoes continuous transformations. As a result of these changes its perigranular envelope may wear away and the inert nucleus enlarge and lose its faculty of movement—a process called ripening. As a result of this ripening it amalgamates with other micellæ and so-called flocculation occurs, the entire mass forming a coagulum. These minute micellæ have collectively an enormous surface estimated as two millions of square meters for an adult man. Sudden flocculation means death by so-called anaphylactic shock. Slow flocculation produces diseased states of the nature of chronic anaphylaxis. Protein antigens accidentally introduced into the body threaten flocculation, and the aim of treatment of the future will be to prevent flocculation or dissolve the coagula thus produced.

This, in brief, is the biological thesis which M. Lumière sustains in the book before us. He formulates his conception of micellar evolution in saying that life depends upon maintenance of the colloidal state, while flocculation causes disease and death. The book is interesting, and the theory, if found correct, would explain many biological phenomena which are as yet not well understood.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held May 17, 1921.

DR. SAMUEL BRADBURY IN THE CHAIR.

The Coronaries and Aneurysm of the Left Ventricle.—Dr. MORRIS H. KAHN made this presentation. He stated that aneurysm of the left ventricle, being the most common, might be taken as the type of aneurysm affecting the heart wall. Its usual site was at the apex or in the anterior wall immediately above it. The anterior or descending branch of the left coronary was the one involved when the left apex was affected and might be obstructed atheroma, fibrinous clot, or calcareous deposit. The pouch varied in size and was lined by stretched endocardium, white, opaque and greatly thickened. Dr. Kahn had had occasion to observe two cases at the Beth Israel Hospital, both clinically and pathologically, which were of interest. The first case showed a localized aneurysm involving the apex and not very extensive, while the second involved almost the entire wall of the left ventricle. The wall of the ventricle at the site of the aneurysm was frequently much thinned out, even as thin as a sheet of blotting paper, and the muscle was replaced by connective tissue. The aneurysm usually contained blood clot which was laminated and adherent to the endocardium. The symptoms of aneurysm of the heart were not otherwise distinctive from the symptoms of the cardiovascular disease in the course of which the aneurysm developed. Whenever extensive myocardial changes existed, as indicated by the symptoms and by electrocardiographic observations, or when symptoms of coronary thrombosis were diagnosed, myocardial degeneration and thinning of a portion of the ventricular wall should be suspected. The form usually taken by the clinical picture was, first, an attack of angina that might be synchronous with the closure of the coronary artery and might be associated with pericarditis; second, infarction of the cardiac muscle producing a pericardial reaction with localized adhesions. There might be severe pain in the precordium associated with a constant point of tenderness over a localized area of the precordium. Examination usually showed a feeble apex beat and weak heart sounds such as one naturally obtained where there was myocardial involvement. Sometimes there was gallop rhythm and splitting of the first sound. Reduplication might occur in the systole; this was explained by the myocardial inadequacy to overcome pressure. Pericardial changes were frequent, so much so that they had been given as the cause of the aneurysm. There might be pulsus alternans. Leucocytosis was present and might occur synchronously with the coronary closure. The electrocardiographic findings were significant in myocarditis. Changes that took place in electrocardiographic findings within a short interval of time and without the influence of medication must necessarily be attributed to functional, nervous, toxic, or organic causes. When changes were so important as widening or notching of the Q R S wave, or variation in the T phase, they indicated changes in the myocardium. A characteristic alteration took place in the form of the T wave following ligation of branches of the left coronary artery. There was a change of the T wave from a strongly positive peak, immediately after ligation, to a markedly negative one, and then a slower return to the positive or isoelectric form. The *x*-ray and the fluoroscope were of little help, though usually they would show dilatation of the left ventricle. The leaden pallor said to be characteristic of these cases of ventricular aneurysm was supposed to be due to peripheral vasoconstriction. Dr. Kahn gave a lantern slide demonstration of the findings of the two cases referred to in his paper and reported these cases more in detail.

Dr. E. LIBMAN said that he had noted, as Dr. Kahn had mentioned, a peculiar color of the face in patients who had an old thrombosis in the distribution of the left coronary artery. It had been difficult to describe this color. The best description he had found was that given by Sansom, who, however, did not interpret correctly the type of case in which it occurred. Sansom described a "leaden color covering an earthy tint of skin" as being characteristic of certain cases of aortitis. At that time the coronary arteries were not usually investigated, and Sansom had probably not noted that that color was quite characteristic of the cases of old thrombosis. Dr. Libman believed that the color was dependent upon nutritional changes in the skin and not a spastic condition of the vessels. It was true that there was a similar color present at the time of some severe attacks of coronary thrombosis. As regards the leucocytosis, to which Dr. Kahn referred, Dr. Libman said that he had for a long time used that as a means of diagnosis of thrombosis of the coronary artery as differentiated from conditions causing severe pain in the cardiac area which were not associated with thrombosis. If the initial thrombosis closed a larger vessel, and particularly if there was present disease of the collateral arteries, necrosis of the myocardium ensued, and often pericarditis. If, after an attack of so-called angina pectoris, there developed a leucocytosis within the first thirty-six hours, and no other cause was present for the leucocytosis, one could say that the lesion was a thrombosis. Of course, leucocytosis might also occur with large myocardial lesions unassociated with coronary thrombosis, but such lesions were exceedingly rare. He believed that the diagnosis of aneurysm of the heart secondary to coronary thrombosis could be made more frequently than it had been done in the past. Sternberg had stated that aneurysm of the heart had been diagnosed correctly only twice in the series of cases reported in the literature up to the time he had published his monograph. Dr. Libman had diagnosed the condition in a number of cases, and in those cases which had come to post mortem examination the diagnosis had been verified. The aneurysms were most frequent in the left ventricle near the apex, because the thrombosis was most common in the descending branch of the left coronary artery. The aneurysms were less common in the septum and rarest in the auricle. One could entertain the suspicion that aneurysm was present if one found a marked pulsation of the heart between the apex and the left border of the sternum, with the presence of very poor heart sounds. This was especially true if in the previous history there was evidence of a clinical picture which pointed to a thrombosis in the coronary system. Other points had been given by various authors which were supposed to be of value for the diagnosis. Skoda had stated that marked pulsation of the heart accompanied by a poor pulse was suspicious. In some cases of aneurysm of the heart, however, the pulse was often not poor in quality during a large part of the period of observation. The murmurs that had been described as occurring with aneurysm of the heart were quite varied. There had been noted a presystolic murmur, a musical murmur, a squeaky murmur, a continuous murmur, systolic, and diastolic murmurs. Dr. Libman stated that there was one difficulty that must be understood if one wished to use the signs which he described as being of value for the diagnosis. The symptomatology of coronary thrombosis was simulated much more often in cases of disease of the root of the aorta than in cases of hypertension. In such cases of atherosclerosis of the aorta, however, one usually encountered a marked hypertrophy of the left ventricle. If a coronary thrombosis occurred in such a case, even though the heart were weakened, the thrust of the left ventricle might be still evident, and the heart sounds would be poor. On such instances, however, the most marked thrust was mainly in the region of the apex, whereas in cases of aneurysm of the heart one encountered a marked pulsation which reached from the apex over to the left border of the sternum. In fact, it had been claimed by one writer that in cases of aneurysm of the left ventricle (those that occurred in the front of the heart were the only ones now being discussed), the pulsation was to the right of the apex, and the apex itself did not share in the pulsation. In connection with the question of diagnosis of aneurysm due to closure of the coronary artery, Dr. Libman related the case of a

man, forty-one years of age, who gave a history of having suffered from pain on exertion, located between the scapuli for a period of seven years. When he came under observation the systolic blood pressure was only seventy, and the diastolic fifty. On testing the spine, no evidence of spondylitis was brought out. There was marked pulsation of the heart extending from just to the right of the apex over to the left border of the sternum. The first sound of the heart was almost inaudible. The pulsation in the radial artery was easily palpable. Because of these physical signs, the patient was carefully questioned for a history of any attacks that might have been presumed to mean coronary thrombosis, and a history was obtained of three such attacks. The following morning the family physician was informed that the patient, who up to that time was supposed to have been suffering from some spinal disease, was liable to die suddenly. The physician stated that the patient had already died suddenly. Dr. Libman pointed out that aneurysm of the heart occurred not only with disease of the coronary artery, but also secondary to other forms of myocardial disease, especially gummata. One patient had developed an aneurysm of the heart a few days after she had been operated upon for intestinal obstruction due to carcinoma of the ascending colon. Two days after the operation there were evidences of cardiac insufficiency, and there was a loud murmur and marked thrill just to the left of the sternum. A possibility was entertained that the patient had a communication between the two ventricles, of congenital origin, and that perhaps the physical signs had been overlooked until the patient developed the evidences of cardiac insufficiency. At autopsy, however, there was found to be present an aneurysm of the septum with perforation into the right ventricle. The aneurysm was due to necrosis of the heart muscle. The coronary arteries showed practically no change. The necrosis was apparently of toxic origin, an idea that was confirmed by the fact that there were found a number of very small areas of necrosis throughout the musculature of the heart.

Dr. MARCUS A. ROTHSCHILD emphasized that it was incorrect to speak of electrocardiographic diagnosis of coronary artery disease or of myocarditis. The electrocardiogram only gave a physiological diagnosis, it demonstrates disturbances of conduction. Clinically, the cause of these defects must be determined. It had been demonstrated that the usual pathological lesions found were muscular damage resulting from coronary artery disease or interstitial myocarditis. However, it was not fair to infer, as Drury had recently done, that electrocardiographic changes were necessarily found whenever the coronary circulation was disturbed. As yet it was not known how great a defect in conduction was necessary to deform the electrocardiogram. Dr. Rothschild also emphasized that a negative finding did not exclude the possibility of pathological change. A positive electrocardiographic finding, however, which was permanent, he believed to be a distinct aid in diagnosis and prognosis. The electrocardiogram was another example of an instrument of precision which was of value if used in conjunction with clinical medicine, but of little value if used by itself.

Dr. KAHN, in closing the discussion, said speaking of the value of leucocytosis as a diagnostic aid that in a number of cases the leucocytosis was a hindering factor in the diagnosis. In two cases with abdominal angina and leucocytosis, on the basis of the leucocytosis, abdominal operation had been performed and nothing found. Autopsy in these cases showed coronary closure with myocarditis.

Leucopenic Leucemia.—Drs. NATHAN E. BRILL and N. ROSENTHAL presented this paper which was read by Dr. Rosenthal and illustrated by lantern slides.

Dr. BRILL first spoke, saying that he had asked Dr. Rosenthal to read the paper for two reasons, first, to spare his own voice, and, second, which was most important, because Dr. Rosenthal was really the author. He has insisted on having Dr. Brill's name associated with the work because he felt that he had learned from the speaker many of the facts about leucemia and its special types. Few observers in this country had had the opportunities of studying so many examples of leucemia as had the physicians at Mt. Sinai Hospital, where a yearly average of fourteen to sixteen cases of this disease had been steadily maintained for years. When one reflected that in the fifteen years of Osler's service at Johns Hopkins Hospital only twenty-four patients with this disease were admitted one realized what a wealth of material in the study of leucemia was offered at Mt. Sinai Hospital. This number would seem to indicate that possibly leucemia was more prevalent in the Jewish race. However, anybody who worked with the study of the histology of the blood would recognize what a severe task, what a strain upon the eyes, such a study demanded. Therefore, Dr. Rosenthal deserved the greatest credit on having applied himself to this study with untiring zeal and with uncommon intelligence so that the speaker could conscientiously say that the author of the paper was in every way qualified to present the subject of leucopenic leucemia as an expert.

Dr. ROSENTHAL then presented the paper. He said that most pathologists and hematologists considered aleucemia or leucopenic leucemia to be true leucopenia on account of the similarity of the lesions in the hematopoietic organs. There was, however, considerable difference of opinion in regard to the blood picture. Based upon studies carried on at the Mt. Sinai Hospital, they had come to the conclusion that the leucopenic leucemias were true leucemias both clinically and pathologically. The blood picture also resembled that of ordinary leucemias with the exception of the leucocytosis. Whenever leucopenic leucemia was suspected the differential blood examination must be done with the greatest care. In such leucemias they had always found a slightly increased, normal or subnormal white blood cell count associated with an absolute and often relative increase of a certain group of mature or of premature white blood cells responsible for the leucemia. A leucemic blood picture was absolutely essential for the diagnosis of leucopenic leucemia. One must also bear in mind that transitions might occur from the leucopenic to the leucocytic form and *vice versa*. The underlying pathogenesis of the leucopenic form of leucemia was not clear. From their studies of the lesions of leucopenic leucemia the cause of the failure of the appearance of more cells in the circulating blood could not be determined in all cases. In one case of leucopenic monocytic leucemia they came to the conclusion that most of the large monocytic cells were derived from the liver and spleen, but were held back by the capillaries of the lungs. The capillaries of the lungs were filled with large numbers of cells, while the peripheral capillaries contained very few cells. This was in accord with Aschoff's idea. He pointed out this infiltrative action on the part of the lung and considered it one of the chief reasons for the failure of numerous histiocytes present in the splenic and hepatic veins from reaching the general circulation. The classification of leucopenic leucemias was similar to that of the ordinary varieties. They formed three main groups, namely, the lymphoid, myeloid and monocytic leucopenic leucemias. Leucopenic leucemia of the lymphoid type had been studied and described since 1865, when Cohelm called attention to it. The symptoms and course of this leucemia resembled the leucocytic form. General adenopathy, splenic enlargement, weakness and loss of weight were the chief symptoms. The leucopenic type was less frequent and might occur at any age. The pathological lesions were similar to the leucocytic form, but the bone marrow and other organs were usually much less infiltrated. The blood picture was characterized by a slightly increased, normal, or subnormal white cell count with both an absolute and a relative lymphocytosis. Transitions to the ordinary lymphatic leucemia might occur as a terminal manifestation, and *vice versa*. The course was rarely acute. Most of the cases were chronic and appeared less malignant than the common forms. The following cases were then reported in detail, in which the blood pictures were as follows: A case of *leucopenic lymphemia:* Red blood cells 5,220,000, hemoglobin 98 per cent; white blood cells, 12,600; platelets, 128,000; polymorphonuclear neutrophiles 13.0 per cent.; polymorphonuclear eosinophiles, 0.5 per cent.; lymphocytes, 85.0; monocytes 1.0 per cent. One lymphoid cell with two nuclei. The oxidase reaction was present only in the polymorphonuclear cells. A case of *leucopenia of the myeloid type*, in which the onset was usually insidious with weak-

ness, pallor, and often pains in the upper left quadrant of the abdomen. The lymph nodes were not enlarged. The liver and spleen were usually enlarged. The course was usually chronic extending five or six years; acute cases also occurred. In this case the blood picture was as follows: Red blood cells, 1,976,000; hemoglobin, 38 per cent.; white blood cells, 2200; platelets, 190,000; polymorphonuclear neutrophiles, 23 per cent.; polymorphonuclear eosinophiles, 1 per cent.; polumorphonuclear basophiles, 1 per cent.; lymphocytes, 40 per cent.; monocytes, 1 per cent.; myeloblasts, 28 per cent.; myeloblasts and Auer bodies, 1 per cent.; myelogones, 2 per cent.; myelogones and Auer bodies, 2 per cent. In this type of leucemia the recognition of premature myeloid cells, such as myelocytes, myeloblasts and myelogones was of great importance. As there was no reports of cases of leucopenic monocythemia in the literature Dr. Rosenthal said he wished to cite one case admitted to the service of Dr. Brill about two years ago. This man came into the hospital complaining of progressive weakness for a period of ten months, with a typical attack of grippe a few days before. At the time of admission he complained of profound weakness and was practically unable to move; no bone or joint pains; fever, but no chills or night sweats. He was removed to Lincoln Hospital, where he gradually improved and was discharged at the end of five weeks, but never entirely recovered. Five months ago he began to have profuse drenching night sweats; became progressively weaker, and had had a cough with whitish expectoration. The liver was palpable about two inches below the free border of the ribs. The spleen filled half the abdomen, was hard, smooth, but not tender. The patient gradually lost ground. Transfusions and *x*-ray treatments were of no avail, except that the spleen became slightly smaller. About one week before death he developed ascites and some purpuric manifestations. *X*-ray therapy in this case produced an extreme leucopenia, even to a count as low as 600 which, on discontinuation of the *x*-ray treatment, rose to 3000. A blood examination at this time showed a monocytic crisis of 44 per cent., which warranted the diagnosis of leucopenic leucemia of the monocytic type. The relative and absolute monocytosis was present also on a later examination. The oxidase reaction of most of the large mononuclear and transitional cells in this case was positive. On the basis of their studies they concluded that (1) leucopenic leucemia was a general term for the leucemias without lymphocytosis; (2) the symptoms, course and varieties of the leucopenic forms of leucemia were similar to the leucocytic forms, and (3) that an absolute increase of mature or premature white blood cells was essential for the diagnosis in addition to the clinical manifestations.

Dr. BRILL opened the discussion (See page 888).

The Occurrence of Hyperchromic Anemia in Chronic Nephritis.—Dr. BENJAMIN BERG made this presentation, in which he said that during the course of certain forms of chronic nephritis, anemia played a prominent role in the picture of the disease. Attempts had been made to correlate the anemia with the presence of edema, dilution of the blood being considered a possible explanation. Reference was made to a number of these attempts and attention called to the work of Aubertin and Yacoel (*Presse Médicale*, xxviii, 461, 1920), who collected a series of cases which demonstrated that anemia was practically exclusively encountered in cases of chronic nephritis showing nitrogen retention, and no edema. Two cases were reported with repeated blood and urine examinations which presented two syndromes: The first a severe anemia characterized by a high hemoglobin index, relatively little change in the morphology of the erythrocytes, absence of abnormal forms in the blood, and a leucopenia; the second was a chronic nephritis with high nitrogen figures, and uremic symptoms. Two series of cases were studied, the first series being twelve cases of chronic nephritis with nitrogen retention, and the second fifteen cases of chronic nephritis with non-nitrogen retention. As far as possible those cases were chosen in which one could be reasonably certain that the anemia was not secondary to some complication such as hemorrhages, parasitic disease, or new growth. A study of these cases indicated that severe anemias occurred nearly exclusively in chronic nephritis associated with nitrogen retention. There was, however, a large group of cases which did not fit in either group. These cases might be in a stage transition. Through the nitrogen figures had not increased, there was present a moderate anemia. In such cases the anemia might be the precursor of changes in the figures for blood chemistry. In the writer's series of cases, the relative frequency of anemia in all types of chronic nephritis coincided, approximately, with Cabot's figures. The erythrocytes in this series, however, did not reach the low levels reported by Cabot and Aubertin. Edema held no constant relation to the presence or absence of anemia. Anemia might occur in the absence of edema, and edema might occur without the associated anemia. The most striking feature of the anemia in the nitrogen retention group was the hemoglobin index. Blood smears in cases of chronic nephritis with nitrogen retention and a severe anemia in the cases studied by the author were usually negative for the abnormal forms found in pernicious anemia. However, a few polychromatophilic macrocytes were found in a case studied by Dr. N. Rosenthal. Further studies were needed on this point. The erythrocytes were usually well preserved and well filled with hemoglobin; macrocytes and normoblasts were not found. The leucocytes showed no marked changes either in number or character. The differential count, except for a slight polynucleosis, was not abnormal. The blood picture presented by these cases was not uncommonly found in such conditions as carcinomatosis, accompanied by severe anemia; in the latter form, however, abnormal erythrocytes or leucocytes, or both, were apt to be present. The nature of the anemia in chronic nephritis with nitrogen retention, therefore, could not be determined from the blood picture alone. Studies of the bone marrow and spleen were necessary to properly interpret the anemia. Studies made thus far seemed to suggest that the hematopoietic organs were profoundly affected in this form of nephritis. So far as the etiological factor was concerned, nothing could be determined until more was known about the etiology of uremia. The anemia might be due to an hemolytic agent acting directly upon the erythrocytes; it might also be due to an inhibitory action, by the same agent or some other toxic factor, upon the hematopoietic organs; a combination of both factors would probably be responsible. The writer expected to undertake investigations directed toward determining more accurately the reaction of the bone marrow and spleen in cases of chronic nephritis associated with nitrogen retention, and accompanied by severe anemia.

Dr. LIBMAN said that it was interesting that nearly everybody had overlooked the occurrence of this hyperchromic form of anemia in cases of chronic nephritis associated with nitrogen retention. He had seen blood examinations in such cases that showed an index as high as 1.5. The important point was that the observations of Widal and Aubertin, as well as those of Dr. Berg, added another condition to those in which anemia was present with an index of over one. The other conditions were pernicious anemia, certain cases of leucemia, neoplasm, especially those involving the bone marrow, infection by the *Bothriocephalus latus*, and the pernicious anemia of pregnancy (anemia gravidarum). It did not appear that there would be any great difficulty in the differentiation of cases of nephritis with hyperchromic nephritis from pernicious anemia, even though there had been described by Christian a diminution in renal function in cases of pernicious anemia. Although nitrogen retention might occur, partly due to this cause and partly to congestion of the kidney toward the end of the disease, the figures did not rise as high as they did in the cases of nephritis, and the uremic breath was not present.

Dr. BERG, in closing the discussion, said that this one patient in whom transfusion was done showed such a remarkable change that he thought it was a remedy that should be thought of in severe anemia in chronic nephritis.

SECTION ON PEDIATRICS.

Stated Meeting, Held February 10, 1921.

DR. MINER C. HILL IN THE CHAIR.

A Case for Diagnosis.—Dr. GAYLORD W. GRAVES pre-

sented this patient, a girl 11½ years of age. Her mother had died from carcinoma; her father and sister, 10 years old, were in good health. With a single exception there was no record of disease in her family that could have a bearing on the case. The patient's history was negative except for the occurrence of chickenpox, otitis media, and influenza. Recently she had lived with an aunt in a surburban town, attended school, and apparently been in good health. About December 20, 1920, she became mildly ill with nausea and abdominal pain, which was annoying only when she moved about. There was no vomiting or diarrhea and the symptoms subsided within two days. About a week later they recurred and then culminated in vomiting which was not explained by any indiscretion in diet. Examination showed that the patient belonged to the thin, rapidly growing, rather neurotic type, somewhat apprehensive, and devoid of elasticity in her movements, particularly her gait, which had at first seemed unnatural following her few days' illness. She walked a trifle stooped as though favoring a sore appendix or a bladder with a stone in it, but her steps were more like those of a person treading a series of rough railroad ties under the compulsion of keeping a rail between the feet. There was a suggestion of increased tension on the right side of the abdomen but no definite tenderness or rigidity. Both knee jerks were active and there was no apparent weakness in the foot or leg action. The urine showed a very faint trace of albumin, an occasional hyaline cast, one finely granular cast, and about 40 leucocytes per field. Eight days later, following dosage with an alkaline diuretic mixture, the urine was normal. During this time there had been no recurrence of the symptoms but the child still walked unnaturally. A more careful examination was made, looking for the existence of flat foot and pressure sores, but nothing was remarked except that the feet showed good arches when the child's weight was not imposed upon them in standing. It developed that rising up and down on the toes, walking on tiptoe, and standing on one foot were all extremely difficult owing to failure of balance. The knee jerks were somewhat overactive. It was only at this time that the writer became convinced that the case was actually neurological. During the ten days before the next visit, the aunt noticed that the child's feet at times assumed a peculiar position with the toes involuntarily turned up. On inspection this was confirmed and at the same time a slightly exaggerated hollowing of the arch of the rest of the foot and unnatural convexity of the dorsum were remarked, the condition being bilateral. Both knee jerks were now found to be definitely exaggerated; a bilateral Babinski was found, and a Romberg test though a bit uncertain seemed strongly suggestive. Vision, pupillary reactions, speech and bladder and rectal control had been normal and there had been no disturbances in cutaneous sensation. A blood Wassermann taken on January 22 was negative.

The patient was last seen on February 5, and seemed much improved generally, having gained three pounds during the last month. The suggestive signs, on February 5, though less marked, still presented practically all those mentioned, with possibly a very slight jerking of the eyes laterally when they were held voluntarily in extreme conjugate deviation. No actual nystagmus was found. The writer was inclined to believe that this was a case of Freidrich's ataxia. This view furthermore occurred quite independently to Dr. Frank McLaury even before he saw the patient on January 22, after having heard the story from the child's relatives. No spinal Wassermann had been taken but it seemed highly unlikely that the symptoms could be explained by spinal syphilis. An active knee jerk did not militate seriously against the diagnosis of Friedrich's ataxia as this sign had been repeatedly present in similar cases when cerebellar ataxia was excluded and the latter course proved that of so-called hereditary spinal ataxia. A history note in connection with the case was that the patient's maternal grandmother's cousin's daughter, the offspring of the marriage of first cousins, developed a form of paralysis of the legs at about this age, and died at about 25 years.

A New Method for Treating Acute and Chronic Empyema in Children.—Dr. A. L. SORESI presented these patients and described a device which he had invented for the drainage of empyema, illustrating it with lantern slides. The first patient was a little boy operated upon for empyema three times at the Greenpoint Hospital. He was in very poor condition; his hemoglobin was down to 35. He had had incision and finally rib resection. The empyema had lasted 1½ years. A radical operation, it seemed, would have killed the child, so this tube was used and the child made a good recovery. The second patient was a child who had had chronic empyema of two years' standing, which had been operated upon. The child was in exceedingly poor condition. Again he used the tube described and the child recovered. The third patient was a child operated upon at St. Catherine's Hospital. The child gave a history of having had hydrocephalus when born, and later had a severe empyema. In this case also rapid drainage had been secured with this tube and recovery ensued. Dr. Soresi stated that the formation of pus he regarded as a defense mechanism, and he never removed fluid, whether purulent or clear, until the acute process was over. There was during the acute stage very little danger from the absorption of pus because the lymphatics were clogged. Sometimes, however, fluid collected to such an extent that it caused severe pressure symptoms, and it became necessary to drain the chest in order to relieve these pressure symptoms. In operating upon a child for empyema, one of the first essentials was that the child should be comfortable. A child that had empyema usually had such a low vitality that the pain and discomfort of frequent dressings might be a determining factor as to life or death. The child must be comfortable during operation and immediately after, and all the time until he was well. In operating upon children Dr. Soresi stated that he did not use a general anesthetic, but used cocaine 1-500, and went very slowly. The use of a general anesthetic in these children he regarded as a surgical crime. He said that nearly everyone had devised a treatment for empyema for which he claimed 100 per cent. cures. Personally he was convinced that there was no such thing as 100 per cent. of cures in empyema because one might strike cases in which no method of treatment could effect a cure. The introduction of a rubber tube kept up irritation and so kept the lung draining for a long time. The device presented was so constructed that it was flush with the pleural cavity so that it caused no irritation and usually pus ceased to discharge after three or four days. The device consisted of a metal tube about an inch in length and having an oval lumen, the long axis of which measured ½ inch and the short axis ¼ inch at the widest part. The tube was constructed in two sections so that the lower one-half could be inserted through a very narrow incision and the upper half then inserted into a grooved track in the lower half. The tube was fitted with a one-way rubber valve which permitted the escape of pus and prevented the entrance of air. The tissues were closely approximated to this cannula by a suture, and a rubber tube was connected which drained into a bottle swung about the patient's neck by a cord. This was a great advantage because it permitted the child to be up and about, and as a rule, after twenty-four to forty-eight hours the bottle was no longer required. The incision was usually made between the ninth and tenth ribs, close to the lower border, to avoid injury to the diaphragm. Dr. Soresi advised against the introduction of the finger for the purpose of breaking adhesions during the treatment of an empyema.

Dr. HENRY KOPLIK said he had done a great deal of work on empyema and appreciated the value of the apparatus presented. The ingenious part of it was the valve that allowed the pus to escape and prevented the entrance of air. Dr. Koplik stated that he had invented a device for the drainage of empyema which consisted of a rubber tube inside of a flange, but the rubber tube sometimes became clogged. He thought Dr. Soresi's device was more ingenious because it never could become clogged and in a young child it would be an ideal procedure. The devices for the treatment of empyema were as many as the books that were written and one of the most ingenious was that used at Mount Sinai Hospital, where the patient was placed on a stretcher above the bed and the pus collected in a bottle by means of a tube inserted into the pleural cavity, and drainage brought about by negative pres-

sure that was there was a suction on the pleural cavity that expanded the lung. Dr. Soresi's device, however, had the advantage that it could be introduced into private practice, whereas the procedure just mentioned was only suitable for hospital use. Dr. Koplik said he agreed with Dr. Soresi that it was sometimes very disastrous to introduce a finger into the pleural cavity to break up adhesions as this might result in setting up a septic pneumonia. He thought the point should be emphasized that in children under two years of age the incision should be made without any resection of any kind; or a modification of the Bülow operation which is a suction method. In children above two years of age we should resect in order to have plenty of room and so that a fistula would not form, but failures would occur with any operation. In closing, Dr. Koplik complimented Dr. Soresi in having presented such a simple method of intervention for the treatment of empyema, one that was within the reach of almost every practitioner.

Dr. SORESI emphasized the advantage that was offered by this method in that it permitted the child to be up and walk about. This was a factor that greatly hastened recovery in these weakened and run down children. He stated that the boy he had shown had walked down stairs immediately after the operation. For a young child he did not believe any method could be quicker than this one. As to the valve which Dr. Koplik had praised, he thought that was the weakest part of the device, because he had not been able to obtain good rubber that would not curl when pus stuck to it. He was now trying to have the valve constructed of two layers of rubber with thin wire netting between. In dealing with empyema in children he did not break up adhesions and he made it a point not to be too radical.

Interpretation of the Clinical Pathology of Mastoiditis in Children.—Dr. S. J. KOPETZKY said that in coming before the Section on Pediatrics to speak of the clinical interpretation and pathology of mastoiditis in children he came because the majority of these cases were seen by the pediatrician first, and it was the symptoms that were interpreted by the pediatrician in the first place. The pathology of mastoiditis had developed so far that cases at first considered to be atypical were now considered in groups and were typed. He sketched these types and pointed out the salient clinical characteristics and the pathology that was accepted for those types. As it was very difficult to take a section and correlate that section to bedside findings so as to make the point clear he said he would sketch the principal pathological points first. There was no discussion or argument nowadays as to the ordinary characteristic type of mastoiditis in which there was a coalescence of the mastoid cells, and the intracellular walls broke down and large cavities were formed lined with granulation tissue, and impinged on vital organs. When the periosteum was involved we found induration and pain on pressure and temperature elevation and a decided sinking of the posterior canal wall, and all the other signs with which they were familiar. When the process invaded the cells they were lined by mucous membrane and contained blood vessels, and the inflammation extended along these blood vessels and they became obliterated and the osteoclasts came and absorbed the bone matter. This was the type of mastoiditis that we all knew and very seldom missed. It was the type that one found on the operating table and in the autopsy room and it was more or less independent of the germ which in the beginning infected the patient. There was another type of mastoiditis which was clinically different from the coalescing type in which there was no pain on pressure, no pressure on the periosteum, and no pressure on the tympanic cavity. These patients instead of having a continued rise in temperature, had a drop after a primary rise, and then a subsequent rise, and ran a typically septic temperature. One might carry such a patient along for a considerable time and the sepsis would continue, and finally when they came late to operation they would have sinus involvement and the blood vessels were involved, but the cells were not broken down; the air cells in the mastoid cavity had not coalesced. One found a bony covering but the whole area would be hemorrhagic. This type he called the hemorrhagic type of mastoiditis. It was most common with hemmorrhagic systemic infection such as streptococcus influenza, though he had seen it in other types of infection. When the pathology of mastoiditis was first studied some years ago the contention was made that this was a stage preceding the coalescing stage. He was convinced that these two types were not interchangeable, though one might get mixed types. Each type was a distinct lesion. He had seen instances in which operation was delayed as long as one month and the hemorrhagic type was still present. This brought up a question of the revision of the indications for mastoid operation in the light of pathology. It also brought up the question of repeated paracentesis in cases in which paracentesis was not indicated by the lesion. These patients being septic after paracentesis, even though they might have a reasonable discharge, continue to be septic, and in view of the fact that repeated paracentesis did not remove the cause of sepsis by cutting the ear drum two, three, or four times, they should be submitted to more effective measures of treatment. If a patient had both the hemorrhagic and coalescing types of mastoiditis which went beyond a certain length of time, it should be borne in mind that the primary effort should be directed to saving the patient and mastoidectomy should not be avoided. It should be remembered that after repeated paracentesis we had adhesions, and scar tissue that caused trouble later in life. The histories of patients with ear troubles later in life often showed that they had had middle ear infections and mastoiditis and that operation had been avoided by four or five incisions. It was far better to operate at the time when operation was indicated and the patient would recover with a perfectly functionating middle ear. The slides showed the detail of these two types of mastoiditis better than by attempting a detailed description. The hemorrhagic type of mastoiditis was most dangerous from the standpoint of infection of the larger vessels. A thrombosis might start in the mastoid vessels and extend into the general circulation and this would be marked by a secondary rise in temperature. The point Dr. Kopetzky emphasized was that there was a stage in acute mastoiditis which was dangerous to the life of the patient, which presents sepsis, and the sepsis can be eradicated by radical operation. This group did not always present the classical symptoms of mastoiditis. The otologist would recognize these cases and by bringing them to operation could avoid intracranial complications. The prevention of mastoiditis was largely in the hands of the pediatrician and the general practitioner. If the physician was satisfied to allow his patient to go along with a running ear changes in the bone might occur and the question of preserving the hearing must be weighed against a surgical procedure which in one-half competent hands offers very little danger. The danger of mastoidectomy was exceedingly overestimated.

Dr. LEWIS FISHER of Philadelphia said that as an otologist he naturally had the otological view. The otologist usually saw those cases which had lasted for some time and were not doing well, while the pediatrist, on the other hand, saw many mild cases which never reached the otologist. The otologist was, therefore, prone to be impressed with their seriousness much more than the pediatrist. Dr. Kopetzky had done a great service in calling attention to the seriousness of some of the mastoid infections. A proper classification was always of great value, but unfortunately it was not always easy for the clinician to make such a classification. It is much easier to classify at operation or on the slide than at the bedside. Some cases of mastoiditis unquestionably got well without operation. Mastoiditis might be roughly divided into two classes: (1) a condition where there was a mastoid empyema—the mastoid cells were filled with pus but were not carious; with drainage this condition could get well without interference; (2) where the process had extended and involved the bone itself; these cases did not get well without operation. Occasionally there might occur a more or less prolonged septic temperature as the result of absorption of toxins from the jugular bulb. This might appear early in cases of middle ear infection, but many of these also got well without operation. Mention was made of this simply to emphasize the fact that many cases although threatening in appearance got well without operative interference, *but*, it was impossible to tell

always when one was dealing with a simple mastoid empyema until possibly the case was in grave danger. It was therefore well to weigh the risks the patient ran by waiting. There was, all things considered, probably less risk to the patient in an early operation in competent hands, than there was by waiting for the appearance of unmistakable signs of serious or perhaps intracranial complications.

Dr. KOPLIK said the whole trouble with the question of mastoiditis was that the otologists did not agree among themselves. There was in New York a school of otologists who wished to go in and drain, as they said, "from behind." In his children's wards it was surprising to see that this question divided itself into one of ages. In the younger children under one and one-half years of age having otitis media, which was probably mastoiditis from the start, three or four reincisions might be made; the children ran a temperature but they recovered. If the ear was examined a month later in those cases there was only the old involvement and the child's hearing did not suffer in the future. No less a man than Dr. Whiting incised and reincised ears in babies and they did very well. The question of the subsequent effect on the hearing had not been brought up. Reincision in these young children had not seemed to affect the hearing. Mastoiditis in older children was a different matter. The bones were ossified in children from the third, fourth or fifth year up, and the more cases he saw the more he was inclined to adopt the dictum, "If one or two incisions do not help it is better to drain the mastoid from behind and save the hearing of the patient and subsequent months of suffering." It was not so easy to diagnose the different forms of mastoiditis at the bedside. The temperature was no guide since there were cases in which the temperature did not rise above 100 or 100½° F. and still the ears would be discharging and mastoidectomy indicated. He agreed that in older children the risk of waiting was greater than the risk of early simple mastoid operation.

Dr. SIDNEY V. HAAS said this was a most interesting subject because of the difference of opinion of the pediatricians on the one hand and the otologists on the other. The question arose as to how common real operative mastoiditis was; it was in reality a relatively rare condition, when one considered the number of cases of acute middle ear disease that the average pediatrician saw, and how few required mastoid operation, although mastoid symptoms were present at some time, it must be that cases requiring operation at once were fairly uncommon. It was unnecessary to be frightened by early symptoms. Early operative procedures were often resorted to quite unnecessarily. There are, of course, cases of fulminating mastoiditis just as there are cases of fulminating appendicitis, and excepting in these, urgency in operation rarely exists. There is in most departments of surgery a tendency to wait until the acute inflammation subsides before resorting to operative interference, and this should hold true in the subject under discussion. Mastoiditis may be primary, and there were cases of jugular and sinus thrombosis which gave no otological symptoms and required the pediatrician or the internest to make the diagnosis. Dr. Haas stated that he had had cases in which there had been a delay of six, eight, and ten weeks because the otologist could not find sufficient indications for operating, and these cases with late mastoid operation, ligation of the jugular, and emptying of the sinus were of excellent prognosis.

Dr. WILLIAM A. SCRUTON stated that Dr. Kopetzky had brought to their attention some very important material and those who had taken part in the discussion had added to it. Dr. Scruton said he was an otologist and his viewpoint was frequently at variance with that of the pediatrician, who generally showed a tendency to procrastinate concerning operation for mastoiditis. Unfortunately the diagnosis of mastoiditis and the indications for operation could not be prescribed in the text books with sufficient definiteness, except for the typical case, on account of wide variation; for instance, a very badly involved mastoid might be present and yet the cardinal symptoms of tenderness and temperature might be absent. Concerning septic sinus thrombosis, one of the other speakers stated that the pediatrician found it necessary to make the diagnosis for the otologist. This was the extravagant statement of an individual, and certainly could not be accepted generally. In the matter of myringotomy it was his opinion that one only was necessary as a general rule. If the case did not progress well, there were probably granulations blocking off the aditus, and additional myringotomy would be of no avail. Only men with considerable experience should attempt myringotomy, on account of certain dangers. Paracentesis in the bulging area was quite safe for the inexperienced.

Dr. JAMES G. CALLISON stated that he had just published a report on five and one-half years' experience with mastoiditis and middle ear disease in children. He was quite frequently called in consultation and one of his greatest pleasures was to see the smart young pediatrician who had an elaborate speculum look into the ears. In the older days the general practitioner or the pediatrician might slip by the ear but the younger men were pretty well posted. When we saw thirty thousand men fail to pass their examination and unable to do duty to the nation because of acute suppurative otitis media which had gone on to chronic mastoiditis, it was time to awaken to the importance of this subject. Dr. Kopetzky had shown the slides as they occurred in life as well as at post mortem.

Dr. WALTER LESTER CARR endorsed the opinion of two of the speakers on the question of reincision in cases of otitis media. In his association with an institution for ear diseases he was impressed with the advantages of early operation in mastoiditis and that reincision of the drum would only delay operation. The value of *x*-ray pictures was important. Although the mastoid cells were not fully developed in babies he recently had had a case on his service where there was a positive blood culture and the baby died with a general infection, which on autopsy was found to come from the mastoid. In 200 recent mastoid operations he had learned that 1 per cent could have been delayed, which he thought favorable for any type of operation. With reference to sinus thrombosis, as mentioned by the reader of the paper, the leucocyte counts in five recent cases were 18,000; 10,000; 13,000; 8,000; and 8,000. One gave a positive blood culture and one gave a culture after operation. Credit was due to the otologists and he felt that pediatricians should work in cooperation with them.

Dr. KOPETZKY stated that every one was entitled to his own opinion when that opinion was backed by pathological and anatomical facts, but when an opinion was based simply on a man's observation, and the observation was limited, astigmatic, or otherwise open to criticism, it might be questioned. Dr. Koplik was right for the pathology and the anatomical conditions afforded a basis for his contention. The infant mastoid was simply a cell. Babies had empyema of the mastoid antrum; they had no other mastoid cells, or if there were a few cells they lay low and in that position only. The position of the adult antrum was above the middle ear. In the infant, the external auditory canal was all that covered the antrum, and incision was in the natural place of drainage and one might successfully drain the infant ear in that way. The embryonic tissue was in the process of resolution and if there was scar tissue it would be absorbed and the changes were only temporary. Those children did not get periosteal involvement and intracranial complications. The other cases of which Dr. Koplik spoke had also a pathological basis. In addition to having no temperature, in many cases they had no pain. They were painless because there was no mechanical pressure. The factor which stopped this process was the removal of stagnating pus. In those that had a profuse discharge from the middle ear pus also came from the tympanic cavity and the cells might be all broken down but the periosteum did not become involved and hence there was no pain and no temperature.

Zinc and Fecundation.—The vulgar have been known to speak of the testicular fluid as "lead," but Bertrand and Vladesco actually claim that zinc plays an important role in all vital processes in vertebrate animals and notably in fecundation. This conclusion is based wholly on experiment. Their paper was read before the Academy of Sciences in July last.—*La Presse Médicale.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS OF NEW JERSEY.

June, 1921.

(*Continued from page* 835.)

HISTOLOGY

1. Describe the methods of bone development.
2. Describe the structure of cardiac muscle.
3. What are Brunner's glands, and where do they occur?
4. Describe a non-medullated nerve fiber, and tell where they occur.

PATHOLOGY

5. What are the varieties of leucocytes and what pathological forms do they show?
6. What are the forms of parenchymatous nephritis and what is their histology?
7. What is acidosis and what are its evidences?
8. Define cretinism and distinguish it from myxedema.

BACTERIOLOGY

9. What are the most common intestinal parasites which may be found in man?
10. What are the three principle varieties of *Taenia?* Describe the *Taenia suginata.*

PRACTICE OF MEDICINE

1. Describe five modern instruments of precision available in diagnosis.
2. Describe the eruption of (1) measles, (2) scarlatina, (3) varicella, (4) variola.
3. Differentiate (1) hematemesis, (2) hematuria, (3) hemophilia, (4) hemoptysis.
4. What, how much and how often would you feed a three months old bottle-fed infant?
5. Describe the *x*-ray. What are its uses, its dangers, and how can the latter be avoided?
6. Give names and causes of murmurs heard at the apex of the heart; also the ones heard at the base.
7. Describe ascites and name three chronic diseases of the liver in which it is absent.
8. Name five diseases and give reasons therefor, in which the ophthalmoscope is an important aid in diagnosis.
9. What are the physical signs of a cavity of the lung (1) with elastic walls; (2) communicating with the bronchial tubes?
10. What is the difference in the length of time between inspiration and expiration and the significance of variations therefrom?

ANSWERS.

HISTOLOGY.

1. *Development of Bone.*—"The development of bone is either intramembranous or endochondral. In the latter a cartilage stage intervenes, otherwise the history in each case is the same. A synopsis of endochondral development is as follows: (1) A solid shaft of hyaline cartilage, non-vascular and without any marrow cavity. (2) In the center of this shaft the cartilage cells enlarge, their lacunæ enlarge and coalesce, particularly along lines extending toward the ends of the bone. The rosette produced by this excavation is called the primary areola of Sharpey. (3) Lime salts are deposited in the thin walls of these spaces, making calcified cartilage. (4) Osteogenetic cells and blood vessels from the periosteum enter the cartilage spaces. The cartilage cells disappear with this invasion and the excavation, begun by the cartilage cells, is further enlarged by the bone cells. The excavated areas are now called the secondary areolæ of Sharpey, the cavities having a rich blood supply quite in contrast with the primary areolæ. The marrow cavity is excavated and the shaft becomes longitudinally porous. Endochondral bone, therefore, develops *in* cartilage, not *from* cartilage. (5) Osteogenetic cells attach themselves to the wall of these enlarged Haversian canals and become enclosed in lime deposits, forming thus the outer lamellæ and outer row of bone cells of each Haversian system. Cells with lamellæ are added centripetally to this outer row and thus ultimately complete the Haversian system, leaving a small central canal containing vessels and a nerve. Ossification begins in the center of the cartilage shaft and proceeds gradually toward each end, so that all the above changes occur at one and the same time. After birth these changes go on at the ends of the bone, so long as it keeps growing. During this period the bone is made thicker by deposits from the periosteum forming the circumferential lamellæ of bony shafts. These lamellæ are added without the intervention of a cartilage stage and therefore represent intramembranous development."—(Hill's *Histology.*)

2. *Structure of Cardiac Muscle.*—"The walls of the heart consist mainly of peculiar striped muscle, the myocardium, which is enclosed between the visceral layer of the pericardium, or epicardium, externally, and the endocardium internally. The muscular fibres differ from those of ordinary voluntary striped muscle in several ways: they are shorter, many of them being oblong cells with forked extremities which are closely cemented to similar processes of adjacent cells; they form a reticulum, and the nuclei lie in the centres of the cells. Moreover, in some of the lower mammals, in the young child up to the end of the first year, and occasionally in the human adult also, still more peculiar fibres, the fibres of Purkinje, are found immediately beneath the sub-endocardial tissue. These are large cells which unite with each other at their extremities; their central portions consist of granular protoplasm, in which sometimes one, but more frequently two nuclei are embedded, and the peripheral portion of each cell is transversely striated. These cells, in short, present in a permanent form a condition which is transitory in all other striped muscle cells."—(Cunningham's *Text-book of Anatomy.*)

3. *Brunner's Glands.*—"The submucosa of the dudoenum differs from that of the rest of the small intestine, in that it contains, especially in the upper half of the duodenum, the glands of Brunner (glandulæ duodenales). These are small acinotubular glands, closely resembling the pyloric glands of the stomach, which lie in the submucous coat, and send their ducts through the muscularis mucosæ to open on the surface between Lieberkühn's glands, or sometimes into these glands themselves. They can be exposed by removing the peritoneal and muscular coats, and also some of the submucosa, when they appear as little round or flattened masses of a reddish gray color, varying in size from 1/50th to 1/12th of an inch in diameter (·5 to 2·0 mm.). They form an almost continuous layer as far as the opening of the bile duct; beyond this they diminish progressively, and completely disappear near the duodeno-jejunal flexure."—(Cunningham's *Text-book of Anatomy.*)

4. *Non-medullated Nerve Fibres:* "Most of the fibres of the sympathetic system, and some of the cerebro-spinal, consist of the gray or gelatinous nerve fibres (*fibres of Remak*). Each of these consists of an axis-cylinder to which nuclei are applied at intervals. These nuclei are believed to be in connection with a delicate sheath corresponding with the neurolemma of the medullated nerve fibre. In external appearance the non-medullated nerve fibres are semitransparent and gray or yellowish gray. The individual fibres vary in size, generally averaging about half the size of the medullated fibres."—(Gray's *Anatomy.*)

PATHOLOGY.

5. *Varieties of leucocytes:* Lymphocytes, large mononuclear leucocytes, transitional leucocytes, polynuclear leucocytes, eosinophiles and basophiles.

Pathological forms: Myelocytes, large lymphocytes, plasma cells, and myeloblasts.

6. *The forms of parenchymatous nephritis*, are: Acute, and chronic.

In acute parenchymatous nephritis, the "kidneys are generally swollen, engorged, more vascular, and of red color; in the second stage the organ remains large, irregularly red, especially the cortex; the tubules are engorged and filled with epithelium, blood corpuscles, and fibrin. The capsule is easily detached, and is more opaque than normal. If the termination is favorable the swelling lessens, the vascularity diminishes, and the

tubules gradually return to their normal condition."—(Hughes' *Practice of Medicine.*)

In chronic parenchymatous nephritis, the "kidney is large, often twice its natural size, smooth, and white or yellowish white in color. The capsule is nowhere adherent to the organ. Upon section, considerable tumefaction of the cortical substance and rarity of vascular striæ are recognized. The medullary substance shows no appreciable alteration, its color being normal. The convoluted tubes are irregularly dilated and thickened, and filled with broken-down granulated epithelium and fibrinous casts. In pronounced cases there is fatty degeneration of the tubular epithelium. The intertubular matrix is greatly thickened—a change due to hyperplasia of the connective-tissue elements, to the migration of the white corpuscles and their subsequent multiplication and fatty transformation, and to a quantity of fluid exudation, the product of the increased pressure in the veins. As the affection progresses the connective tissue tends to undergo contraction, and the organ becomes pale and reduced in size, the capsule becomes more or less adherent, and the surface of the kidney becomes uneven. During this contracting stage small hemorrhages may appear, scattered throughout the cortex."—(Hughes' *Practice of Medicine.*)

7. *Acidosis* denotes a decrease in the fixed bases of the blood and other tissues of the body, or a *relative* increase in the acid ions. The alkalinity of the blood is decreased; but it is never acid.

Evidences of acidosis, are: Increase in the respiration rate; lowered carbon dioxide tension in the alveolar air; lowered CO_2 content of the blood; decreased alkalinity of the blood; increased acidity of the urine, with excess of ammonia; sometimes, a fruity odor on the breath.

8. *Cretinism* is a congenital form of myxedema.

In *myxedema:* "The disease is of slow onset. When it is fully developed the patient presents a heavy, stolid countenance. The face is broadened, the lips and tongue thick, and there is a diffuse red flush upon the cheeks, contrasting with the yellowish pallor of the rest of the face. The hair is scanty, coarse, and brittle. The teeth become carious, and the speech is heavy, slow, and thick (leathery voice). There is great intolerance of cold. The skin is enormously thickened, *dry*, and often scaly, but does not pit on pressure. The hands and feet are broad and spade-like, and the gait is clumsy. The temperature is always subnormal. The menses are irregular, and there is often a tendency to hæmorrhages. The bowels are constipated. The mind is slow and dull, and later the mental condition may become very grave; hallucinations or delusions leading to dementia or suicidal tendencies may appear. It must not be forgotten that often toward the end albuminuria may occur, and the skin may pit on pressure. Glycosuria is an occasional symptom."—(Wheeler and Jack's *Handbook of Medicine.*)

In *cretinism:* "As regards the subcutaneous infiltration, supraclavicular swellings, and mental defects, the condition resembles an exaggerated form of myxœdema. No disease presents more strikingly characteristic features. The child is dwarfed or stunted in growth; the face is very ugly, moon-shaped, and the cheeks hang in pendulous folds; the tongue is too large for the mouth; and the voice is harsh or squeaky. The hair is coarse, except over the swelling between the scapulæ, which are covered by a soft down-like hair. The belly is very prominent and pendulous; umbilical and inguinal herniæ are common. The gait is clumsy, and of a waddling type. The sexual organs are rarely developed, though in female children the menses may appear once or twice; but sexual desire is never excited, even in those cases that live to adult age. Cretins are usually incapable of being taught reading or writing, and their vocabulary is always limited. They are sometimes peevish and cross, but the majority are placid and affectionate. In untreated cases death usually occurs during childhood, but a few cases reach adult life, without, however, advancing at all in intelligence."—(Wheeler and Jack's *Handbook of Medicine.*)

BACTERIOLOGY.

9. *The most common intestinal parasites, found in man* are: Tæniæ, or tapeworms; Nematodes, or round worms (trichina spiralis, ascaris lumbricoides, oxyuris vermicularis, ankylostomum duodenale; and Trematoda.

10. *The three principal varieties of Tænia* are: Tænia solium, Tænia mediocanellata, and Tænia echinococcus. The *Tænia saginata* (or *mediocanellata*) is the commonest type of tapeworm; its length may be from 15 to 20 feet; its head has four suckers and no hooklets; its body is provided with many hundreds of proglottides, the size of each being about 16 by 8 millimeters. The intermediate hosts are cattle.

PRACTICE OF MEDICINE.

1. FIVE MODERN INSTRUMENTS OF PRECISION:

(1) The *spectroscope* is an instrument for studying the composition of light by the formation of a spectrum. It consists, essentially, of a slit with parallel edges, a biconvex lens, a prism, and a telescope.

Use of spectroscope in medicine.—For the detection of blood stains on clothing, implements, etc.; for examination of the blood in cases of suspected poisoning by carbon monoxide and (other) poisonous gases; to detect blood, bile pigments and their decomposition products in urine, and pathological fluids.

(2) The *ophthalmoscope* is an instrument for examining the interior of the eye by light.

It is used to examine the fundus of the eye, the sclerotic, choroid, retina, optic nerve, vessels of the retina; for the detection of optic neuritis, retinitis and hemorrhages, embolism of the central artery of the retina. It is an aid to diagnosis in various injuries of the head, and spinal cord, in nephritis, diabetes, pernicious anemia, syphilis, tuberculosis, alcoholism, lead poisoning, and other diseases.

(3) The *laryngoscope* is an instrument for examining the interior of the larynx; it is, essentially, a combination of two mirrors by which a view of the larynx is obtained. The vocal cords, epiglottis, cartilages, base of the tongue, and lower parts of the pharynx may be inspected by its use; changes in the color, form, mobility, and functional activity of these parts may be observed.

(4) *The sphygmanometer* (for blood pressure).

"The portable instrument of Janeway is accurate and practical because of its broad arm piece, which excludes the errors (high readings) inherent in the narrow compression bands when applied to unusually fat or muscular arms, and because of its accurate regulation of pressure by stopcock. *Technique:* The hollow armlet applied midway between shoulder and elbow is inflated by the hand bulb until the radial pulse is lost, then by the outlet thumbscrew the pressure is lowered until the pulse return is just perceptible. As the pressure is equal in all parts of the closed system, the height of the mercury column in the manometer tube is an exact index, and the reading represents the 'maximum' or 'systolic' pressure. 'Diastolic' or 'minimum' pressure is determined by noting for ten or twelve pulsations the increasing amplitude of the pulse wave registered by the mercury column as the pressure is reduced in 5-mm. series. The point causing maximum excursion is the index of diastolic pressure. Below that is a limited pressure area of equal amplitudes. The 'mean' pressure represents the average of systolic and diastolic readings. Diastolic readings run about 25 to 40 below systolic, and in low tension vary 50 to 80, and in regurgitation up to 100 mm. A loose band or a rapid or excessively small pulse makes diastolic pressure determination impossible, and in every case the arm band should be closely adjusted, the arm supported at the heart level and the same position taken for a series of tests. The limit of error in calcareous arteries is but 5 to 10 mm., and is negligible or easily estimated. The same figures represent the difference between females and <males and the standing> and sitting posture. In normal pressure four factors are concerned, viz., the initial heart energy, peripheral resistance, blood volume, and the elasticity of the vessels. The normal readings, according to Janeway, are: For young adults, 100 to 130; older adults, 100 to 145; children, 90 to 110; infants under two years, 75 to 90. Excitement may cause a rise of 40 mm., and concentrated physical effort a slight increase."—(Greene's *Diagnosis.*)

(5) *Dare's Hemoglobinometer:* "A circular disc of tinted glass, representing variations in blood coloring matter of a known degree, is brought into direct con-

trast by transmitted candle light with a film of the fresh whole blood drawn by capillary attraction between two glass plates, one transparent, the other translucent and white. A detachable observation tube and a circular shield protect the eyes from extraneous light, and the percentage of hemoglobin may be read directly from the scale. The instrument may be used in daylight if pointed at some dark object, and its readings are not affected by an excess of leucocytes."—(Greene's *Diagnosis.*)

2. *Scarlet fever:* Period of incubation, from a few hours to seven days. Stage of invasion, twenty-four hours. Character of eruption, a scarlet punctate rash, beginning on neck and chest, then covering face and body; desquamation is scaly or in flakes. The eruption is brighter, is on a red background, punctiform, and is more uniform; the temperature is higher, the pulse quicker; the tongue is of the "strawberry" type, the lymphatics in the neck may be swollen, and there is sore throat; Koplik's spots are absent.

Measles: Period of incubation, ten to twelve days. Stage of invasion, four days. Character of eruption, small, dark red papules with crescentic borders, beginning on face and rapidly spreading over the entire body; desquamation is branny. The eruption is darker, less uniform, more shotty; the temperature is lower, pulse slower, the tongue is not of the "strawberry" type; coryza, coughing, and sneezing may be present; Koplik's spots are present.

Smallpox: The eruption usually appears first on the forehead and wrists, and on the third or fourth day; it is first macular, then papular, then vesicular, and finally pustular; it does not appear in successive crops; the spots are multilocular, and do not collapse on being punctured; the papule is hard and shotty, and does not disappear on stretching the skin. Period of incubation is from eight to fourteen days.

Chickenpox: The eruption usually appears first on the trunk, is evident on the first day, comes in successive crops, is not shotty, and disappears on stretching the skin; the spots are unilocular, and collapse on being punctured. The period of incubation is from four to fourteen days.

3. *Hematemesis* is the vomiting of blood; the blood comes from the stomach.

Hematuria is the condition in which blood is voided in the urine.

Hemophilia is the condition in which a person has a tendency to bleed freely on the smallest injury; the coagulability of the blood is lessened.

Hemoptysis is the spitting of blood.

The only two of these conditions which require differentiation are hematemesis and hemoptysis.

Hematemesis.	Hemoptysis.
1. Previous history of gastric, hepatic, or splenic disease.	1. Previous history of pulmonary troubles.
2. Blood is vomited.	2. Blood is coughed up.
3. Blood is dark colored and not frothy.	3. Blood is frothy and bright red.
4. Blood may be mixed with food.	4. Blood may be mixed sputa.
5. Giddiness or faintness usually precedes vomiting.	5. Sensation of tickling in the throat usually precedes.
6. Nausea and weight in epigastrium.	6. Dyspnea and pains in the chest.
7. Often followed by melena (black, tarry stools).	7. Is not usually succeeded by melena.

4. *For three months' old bottle-fed baby:* Milk, six tablespoonfuls; barleywater, six tablespoonfuls; sugar, two teaspoonfuls.

Six such feedings in the twenty-four hours.—(From Chapin and Pisek's *Diseases of Children*).

5. "The *x-rays* are invisible; cannot be deflected, refracted, or concentrated; are not influenced by the magnet, and produce none of the ordinarily recognized effects of heat. The rays cannot be polarized, travel with the velocity of light, and cause fluorescence in certain substanes, notably in the tungstate of calcium, platocyanid of barium, and the platocyanid of potassium. They have a marvellous power of penetration. . . . The real nature of the rays remains unknown. They resemble the ultraviolet and Becquerel rays in their action on a charged electroscope and in producing fluorescence in certain substances, but the latter have not the penetrating power of the former."

Uses: "In fractures the rays enable us to determine the nature of the injury, the amount of splintering, the existence of impaction, the question whether or not the fragments are in contact or can be brought in contact, the direction of the line of fracture, the variety of deformity, the existence of more than one fracture, the presence of epiphyseal separation or dislocation alone or with a fracture, the existence of an ununited fracture, the presence of callus, and if the splints are holding the fragments in apposition." . . . The relations of parts can be determined; diseases, cysts, tumors and other pathologial conditions of bone can be recognized; conditions about a joint, arthritis deformans, ossifying bursitis, foreign substances within the joints, the character of deformity or defect can be determined; intrathoracic conditions can be recognized, such as thickened pleura, extensive effusion, cavity formation, consolidation; variations in the size, shape and position of the heart; aneurysm; dilated aorta; enlarged glands; constriction, dilatation, diverticulum, and tumors of esophagus; size, shape, position, motor activity, contraction, tumors, stenosis of stomach; obstruction, ptosis and dilatation of intestine; position of kidneys, renal calculus; ureteral calculus or kinks; vesical calculus; foreign bodies in any part of the body. The *x*-rays are also used in the treatment of various diseased conditions.

Dangers vary "from falling out of hair or slight irritation of skin to the production of sterility, extensive sloughing or even chronic non-healing and painful ulcers, cancer, and death."

"Unnecessary exposure to *x*-rays is to be avoided. The operator should remain as far away from the excited tube as possible, and have between it and him a lead screen no less than one-quarter of an inch in thickness and of dimensions sufficient to protect his entire person. The patient is to be protected from undue irradiation by means of lead-glass or lead-covered tube-holders and lead diaphragms. In treatment of lesions beneath the skin some form of filter should be used over the exposed area."—(From DaCosta's *Modern Surgery*).

6. (1) A systolic murmur, soft and blowing, heard best at the apex, and transmitted to the left axilla and toward the angle of the left scapula, indicates mitral regurgitation. (2) A presystolic murmur, harsh and rough, heard best very near the apex, and not transmitted, denotes mitral stenosis. (3) A diastolic murmur, soft, heard best in the second right intercostal space, and transmitted down the sternum or toward the apex, denotes aortic regurgitation. (4) A systolic murmur, harsh, heard best in the second right intercostal space, and transmitted into the carotids, denotes aortic stenosis. (5) A diastolic murmur, heard best in the second left intercostal space, denotes pulmonary regurgitation. (6) A systolic murmur, heard best in the second left intercostal space, and not transmitted to the large vessels of the neck, denotes pulmonary stenosis. (7) A murmur, usually systolic, soft, and blowing, heard best over the pulmonic area, associated with evidences of chlorosis or anemia, and affected by the position of the patient, is a hemic or functional murmur, and denotes as a rule an impoverished condition of the blood.

7. *Ascites* is a collection of serous fluid in the peritoneal cavity.

The *causes* are: Portal obstruction, chronic inflammation of the peritoneum, abdominal tumors, cardiac disease, Bright's disease, chronic emphysema, anemia, cirrhosis of the liver.

Symptoms, etc.: Generally of gradual onset; abdominal distention, sense of weight and fulness; dyspnea; gastrointestinal disturbances; lineæ albicantes, presence of fluid may be detected by palpation, percussion or aspiration. If due to heart or lung disease, ascites will occur elsewhere, and the legs are generally affected first; in hepatic disorders the abdominal distention is marked and appears early; in renal disease, the abdominal fluid is generally small in amount.

8. *Five diseases in which the ophthalmoscope may be an aid in diagnosis:* (1) *Optic neuritis.* "Instead of the pale pink, clearly defined, disc, we may note that the papilla is swollen and hyperæmic, the margins hazy or woolly, the central vein increased in size, while the central artery may be of normal size or contracted."

(2) *Optic atrophy.* "Instead of a swollen hyperæmic papilla, we may find the disc pale and hollowed on the surface ("cupped"), the vessels shrunken, and often outlined by two white lines representing their thickened coats."

(3) *Retinitis.* "There may be a diffuse cloudiness of the fundus, especially of its central regions. The papilla may be congested, swollen, and indistinctly outlined; the retinal veins may be engorged; bright or dark red hemorrhagic patches and white exudations and degenerations may be observed."

(4) *Cataract.* "The fundus may be invisible owing to opacity of the lens; or the opacity may be in striæ, flocculi, or dots. Light thrown obliquely on the lens will show up the opacity better than the transmitted light from the ophthalmoscope."

(5) *Tubercle* "may be seen as one or more round, yellowish spots in the choroid, usually near the disc, occurring in the later stages of miliary tuberculosis."—(From McKisack's *Dictionary of Medical Diagnosis.*)

9. Signs of cavity of the lung:— "(*a*) When there is not much thickening of the pleura or condensation of the surrounding lung-tissue, the percussion sound may be full and clear, resembling the normal note. More commonly there is defective resonance or a tympanitic quality which may at times be purely amphoric. The pitch of the percussion note changes over a cavity when the mouth is opened or closed (Wintrich's sign), or it may be brought out more clearly on change of position. The cracked-pot sound is obtainable only over tolerably large cavities with thin walls. It is best elicited by a firm, quick stroke, the patient at the time having the mouth open. In those rare instances of almost total excavation of one lung the percussion note may be amphoric in quality. (*b*) On auscultation the so-called cavernous sounds are heard: (1) Various grades of modified breathing—blowing or tubular, cavernous or amphoric. There may be a curiously sharp hissing sound, as if the air was passing from a narrow opening into a wide space. In very large cavities both inspiration and expiration may be typically amphoric. (2) There are coarse bubbling râles which have a resonant quality, and on coughing may have a metallic or ringing character. On coughing they are often loud and gurgling. In very large thin-walled cavities, and more rarely in medium-sized cavities, surrounded by recent consolidation, the râles may have a distinctly amphoric echo, simulating those of pneumothorax. There are dry cavities in which no râles are heard. (3) The vocal resonance is greatly intensified, and whispered pectoriloquy is clearly heard. In large apical cavities the heart-sounds are well heard, and occasionally there may be an intense systolic murmur, probably always transmitted to, and not produced, as has been supposed, in the cavity itself. In large excavations of the left apex the heart impulse may cause gurgling sounds or clicks synchronous with the systole. They may even be loud enough to be heard at a little distance from the chest wall. A large cavity with smooth walls and thin fluid contents may give the succussion sound when the trunk is abruptly shaken, and even the coin sound may be obtained."—(Osler's *Practice of Medicine.*)

10. "The *interval between inspiration and expiration may be prolonged,* instead of these two sounds closely succeeding each other. When this occurs the inspiratory sound may be shortened, or the expiratory sound may be delayed in its commencement. If the inspiratory sound is shortened, it is the result of consolidation of the lungs; if the expiratory sound is delayed, it is the result of lessened elasticity of the lung-structure, and is most commonly associated with emphysema."—(Hughes' *Practice of Medicine.*)

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	S. W. Welch, Montgomery	Montgomery	Jan. 10

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

SYPHILIS AND ITS TREATMENT. By Wilfrid S. Fox. 195 pages with 53 illustrations. Price $9.00. Published by Paul B. Hoeber, New York.

THE HEART—OLD AND NEW VIEWS. By H. L. FLINT. 177 pages with illustrations. Price $4.00. Published by Paul B. Hoeber, New York.

AUTOEROTIC PHENOMENA IN ADOLESCENCE. By K. MENZIES 100 pages. Price $1.50. Published by Paul B. Hoeber, New York.

WHAT TO DO IN CASES OF POISONING. By WILLIAM MURRELL. 273 pages. Price $1.25. Published by Paul B. Hoeber, New York.

THE MORPHOLOGIC ASPECT OF INTELLIGENCE. By SANTE NACCARATI. 44 pages. Published by G. E. Stechert & Co., New York.

THE MEDICAL CLINICS OF NORTH AMERICA, July, 1921. 273 pages with illustrations. Published by W. B. Saunders Company, Philadelphia.

THE SURGICAL CLINICS OF NORTH AMERICA, August, 1921. 297 pages with illustrations. Published by W. B. Saunders Company, Philadelphia.

LA FUNCION DE LOS CUERPOS AMARILLOS. By Armando F. QUINTERNO. 188 pages. Published by Luis L. Gotelli, Buenos Aires.

NUT GROWING. By ROBERT T. MORRIS. 236 pages with illustrations. Price, $2.50. Published by The Macmillan Company, New York.

Medical History.

DR. ELIZABETH BLACKWELL*

HER CHARACTER AND PERSONALITY.

By SARAH J. McNUTT, M.D.,

NEW YORK.

WHEN in 1873 I entered the College of the New York Infirmary for Women and Children, four years had passed since Dr. Elizabeth Blackwell had left the institution to make her home in London, yet the whole atmosphere of the College and Hospital was still surcharged with her wonderful personality. This influence clung to me during my College and Hospital experiences and has been an inspiration through my entire professional life. So strong was this feeling that when I went to Europe in 1896 one of my strongest desires was to meet the woman who had so greatly helped in shaping my life, and therefore my first pilgrimage was to Hastings-by-the-Sea, the summer home of Dr. Elizabeth Blackwell.

I found her, small and gray haired, but one of the most vivacious women I had ever met. So young looking and appearing, one could never

Elizabeth Blackwell.

think of her as old. She was charming in manner, likeable, and above all perfectly human. Her bright, intelligent eyes and smiling face showed her delight at seeing one so recently from New York who could tell her directly of the people she knew and the work in which she was so deeply interested. Every moment was spent in answering her rapid pointed questions.

I left her presence feeling that I had received a benediction. Never again would I need to wonder why she had been such a power in work for women. My brief visit had shown me that, once convinced that a cause was right and just, and a need in the world, she would with masterful persistency, keep on to the end, kindly and untiringly until victory was won. She could see clearly the vision through intervening clouds and forecast the success ahead!

Elizabeth Blackwell was born in England in 1821 where the first eleven years of her life were spent. She was the third daughter in a large family of nine brothers and sisters who grew up to adult life, bound together by strong ties of natural affection. She had the advantage of the give and take, which always comes in large families, and does so much to develop character.

It was a healthy, out-of-doors home life passed chiefly in the then small town of Bristol. The children were taught at home by governesses, and all developed such a passion for books that no gift was so greatly prized as a new book, and all their pocket money was spent in adding to their bookish treasure.

In 1832 a great change took place when her father emigrated to the United States with his large and increasing family. The trip took seven weeks. The following six years were spent by Elizabeth in New York City, as a day pupil in an excellent school. Here the family first met William Lloyd Garrison, who became a life long friend, and whose daughter, Mrs. Henry Villard, is still one of the Infirmary Trustees.

In 1838, when Elizabeth was seventeen years old, her father removed to Cincinnati, Ohio, and within a few months after their arrival he died suddenly, leaving the widow and nine children unprovided for.

The family ties were very closely knit among the Blackwells, centering in the father, whose warm affection, sense of fun, and talent for rhyming represented a beneficent providence to his adoring children and we can well understand what his passing on meant to them. In reply to a petition that a small telescope, which the children had been using from the garret window, might be moved to a parapet wall on the roof for a more extended view, a disappointing reply was received, but so full of fun that they accepted it meekly and enjoyed the denial.

Anna, Bessie, and Polly:—
Your request is mere folly
The leads are too high
For those who can't fly.
If I let you go there
I suppose your next prayer
Will be for a hop
To the chimney top!

So I charge you three misses
Not to show your phizzes
On parapet wall or chimney so tall,
But to keep on the earth,
The place of your birth.
"Even so," says Papa, "Amen," says Mama,
"Be it so," says Aunt Bar.

Of the strenuous graduating days a brother writes: "Our Sis came off with flying colors and the reputation of being altogether the leader of the class. All the class agreed that our Elib was a great girl and I found that she was a universal favorite with both professors and students." One can hardly imagine a sweeter family atmosphere. The three elder sisters soon established a Day and Boarding School for Young Ladies, and the eldest brother obtained a position in the court house. Dr. Blackwell, in writing of herself at that time said: "Notwithstanding our close and arduous teaching occupation, we eagerly shared in the active awakening of thought that marked the times, such as political interests and the higher education of women."

In 1842 the elder brothers, entering into business, the boarding school was given up and Elizabeth

*Read at a meeting of the Alumni Association of the College of the New York Infirmary for Women and Children, March 16, 1921. Much of the material used was gained from the autobiography of Dr. Blackwell, now in the Library of the Academy of Medicine. I have quoted freely from this book.

occupied herself with private pupils. The family removed to the pleasant suburb of Walnut Hills just outside of Cincinnati, where the Lane Seminary was situated, with Prof. Stowe (husband of Harriet Beecher Stowe) as its head. This healthy place, with its intellectual resources became the home of the Blackwell family for many years. At this time Lucy Stone became the wife of Elizabeth's elder brother.

The family life was still full and active and of this period Dr. Blackwell writes: "I keenly enjoyed the home, but felt the need of a more engrossing pursuit than the study of Music, German, and Metaphysics and the ordinary interests that social life presented." It was at this time that the suggestion of studying medicine was first presented to her by an interested woman friend. This friend finally died of a painful disease. A little before her death she said to Elizabeth: "You are fond of study, have health and leisure; why not study medicine? If I could have been treated by a woman physician, my worst sufferings would have been spared me." Elizabeth at once repudiated the suggestion as an impossible one, saying, "I hated everything connected with the body, and could not bear the sight of a medical book." She resolutely tried for weeks to put aside the idea suggested by her friend but it constantly recurred to her. Of these days Dr. Blackwell writes:

Other circumstances forced upon me the necessity of devoting myself to some absorbing occupation. I became impatient of the disturbing influence exerted by the other sex. I never remember the time, from my first adoration at seven years old, of a little boy with rosy cheeks and flaxen curls, when I had not suffered more or less from the common malady, falling in love. But whenever I became sufficiently intimate with any individual, to be able to realize what a life association might mean, I shrank from the prospect, disappointed or repelled. In my journal of that time can be found the following sentence, written during an acute attack:—"I felt more determined than ever to become a physician, and thus place a strong barrier between me and all ordinary marriage. I must have something to engross my thoughts." But the struggle with natural repugnance to the medical line of life was so strong, that I hesitated to pass the Rubicon, and fought many a severe battle with myself on the subject.

As the idea still continued to gain force, however, she wrote to, and consulted with, several physicians known to her family in various parts of the country, as to the possibility of a woman becoming a doctor. The answers she received were curiously unanimous, and briefly amounted to this: the idea, though a valuable one, was impossible of execution. This verdict however, was rather an encouragement than otherwise to a young and active person who needed an absorbing occupation. She reasoned, if an idea was really a valuable one, there must be some way of realizing it. The idea of winning a doctor's degree gradually assumed the aspect of a great moral struggle, and as such possessed immense attraction for Elizabeth. This aspect of the subject was increased by a circumstance which made a very strong impression on her mind.

There was at that time, a certain Madam Restell, flourishing in New York City. This person was a noted abortionist and known all over the country. She was a woman of great ability, and defended her course in the public papers. She made a large fortune, drove a fine carriage, had a pew in a fashionable church, and though often arrested was always bailed out. She was known distinctively as a "Female Physician," a term exclusively applied at that time, to the women who carried on this vile occupation. This undoubtedly accounted in part for the ostracism shown the Drs. Elizabeth and Emily Blackwell when they commenced to practise legitimate medicine in New York City. Dr. Blackwell wrote at this time:

That the honorable term Female Physician should be exclusively applied to those women who carried on this shocking trade, seemed to me a horror. It was such an utter degradation of what might and should become a noble position for women! I made up my mind fully to undertake the Study of Medicine, if the friend who had promised to help me fulfilled her promise, and already I felt separated from the rest of womankind. But alas for promises and plans, she offered to lend me one hundred dollars when I had been told I needed three thousand dollars! A force stronger than myself, then and afterwards, seemed to lead me on, a purpose was before me which I must inevitably seek to accomplish. I knew, however insignificant my individual effort might be, that it was in a right direction and in accordance with the great providential ordering of our race. Thrown entirely upon my own resources, I decided to spend the next few years in teaching in the South to accumulate the necessary funds for future use; meanwhile doing preliminary work wherever I was situated, and could find doctors in sympathy with my aims.

In spite of these prejudices, wherever Dr. Blackwell went she made warm personal friends among the most intelligent people. To continue in her own words:

In the summer of 1847 with my carefully hoarded earnings I resolved to seek an entrance into a medical school. Philadelphia was then considered the chief seat of medical learning in America. So to Philadelphia I went and cautiously but persistently made application to the four medical colleges for admission as a regular student. I also enlisted the services of my friends in the search for an Alma-Mater. During these fruitless efforts my kindly Quaker adviser said to me: "Elizabeth, it is no use trying, thee cannot get admission to these schools. Thee must go to Paris and don masculine attire to gain the necessary knowledge. This suggestion of disguise was also made to me by some of my medical friends. But neither the advice to go to Paris, nor the suggestion of disguise tempted me for a moment. It was to my mind a moral crusade, on which I had entered, a course of justice and common sense, and it must be pursued in the light of day and with public sanction in order to accomplish its ends.

Applications for admission to the schools of Philadelphia and New York City were refused. She therefore obtained a complete list of the smaller schools of the Northern States (country schools as they were called). She sent her application for admission to twelve of the most promising, where full courses of instruction were given under able professors. The result was awaited with much anxiety. No answers came for some time, but at last to her immense relief (though not surprise, for failure never seemed possible), she received a favorable answer. Hobart College, Geneva, New York, now the medical department of Syracuse University, alone had the vision, and to it came finally the honor of conferring the first medical degree ever granted a woman on the American continent. Upon receipt of her letter, the faculty referred her matter to the students and they decided to invite the courageous applicant, and passed resolutions, a copy of which was sent to her, and reads as follows:—

At a meeting of the entire medical class of Geneva Medical College, held this day, October 20th, 1847, the following resolutions were unanimously adopted:

1. *Resolved:* That one of the radical Principles of a Republican Government is the universal education of both sexes; that to every branch of Scientific Education the door should be opened equally to all; that the application of Elizabeth Blackwell to become a member of our class meets with our entire approbation; and in extending our unanimous invitation we pledge ourselves that no conduct of ours shall cause her to regret her attendance at this institution.

2. *Resolved:* That a copy of these proceedings be signed by the Chairman and transmitted to Elizabeth Blackwell.

T. J. STRATTON, Chairman.

Dr. Stephen Smith, her loyal classmate has presented an account of their college years, so I largely omit them.

She spent the summer of 1848 studying in the hospital wards of the Great Blockly Alms House of Philadelphia. Blockly was the pioneer hospital of America to admit a woman to study in its wards. In making her application she had a letter of introduction to one of the directors.

She says:

He received me most kindly, but informed me that the Hospital was so dominated by politics that if he, as a Whig, should bring forward my application it would be inevitably opposed by the other two parties, viz., the Democrats and Native Americans. My only chance of admission lay in securing the support of each of those parties without referring in any way to the rival factions. I accordingly undertook my sole act of "lobbying." I interviewed each political leader with favorable results and then sent in a petition to the first Board meeting, when lo! a unique scene took place. All were prepared to fight in my behalf, but there was no one to fight. I was unanimously admitted, to reside in the hospital. This unanimity, I was afterwards told, was quite without precedent in the records of the institution.

During the summer of 1848 the famine fever was raging in Ireland. Multitudes of emigrants were attacked with fever while crossing the ocean, and so many were brought to Blockly that it was difficult to provide accommodation for them, many being laid on beds on the floor. But this terrible epidemic furnished an impressive object lesson, and I chose this form of typhus as the subject of my graduation thesis, studying in the midst of the poor dying sufferers. Leaving Blockly, I was conscious of the great gain in medical knowledge and worldly experience which it had afforded.

At last the day arrived, January 23, 1849, which should be a Red Letter date for all Medical Women, for then the first full medical degree was conferred upon an Anglo-Saxon Woman. The graduating exercises of the class of 1849 took place in the large Presbyterian Church in Geneva, New York, which the interest in the girl graduate crowded to the door. While the student body marched two and two from the college to the Church, Elizabeth considering it more ladylike, went to the Church on the arm of her brother and sat with him apart from the others. Her historian quaintly remarked that she was modestly but suitably garbed in a black brocade silk gown, invisible green gloves, black silk stockings, etc.

After her classmates had received their diplomas, Elizabeth was called up alone, the President rising to receive her and present her diploma. (He had remained seated while presenting the others). Her biography says, "On receiving her diploma, Elizabeth said, 'I thank you, and by the help of the Most High, it shall be the effort of my life to shed honor upon this diploma.' She then bowed, the President returned her salutation, the audience applauded, Dr. Webster, Prof. of Anatomy, rubbed his hands gleefully, and the learned counsellors and the Faculty nodded grave approbation to each other." Elizabeth says in her diary, "As I came down from the platform, I was much touched by the graduates making room for me in the front row and insisting that I sit with them for the remainder of the exercises." As the audience passed out, the Bishop of New York, Right Reverend Alonzo Potter, congratulated her on her course, to the great astonishment of the conservatives. The ladies collected in the yard as she appeared and opened their ranks to let her pass. Several spoke to her most kindly, apparently forgetting how they had maligned and ostracized her during her college course.

The admission of a woman for the first time to a complete medical education, and full equality in the privileges and the responsibilities of the profession, produced a widespread effect in America. The National Medical Association meeting in 1849 at Boston censured Hobart College for granting a degree to a woman, but on receipt of her College record her honor list and her thesis on Typhus, they acknowledged that the college was justified in granting her, her degree. Concerning this criticism on her beloved Alma Mater, she writes from Europe: "I received today a very pleasant letter from Dr. Webster (Anatomy Professor at Geneva). I was much gratified to find that their course to me has been approved by the profession in America. It would have grieved me inexpressibly if they had been condemned for the aid they had given me, and there seemed to be a decided possibility of it when I left. But he tells me, my thesis was commented on in the Report on Medicine at the National Medical Convention held in Boston, and their course in relation to me justified and approved. The thesis was received with applause. This information is quite a relief to me, for the thought would be too painful that I could injure the college friends who did so much for me."

Immediately after graduation, Dr. Blackwell went to Europe, a rare extravagance in those days, even for male students. She succeeded in visiting hospitals in London and Paris, and for some months submitted to the severe imprisonment of the great school for Midwives, La Maternité, where she gained most valuable experience in maternity work, not obtainable as well elsewhere. After two years study in Europe she returned to America in 1851. The next seven years of New York life were years of very difficult, uphill, unceasing work. She says: "I had no medical companions, the profession stood aloof, and society was distrustful of the innovation."

The utter loneliness of her life became so intolerable that she decided that she must have some personal interest to fill her heart. Just at this time, while visiting a public institution for children, a little red-haired tot left her companions and ran directly toward Dr. Blackwell, smiling and seeming absolutely confident of a welcome as she clasped the strange lady's knees with her tiny arms. Her faith found an instant answer in Dr. Blackwell's heart, and little Kittie soon took the vacant place and satisfied the innate motherhood with which few

have credited this practical woman. She soon proved so congenial that the Doctor very soon adopted her, an act which she never regretted. Was it not the "Divine Hand" that reached down and gently drew together for their mutual comfort and satisfaction, those two who so greatly needed each other, the friendless sunny hearted child and the sweetfaced, yearning hungry-eyed woman.

Dr. Elizabeth was essentially a pioneer, not only in studying for her degree but throughout her entire medical life. Of this period she writes, "I am glad I and not another have had to bear this pioneer work."

In the spring of 1852, she gave a course of lectures on the physical education of girls, something unheard of then, though common enough today. These lectures were published by George Putnam in 1852 under the title: "The Law of Life, with Special Reference to the Physical Education of Girls," by Elizabeth Blackwell, M. D. With the following dedication: "To American Women. These lectures were delivered to a class of ladies during the past Spring; the wish of the class and an earnest desire to call attention to a much neglected part of education have induced me to publish them. They are the first fruits of my medical studies. I would offer them as an earnest of future work."

The social and professional connections which resulted from these lectures gave her her first start in her practical medical life. Many of the intelligent circle to which these lectures were given belonged to the Society of Friends who have always been the warm supporters of the various institutions she founded. In the early days, her practice was largely a "Quaker" practice. Dr. Mary B. Hussy, her first baby, was the granddaughter of her staunch Quaker supporter, Stacy B. Collins. From this time also dates the friendship of Robert Haydock and Hannah, his wife, daughter of Deborah Wharton of Philadelphia, a Quaker minister of that day, Samuel B. Willetts, and others.

Being refused admittance to all the dispensaries and so deprived of their valuable practical work she decided to take the advice given in jest when work was refused in the City dispensaries to "get a dispensary of your own." So in 1853 with the aid of friends, she hired a room on Tompkins Square for a dispensary. Mrs. Cornelia Hussy, Dr. Hussy's mother, actively assisted her in arranging the room and the medicines, thus instituting the first dispensary in the world run by women physicians. A charter was obtained in 1854. From this modest beginning has grown the New York Infirmary for Women and Children.

There was, as yet, no hospital opportunity for medical women therefore in 1857 indoor, or hospital patients, were admitted to the infirmary, and a ward for twelve lying-in patients was added at that time. In 1859 the out-practice department was started, and also this same year a "sanitary visitor" was employed, who went into the homes of the poor to give simple practical instruction to the mothers in the care of their infants. In 1865, upon the urgent advice of several prominent physicians who felt, that otherwise a low grade college then attempting to secure a charter would succeed, the New York Infirmary applied for and obtained its college charter.

In 1868, Dr. Elizabeth in her opening address said "The College must be an honest and earnest attempt to give to women, the very highest education that modern Science will afford." These ideas of Dr. Blackwell in the years that followed were never lost sight of as long as the College lived. It was resolved at the first to make the quality of the instruction and the requirements for graduation equal to the best schools for men in the country.

In New York the first meeting to consider the organization of nursing for our army in the Civil War was held at the suggestion of Dr. Blackwell in the parlors of the Infirmary. This little meeting was the germ from which subsequently developed the splendid organization of the United States Sanitary Commission. This association rendered to our soldiers aid much like that which the Red Cross rendered in the World's War, and in fact it was the forerunner of our American Red Cross.

Great strides had been made in medical opportunities for women during the twenty years since Dr. Blackwell graduated. Opportunities for the highest medical education were opened to them. Boston, Philadelphia, Chicago, and New York each had a hospital which medical women controlled, and in 1869, considering her pioneer work in America ended, Dr. Blackwell decided to return to Great Britain. During all these years she had been in frequent communication with her many warm friends in England who had continuously urged her to return and assist them to secure medical opportunities for women in London and Edinburgh. Among these friends she counted Sir Philip Paget, then leading surgeon of England, Florence Nightingale, Ruskin, and many other notable people whose approbation greatly encouraged her.

After a short rest in England Dr. Blackwell entered eagerly into the pioneer work, so bravely commencing in London. The campaign against the double standard of morality had just been commenced, and in it she took an active part for the next seventeen years.

Convinced of the supreme importance of the medical profession as the great conservator of health we find her aiding in the formation of the National Health Society and seizing every opportunity to lecture to all classes. She lectured to working women on how to keep a household in health, and on the religion of health before the Sunday Lecture Society. In addition to a large and growing practice she worked in the little Dispensary which afterward became the New Hospital and London School of Medicine for Women.

A severe illness in 1873 broke up her plan of life and she went to the continent in the hopes of regaining her health. When the London School of Medicine was established she was able to return and accept the chair of Gynecology, but by the end of the term returning ill health made her realize that future residence in London must be given up. From then until she settled down permanently at Hastings, her time was divided between Southern Europe and her English home. She took a lively interest in all the vital medical and Social questions of the times. Her interest in the medical education of women never flagged. The last few years of her life were spent at Hastings, lovingly and tenderly cared for by the adopted daughter, Kittie now grown to womanhood.

Dr. Mary Putnam Jacobi has stated of the Blackwell sisters—"They did not seek wider opportunities in order to study medicine but they studied medicine in order to secure wider opportunities for all women."* Elizabeth said, "The thorough education of a class of women in medicine will exert an important influence upon the life and interests of women in general." As I have shown, it was more a sense of duty than an intense interest in the subject that led Elizabeth Blackwell to study medicine so it has been well said "Among all the pioneer group of women physicians, hers chiefly deserves to be called the record of an heroic life."

When Elizabeth Blackwell died on June 1, 1910, a great light went out.

Distinguished Jewish Physicians in Christian Rome.—Doctor Blustein, having recently made the statement that the Jews were victims of papal persecution in Rome, he is answered by Dr. Cecchetelli, who asserts that this race received better treatment in the Eternal City than in any other place in Europe. At the close of the XII and beginning of the XIII centuries there flourished in Rome Emanuel Zifroni, Jewish physician, poet, astronomer and mathematician. He is believed to have been on friendly terms with Dante and even to have suggested to him, in part at least, his great trilogy, by writing a poem of the same scope—the journey of a Jew through Hell and Heaven, accompanied by the prophet Daniel. The name of this prototype poem was "Mechabberoth." During a long interval the Popes were attended by Jewish physicians. In 1385 the Roman Senate reduced the amount of tribute payable by the Jewish community because medical men of that race had refused to charge poor people for their services. Pope Boniface IX gave a certificate or diploma to the Jewish physician Elias Sabbas and latter addressed a document of the same scope—a sort of letter of recommendation— to Angelo di Manuele. Although Pope Sixtus IV was implacable against the Marani or Spanish Jews he employed as physicians Roman Hebrews. Leo the Great, patron of Raphael and Michelangelo, held a veritable court of Jewish practitioners. The German Reuchlin wrote to Bonetto, one of the latter, asking him to use his influence over Leo to obtain some sort of concession. Many other examples are enumerated of Popes who patronized Jewish physicians. An exception was Paul IV who introduced the Ghetto into Rome, but at least a score of popes seem to have gone out of their way in extending friendly recognition of the medical members of this race.—*Il Policlinico.*

The Pharmacopœia of Nicolas Lemery.—Lemery lived in the reign of Louis XIV of France, he was familiarly known as "the great Lemery," and was a doctor of medicine and pharmacy, a chemist, and a laboratory man. He was endorsed by the Faculty of the Medical School and the King's physician. Imagine yourself in the rue Galande following a crowd of medical students. It turns into a court, at the end of which is a low placed door through which you pass to descend into a cellar lit with the glow of furnaces. Here Lemery, barely 30 years of age, is delivering a lecture on chemistry. You would naturally be much impressed. But what does he tell you? That oil of new-born pups mixed with earthworms is a sovereign remedy for sciatica. The pups and worms are boiled together in oil to obtain this drug. For gout and "vapors" the best medicine is the freshly voided urine of a cow. To stop nosebleed, hold in the armpit a dried frog (this idea he pilfered from an earlier adept). There is found in his book mention of many of the tissues or fluids of the human body. The saliva of a healthy young man taken in the fasting state is recommended for snake and mad-dog bites. A cranial bone, dried and pulverised, is the treatment for epilepsy, but it must be taken from a young, robust man, immediately after a violent death, so as to conserve the vitality of the tissues. Finger- and toenails are good emetics, earwax is good for whitlow, and so on. One reads through the list without finding a single foundation for the use of any of these substances; not once even by accident is there any connection between cause and effect. But some of these superstitions come down to our day, as the use of cobwebs for hemorrhage, wearing amber beads for infantile convulsions, and of course, the horsechestnut carried in the pocket for rheumatism.—*Le Progrès Médical.*

The Earliest Obstetrical Literature.—Josephson discusses in succession the accounts of the birth of the children of Red-dedet in the Westcar papyrus, of Esau and Jacob from the Hebrew Scriptures and of Hercules as narrated by Hesiod, Homer, and Ovid. When Red-dedet felt the first pains she received a visit from Isis and other goddesses disguised as dancers. They took the parturient woman in a room and shut themselves in with her. Isis stood in front and another behind her, while the third acted as accelerate. When Isis repeated some mystic words the child escaped into her hands, whereupon she washed it and tied the cord, placing the newborn in a special bed. One goddess foretold that it would be King, and another endowed it with health. But the mother was in reality pregnant with triplets. A second child was now born followed by the third and the ceremonies were repeated.

This myth needs an interpretation. It represents, in part, the accouchement of an Egyptian lady of quality in the Middle Dynasty. Four midwives are supposedly present. Isis, the chief midwife in the myth stands before the parturient woman (compare the Latin word *obstetrix*), pronounces the magic word which causes the delivery, washes and names the infant. Another midwife who is behind the mother is believed to sit in a chair and support her (the socalled obstetrical chair was a recognized piece of furniture among ancient and medieval peoples and was used as late as the XVIII century. The third midwife pressed on the belly and aided in expulsion. Two goddesses took no part in the confinement, one making the prophecy while the other conferred health as above stated. The explanation of the confinement comes about in part from hieroglyphs of the period. There is much more to the myth but it does not bear on midwifery.—*Upsala Läkareförenings Forhandlingar.*

X-RAY DERMATITIS.*

BY MARY L. H. ARNOLD SNOW, M.D.,
NEW YORK.

X-RAY and radium, representing the most powerful therapeutic agents possessed by the medical profession in the relief of human suffering, may also produce deleterious effects, dermatitis or sequelæ, conditions dreaded by the operator as well as the patient. Such effects may occur in any *x*-ray practice where the *x*-ray is operated by a novice or one unskilled or careless in technique. Important factors in its production are lack of adequate protective apparatus for the operator and patient; lack of or inadequate filters; the strength of the rays including their cumulative effect; the proximity of the tube, and the duration of the treatment including repetitions. Besides the factors dependable upon the operator, are the patient's susceptibility and idiosyncrasy.

Proper protective apparatus should include a "box opaque to *x*-rays," entirely enclosing the tube. "The diaphragm leaves, the lead glass in front of the screen, must also be opaque" to the *x*-ray. Test this by placing a second screen over the first which if it fluoresces shows the first screen unsafe.

Although we are usually protected from "the direct beam," scattered or "vagrant" radiation is ignored and yet it "is of the same penetration as the original beam." The human body "also scatters *x*-rays as translucent material scatters light." These scattered radiations according to Hernaman-Johnson[1] are overcome "(*a*) In the diascope by making the whole front opaque to *x*-rays; (*b*) in the couch, by a moving 'panel' and by extensive flaps of lead rubber attached to the screen." The same authority warns against the danger of true secondary radiation when "certain metal articles are worn close to the body, and then only if the precautions," noted above, "are not effectively carried out." A. E. Barclay,[2] in an article entitled "A Danger of the Coolidge Tube for Screen Work," well illustrates the radiations producing a "secondary screen image (5 per cent. of the strength of the primary image) from the anticathode," and advises when the upright screen stand is used to prevent the danger "by turning the tube upside down with the anticathode below so that its image goes upward above the primary *x*-ray shadow," or the use of an experimental hooded tube. Protective working paraphernalia, gloves, aprons, etc., are necessary essentials.

Protection is afforded the patient by exposing only the necessary part. Use proper filters of glass, leather, aluminum, lead, or copper. Some think in fluoroscopic work the use of a sole leather or aluminum screen is necessary for protection. "A new device for increasing the protection of both the patient and the roentgenologist" has been recently described by Geo. E. Pfahler,[3] M.D., consisting of opaque lead rubber—Hercules red rubber packing—forming a protective shield about the tube and "closing off the line of radiation through the opening in the tube."

The use of the ray without proper *filters* is another cause of dermatitis, particularly with heavy doses, and over-exposure, or a series of rayings. The use of aluminum or sole leather for eliminating the short rays which mostly affect the skin increases the number of exposures possible before the production of an erythema. Without filters 5 H. is usually an erythema dose, but with filters a much larger quantity of rays will not produce an erythema, the dosage depending on the thickness of the filters used, other factors being equal. Two methods[4] are commonly used: "1 6 erythema doses are given at intervals of three days until a reaction of the desired degree is gradually produced" as a "6 in. spark, 3 ma., 10 in. distance, 3 mm. aluminum filter for 2 min." The second method necessitates the operator knowing what definite dose will give the reaction when used once, when Holzknecht's chromoradiometer is used. "One H. is about a third of the amount of the *x*-ray that must be applied at one session in order to produce a visible reaction on the face; three or four H. is a full dose and would not be repeated until the reaction had developed and subsided, usually not for several weeks. Two H. repeated every two weeks maintains "a constant moderate reaction." Pfahler's[5] present technique consists of "5 milliamperes at 126,000 volts, filtered through 10 millimeters of aluminum or glass, at a focal skin distance of 30 cm. for a period of 40 to 50 min." He finds "that 40 minutes will rarely give an erythema and that 50 minutes will generally give an erythema." Glass, if of the same standard as aluminum, is preferable to aluminum. Copper may be used "½ mm. of copper being equal to 13 mm. of aluminum measured photographically" according to the same authority. Filters must not only be used, but must be of requisite thickness. Dr. Bèclerè[6] reports ulceration resulting in two cases because of insufficient thickness of filters. Witherbee and Remer[7] have shown with a 3 in. spark gap, 3 ma. 8 in. distance unfiltered with 4 min. exposure an erythema appears in about 15 days. "The hair will fall out in three and one-half weeks and will regrow completely in four months."

*Read before the National Physical Therapeutic Society, Washington, D. C., June 21, 1921.

This dose producing temporary epilation is a skin unit and is thus represented:

$$\frac{3\ (\text{spark gap}) \times 3\ (\text{ma.}) \times 4\ (\text{min.})}{D^2 = 8 \times 8} = \frac{9}{16}$$

"A 3 in. spark gap, 3 ma. 8 inches distance, unfiltered, with a 5 min. exposure, will produce an erythema in about 10 days, the hair will fall out 3 weeks afterward and will not regrow in 6 months. Bronzing of the skin occurs in 4 weeks. This represents an erythema dose, the limit of unfiltered dosage, and is thus represented:

$$\frac{3\ (\text{spark gap}) \times 3\ (\text{ma.}) \times 5\ (\text{min.})}{D^2 = 8 \times 8} = \frac{45}{64}$$

$$\frac{45}{64} \div \frac{9}{16} = 1\tfrac{1}{4}, \text{ or } 1\tfrac{1}{4} \text{ skin units} = 5\text{H}.$$

The filtered doses are similarly figured with "a separate standard or formula for one skin unit," for "each thickness of aluminum," but the divisor is the distance only, not the distance squared. The authors have made a table for varying thicknesses of aluminum filters and consider that with 3 mm. aluminum filters 2½ skin units is a filtered erythema dose.

$$\frac{5\ (\text{spark gap}) \times 9\ (\text{ma.}) \times 7.7\ (\text{min.})}{D. = 6} = 2\tfrac{1}{2} \text{ skin units} = 10\text{H}.$$

This is a formulated dose which in our experience also demands the consideration of the patient's physical condition as to powers of resistance and his susceptibility. Shearer does not agree with them, but Hirsch says that Witherbee and Remer's method is "of value only for the estimation of skin effects." I. Seth Hirsch advocates for the biological dose the "use of a practical ionization chamber (iontoquantimeter) based on biological effects." The same author[8] says "in treating by the modern method, using the heavy dosages so depth absorption will approach surface absorption as closely as possible," to still further increase the absorption quotient at the depth, the ray is filtered with the view of cutting out the softer rays. For practical purposes, however, rays filtered through 1 mm. of copper are homogeneous. Heavier filtration is now in vogue—10 mm. of aluminum, ½ mm. of copper or ½ mm. of zinc. The above methods have been mentioned because in use. Time and experience will prove their worth. In our practice the fractional dose method is employed, using 2 ma. 5 in. spark gap, 15 in. distance, 15 min. 3 times weekly, if conditions warrant, and with or without filters, according to the condition treated.

The *strength* of radiation depends on the energy of the tube and the distance. Reducing the voltage at a constant milliamperage reduces the quantity or intensity and softens the rays; whereas reducing the milliamperage at a constant voltage reduces the intensity but leaves the quality of the ray unaltered, the quantity or intensity or total energy incident on a plate varying inversely as the distance squared.

It has been thought that a low vacuum tube produced a dermatitis more quickly than a higher vacuum tube because the skin more easily absorbed the low penetrating rays, but Remer and Witherbee[8] have demonstrated experimentally that "it took just one-half the time for the same biological effect in the doubled spark gaps." Their conclusion is "that the *quality* of the ray and the absorption of those of long wave length have little to do with the biological effects in the skin. On the other hand, it seems that the factor which determines this effect is solely the *quantity* of *x*-ray reaching the skin, for it is obvious that the high spark gap produces more rays that reach the skin than the same dose with a low spark gap. When the same voltage (if quality depends on voltage) was used with filtered and unfiltered rays, the time was greatly increased to produce the identical erythemas, the filters lessening the quantity of *x*-ray reaching the skin." Diminishing the spark gap with unfiltered doses lengthens the exposure time for an unfiltered erythema dose 1¼ skin units. Diminishing the spark gap and increasing "the thickness of the filter lengthens the time for a filtered erythema dose 2½ skin units." In radiological work dosage is a very important question. How many exposures may a roentgenologist make of a certain portion of the body? How much heavier dose is a safe dose? Has the patient been radiographed before presenting himself? If so, when, how many times, and how long? These are factors for the roentgenologist, be he a radiographer or a radiotherapeutist, to consider when a patient presents himself for a radiogram or for radiotherapeutic treatment. Dr. Witherbee[10] has given us a working formula for the greatest number of exposures in a given case that can be made without producing a roentgen-ray burn or to produce an erythema or a temporary or permanent alopecia, but it is figured without the consideration of the personal index of debility or susceptibility. One skin unit is represented thus:

$$\frac{3\ (\text{spark gap}) \times 3\ (\text{ma.}) \times 4\ (\text{min.})}{8\ \text{in.} \times 8\ \text{in.}} = \frac{9}{16}$$

a dose "producing temporary alopecia."

Substituting skin distance 12 in. for plate distance given in the "Army Manual" of 20 in. in A. P. head of which the factors are 5 inch spark gap, 40 ma., 1/5 min., plate distance 20 inches.

$$\frac{5\ (\text{spark gap}) \times 40\ (\text{ma.}) \times 1/5\ (\text{min.})}{12 \times 12} = \frac{5}{18},$$

and dividing the fraction representing a skin unit by the fraction just obtained where skin distance has been substituted for plate distance we have:

$$\frac{9}{16} \div \frac{5}{18} = 2\ 1\ 40 \text{ plates or } 2 \text{ plates}.$$

That is two exposures for A. P. head radiographic work under above spark gap, ma., time and distance would be a dose producing a temporary alopecia. In like manner the number of safe exposures (excluding the personal index of health, susceptibility, and previous exposures) that will produce said effect can always be computed by dividing $\frac{9}{16}$, representative of 1 skin unit, by the fraction obtained through substituting in the formula the skin distance for the plate distance. An aluminum filter 1 mm. thick will permit "6 times the number of plates" allowed without filters without endangering the patient (excluding the consideration of other

factors as previous exposures, state of health, and susceptibility).

Witherbee warns against "overlapping the areas exposed," and in order to avoid *x*-ray burns from a patient going from one laboratory to another advises the use of an *x*-ray history—we might say chart—including a record of spark gap, milliamperage, time, distance, number of exposures, date of last exposure, and patient's position. We should say "with dates," for who knows with an erratic patient which exposure would be his last? By following Witherbee's advice, and taking into account susceptibility and state of health as factors, *x*-ray burns may be avoided as you may determine whether your dose is given too soon, as to time, or too much, as to strength, remembering the time required for an erythema to appear—10 to 14 days—and to disappear, which is about from 2 to 6 weeks. For those who use an interrupterless machine and a Coolidge tube, valuable information may be found in this article by Dr. Witherbee.

Tousey thinks "about 3 ma.. with a 6 inch resistance, 10 inches distance, for one minute is a normal dose of ½ H. which may be repeated every two or three days until a reaction gradually becomes established." A Holzknecht unit is "the discoloration of the platinocyanid pastil at skin distance or at the same distance as the skin," according to some operators 1 H. measured at skin distance "is an erythema dose equal to 4 H. with the pastil at one-half the distance to the skin," which latter is the original method. Hirsch[12] has noted "the absorption of the roentgen rays by a substance depends upon its thickness, its atomic weight, and its density" . . . . and the penetrability of a body depends not only upon the facts given (inversely in proportion to their density, atomic weight, and thickness), but also upon the variety of *x*-rays used. It is often thought that hard rays are not so dangerous as soft rays, but they have a marked effect on the deep structures as noted in tonsillar radiation, where a 7 in. spark gap, 4 ma. of current, 15 inches distance was used for 7 min. over each tonsil. In one instance it produced an oedema of the neck resembling mumps, only also noticeably affecting the neck below the chin, although no erythema resulted until the second treatment.

X-rays have a *cumulative* effect. Dermatitis may follow a single exposure without filters, the patient being exceptionally susceptible; or, if heavy, even with filters; or if too prolonged; or if the patient is too close to the tube. It may develop in from one to fifteen days. It may follow a number of moderately heavy doses covering too long a period of time. In radiographic practice it is apt to follow one or a few heavy exposures. If raying be combined with fluoroscopy it may follow because of too long exposures. In radiotherapeutic practice, it is more apt to be the cumulative effect of fractional doses covering weeks or even months, or to be the effect of a few heavy doses repeated at, comparatively, too short intervals. Codman[13] reported three cases of dermatitis appearing after the fourth week. Fuchs[14] reported a case where there was a development of vesicles 15 minutes after exposure. I recall one case following twenty-two exposures with a current of 2 ma., 4 in. spark gap, 15 in. distance for 15 min. without filters. Another followed an exposure of 7 inch spark gap, 4 ma., 7 min., 15 inches distance with filters of 2 mm. of aluminum. Dermatitis may also *recur*, as noted by Pusey and Caldwell[15] in the report of three severe cases of dermatitis having "a superficial necrotic membrane; relapses occurred in each case approximately two months after the disappearance of the first dermatitis."

Haxthausen[16] has recently reported the development of a case of *x*-ray ulceration nine months after the treatment. A weeping dermatitis following an erythema occurred several weeks after the last exposure, and disappeared after a few weeks following the use of ointments. A second erythema, followed by ulcerations, occurred nine months later after the exposure.

Precaution must be taken in cases that have been exposed to artificial freezing, fulguration, or any process lessening the vitality of a part as an *x*-ray dermatitis occurs more quickly in such tissue.

The *proximity* of the tube is of considerable importance. As a rule from 13 to 15 inches from the target is the minimum distance from the body, the distance being increased with increased thickness of the body. The operator should never hold the patient where exposed, or hold the film or plate.

The *length* of the exposure depends on the strength of current. The greater the strength, the shorter the time. An intensifying screen or duplitized films will lessen the exposure time and the milleamperage required.

Idiosyncrasy is also a factor in spite of Kienbock's[17] theory. There is a great difference in the susceptibility of people in respect to condition and resistance. Sometimes in a case of lupus erythematosis or butterfly lupus there will be a dermatitis from one or two treatments with 2 ma. of current with a 4 inch back up for 10 min. without filters with the anticathode 15 in. distant. Codman[18] believes that the susceptibility of a patient varies "in the dryness or dampness of his skin, in his electrical resistance, in his anemia or plethora; in the acidity or alkalinity of his sweat, in his vasomotor irritability." The question of alkalinity is of special importance, as in radiotherapeutic practice we are treating debilitated cases representing hyperacidity. Charrin[19] gives the blood's alkaline reaction the first place in the immunizing processes of the body. We use sodium bicarbonate in these cases. It increases the alkalinity of the blood and lymph and so increases the power of the plasma[20] to "absorb CO_2 from the tissue and then to eliminate this gas." Lange also found that unfavorable symptoms are mitigated when an alkaline medium is used.

We once treated a patient who was highly susceptible to the *x*-rays for a fibroid tumor. Severe itching and a stinging condition, "due to secondary overdilatation of the arterioles and hyperemia of the skin, and its sensory nerve endings," occurred similar to that following large therapeutic doses of diphtheretic antitoxin; petechial spots on the lower limbs followed this stage, although the patient had been most carefully screened.

There is also a difference as to the susceptibility of parts, as the ear or nose will react more quickly than the hand, and owing to the cartilaginous character of the ear the dermatitis is more difficult to

cure. Dr. William Benham Snow[24] noted seventeen years ago that the physical condition of the patient should be considered. "Aged people and those whose vitality is reduced by sickness are more susceptible to the injurious effect than persons in good health," which we have since seen emphasized in our practice. This is also true when the patients are cachectic, asthenic, or toxic, as noted by Lange.[25] The blood is also a factor, owing to changes in its cellular content.

In a paper[26] entitled "The Examination of Patients in Ultra-Violet Radiation," reported in the *Archives of Radiology and Electrology*, September, 1920, note was made that at the Institute patients showing a "spotty appearance" on being exposed to a beam of ultra-violet radiation, or in photographs taken in a particular manner with an arc lamp, were more "susceptible to radium radiation than the relatively unspotted. Some are almost free from spots, while others are thickly covered." This might give the radiologist a clue as to a patient's susceptibility to radiations.

Dr. A. J. Pacini[27] has tersely stated factors worthy of consideration as follows: "The same character of relative change in radiability induced by pathology that one secures in a certain location has an entirely different value in some other region of the same viscus. So that the orientation of the modulant must be studied in the light of the reaction of the normal physiology effect against the pathological invasion. All pathology invading the human body, if it produces registrable *x*-ray evidence, that evidence will be manifested as a variant from the normal according to one, two, three, or all four of the *x*-ray modulants. (1) Changes in radiopacity without great change in structure; (2) obliteration of gross histology by superadded material; (3) elimination of gross histology by tissue displacement and (4) changes in the relative size of a histologic group."

An *x*-ray *dermatitis* is similar to any other when beginning. It often passes unnoticed by the novice, so he is apt to ray his patient with the result of a dermatitis of the second degree. It is well to ask a patient to notify you of the presence of a noticeable blush or erythema when bathing, for the change is noticed sooner after bathing the part. Tousey[25] has noted that the Cooper Hewitt mercury vapor lamp, which is deprived of red rays, will reveal the earliest dermatitis. An *x*-ray dermatitis has a well defined outline corresponding to the diaphragmatic opening or size of the cylinder or cone used, or opening in any protective covering used. The patient may first complain of a slight itching or a sensory disturbance. When it follows accumulated doses, as when the fractional dose method is used, it is usually preceded by tanning. Otherwise a single heavy dose may cause an erythema which will be followed later by tanning. Occasionally the redness will develop before the tanning in certain conditions, especially in lupus cases. It may cause freckling in some cases. Telangiectasis sometimes, but rarely, follows one exposure. Some authorities think it follows only a severe burn, but I have seen four such cases follow a light raying. At the present time we are treating a case of epithelioma where the skin shows that tendency even before raying. We are using the static brush discharge and have given her but four rayings besides warning her of the possible outcome if the ray is to be used as her case demands. Dermatitis may occur as an acute or chronic dermatitis, or as relapses. William Benham Snow[28] noted, in 1902, "dermatitis, when it does occur, as it is certain to in all cases except when special precautions are taken, as in the treatment of acne, and the conditions in which it is used for its tonic effect, may appear in one of three types, which are similar to the dermatitis arising from other irritating causes. The condition has been well described by Beck, as follows: "The *first* is characterized by hyperemia, infiltration, increased temperature, exfoliation in small scales, associated with a tormenting itching. It seems that there is a retrogressive metamorphosis (atrophy) of the differentiated elements of the skin, viz, glands, hair, and nails. The main feature of the *second* degree consists in the formation of blisters—the inflammatory signs are well pronounced, the tension considerable, and the pain intense accordingly. After the blisters are removed the corium is exposed as a red and sore surface—bullous form of roentgen ray dermatitis. The *third* and gravest degree is characterized by the escharotic destruction of irradiated tissues. They show the sign of dry gangrene, and appear brownish black. If they exfoliate by a slow suppurative process, or, if they are removed, as they should be, by surgical interference, a granulating ulcer remains, the cicatrization of which may take months—the necrotic form of dermatitis."

Many authorities consider four stages of dermatitis, calling a temporary erythema the first degree. This may last from two to ten days. The second degree of dermatitis ends in vesicles or bullæ. If unable to diagnose an *x*-ray dermatitis from a dermatitis from other sources, factors already mentioned may be considered which, with a perusal of Dr. John H. Stokes' article on a "Scheme for Presenting the Subject of the Inflammatory Dermatoses to Students in Terms of Fundamental Cutaneous Reaction Signs,"[27] will make a decision conclusive. If the vesicles rupture, there is a weeping surface covered later by a pale grayish covering. A third degree shows a dark red surface, ruptured vesicles or bullæ causing a wet surface covered with a yellowish gray membrane which when removed leaves a raw bleeding surface. There may be itching, burning, fever, or sleeplessness, with or without nausea. Recovery takes place in periods varying from six weeks to several months. Pigmentation or telangiectasis, which is apt to persist, may follow. A fourth degree is characterized by a bluish red contracted skin. Necrosis underneath is followed by a "hard, leathery, dark grayish mass of mummified tissue," with an indurated inflamed periphery. In the treatment of many cases it is necessary to bring about a first degree dermatitis in order to obtain the best results, as, for instance, in pustular acne the best results follow after the induction of a temporary erythema. To ray sufficiently to bring this about without having a second or third degree dermatitis following is of the utmost importance. Even in post-operative raying best results follow an erythema dose or its equivalent. The erythema requires no special attention except suspension of treatment until it subsides.

Vaseline or zinc oxide ointment usually allay any slight itching or burning sensation, or a reflected incandescent light arrests troublesome symptoms.

Occasionally a case may show a faint pinkness directly after an exposure which disappears before the next exposure. The freckling may last a long time. The tanning may disappear in a few weeks or may last from six to eight months. Hair as a rule will regenerate in from four to twelve weeks. Sometimes a longer time is required, dependent on the dosage employed. Sometimes, but rarely, the hair does not return. New nails form in the course of a few months, as in cases of paronychia, where a dermatitis of the first degree is desired, but where the operator must be exceedingly careful to induce a first degree dermatitis *only*, as the nails react very quickly. In dermatitis with vesiculation, the crisis of the reaction may occur in from one to two weeks, then follows a period of quiesence from two to seven days. Several weeks may elapse before all signs disappear.

(To be continued.)

VIEWS REGARDING CONDITIONS IN THE BILE TRACT.

By L. WINFIELD KOHN, M.D.,

NEW YORK.

A KEEN interest has lately manifested itself in the study of the biliary system and for the extraordinary revival of spirit in this direction, the work of Lyon[1] must be given its well-earned credit. Through his work our access to the biliary system seems not as far removed as it formerly did, but should it be proven that we are still distant from our goal his work will at least have enjoyed the satisfaction of having given the great impetus to studies that we hope will bring to us a better understanding of the biliary tract. Should Lyon's contentions which are based more or less upon Meltzer's theory of contrary innervation prove not entirely compatible with future ideas that are liable to result from work along these lines, it must be admitted that the effort made by him seemed to be founded upon logical reasoning.

The theory of contrary innervation has been accepted by many of our physiologists in so far as it applies to muscular movement of the alimentary tract, and some of them subscribe their acquiescence as to its control of the musculature of the biliary tract but the fact nevertheless remains that scepticism attaches to such an admission. However, should this be the true nature of the function of the biliary tract, it would still seem improper to solve our biliary problems according to this principle alone, for it appears from the standpoint of the Meltzer-Lyon method that unless the gall bladder or common duct evacuation predominated, our conclusions would be bound to fail us and it is just as likely as not that the flow from the liver itself is quite prominent or even predominant.

Origin of Bile.—A great deal of reflection and thought arises as to the origin of the different types of bile mentioned by Lyon. He contends that the light-colored A bile comes from the common duct, the darker B bile from the gall bladder and the lighter C bile from the liver. If that were absolutely true, our solutions of many of the problems affecting these respective portions of the bile tract would be readily realized, but a great question arises as to the validity of such an assumption. It can readily be appreciated how upon Meltzer's theory of contrary innervation and from the result of his studies with magnesium sulphate solution upon the duodenal mucosa of the dog, Lyon came to the conclusions that he did and his connection of thought in this direction seemed logical but that does not prove that conditions are really as he concluded.

The fact that magnesium sulphate solution when applied to the duodenal mucosa results in the creation of an emission of biliary material into the duodenum is not doubted but rather proved in practically all cases. That the papillary sphincter is more or less relaxed is also admitted because, if it were not so, how then could bile have been ejected into the duodenum. That the gall bladder contracts simultaneously with the relaxation of Oddi's sphincter or that it distinctly contracts at any time during the course of the magnesium sulphate treatment is open to question.

The only evidence thus far indicating possible contractile effort on the part of the gall bladder is experimental in nature. Through the work of Doyon,[2] who made a study of the innervation of the gall bladder and ducts, it was found that stimulation of the peripheral end of the splanchnics caused a contraction of the gall bladder. It was also found that stimulation of the central end of the vagus caused a contraction of the gall bladder. Later Bainbridge and Dale[3] made studies of the nerve supply of these organs and from the results of their experiments and those of Doyon it would seem that the gall bladder receives both motor and inhibitory fibres through the splanchnic nerves. The influence of the vagus is also rather prominent, and Howell[4] states that we may assume that in the normal reflex emptying of the gall bladder the afferent path for the reflex is formed by the vagus fibres while the efferent path is through the splanchnic nerves. According to Bruns[5] no bile appears in the duodenum as long as the stomach is empty but when a meal is taken the ejection of chyme into the duodenum is followed by an ejection of bile.

Shall we account for the ejection of bile into the duodenum after chyme had previously entered it upon the principle of reflex activity? And is this reflex characterized by a contraction of the gall bladder and a simultaneous relaxation of the sphincter of the papilla of Vater? Does the ejection of bile into the duodenum necessarily bespeak a contraction of the gall bladder, or is it possible that this bile flow may have its origin from some other source particularly the liver.

Records made of the contractions of the gall bladder musculature show that the force exerted is quite small. Freese,[6] according to his observations, discovered that the maximal contraction did not exceed 220 mm. of water, a force about equivalent to the secretion pressure of bile as determined by Heidenhain.[7] From this, would it not seem just as logical for us to assume that the ejection of bile during a magnesium sulphate treatment owes its origin as much or even more to the liver than to the gall bladder. This view is strengthened by the fact

that up to the present time no real practical demonstration of the Meltzer theory as applied to the biliary tract has taken place.

Furthermore, in a recent paper read by Crohn,[8] he stated that in experiments performed upon narcotized dogs, he found an almost continuous flow of bile into the duodenum following the administration of food but that this bile was liver and not gall bladder bile. By having previously injected some methylene blue solution into the fundus of the gall bladder so as to distinguish gall bladder bile, he was unable to demonstrate a flow of this bile into the duodenum except upon manual expression. Just how much untoward influence the narcosis had upon any possible contractile effort of the gall bladder should not be overlooked. It is also believed that the metabolic processes in the liver cells which produce the bile secretion probably go on at all times but they are increased when the blood flow is increased.

Now, what conditions may so affect the blood flow as to cause an increased secretion of bile? Is it not likely that magnesium sulphate solution creates a condition which so affects the blood quality or blood flow in the liver as to favor an increased secretion of bile? Before we dare lay any stress upon the nature and significance of B bile, some definite conclusions regarding its origin should be reached.

From the foregoing, it is very evident that difficulty arises when we try to definitely associate A bile with the common bile duct, B bile with the gall bladder and C bile with the liver. We must admit that if the common duct contains bile to any extent, the first bile eliminated or socalled A bile must necessarily have included it, but the question arises, how long was this bile a resident of the common duct and how much of it existed in the common duct long enough to deserve the identification given to it? As already stated Bruns contends that no bile appears in the duodenum so long as the stomach is empty, yet the first thing most of us hope to find after passing our duodenal tube through a fasting stomach into the duodenum is bile or, at least, bile-stained material. That is the usual manner whereby most of us realize that the tube has entered the duodenum. If, as often happens, we find a fairly large biliary content within the duodenum, how long a time has elapsed since the ejection of bile into the duodenum and how long has the present common duct bile resided there? Are we privileged to definitely associate the A bile with the common duct and does this lighter A bile come almost entirely from this region? As for B bile, are we correct in assuming that it comes almost entirely from the gall bladder simply because of its darker color?

Of course it seems logical to associate a dark bile with the principle of concentration and the idea of concentration with the gall bladder, but that does not give us absolute proof nor overwhelm the objections raised. Einhorn[9] and many others feel that this change in color does not necessarily imply an emptying of the gall bladder but that it results rather from the action of magnesium sulphate upon the liver and its secretion, the bile.

I have also observed in a patient upon whom a cholecystectomy had previously been performed (4 years ago) that after a magnesium sulphate treatment a rather dark bile was ejected on a few occasions. Many of us will also recall the fact that in cases following cholecystectomy the biliary fistula for days emits, in many instances, large quantities of dark bile.

From what has been said, it is very evident that dark bile does not of necessity originate only in the gall bladder. That some of the B bile may come from the gall bladder after a magnesium sulphate treatment, cannot be absolutely denied but to contend that it comes principally from the gall bladder raises criticism. That C bile comes from the liver and smaller hepatic ducts is not a poor supposition; the greater part of it very likely does, but to lay no emphasis upon the association with it of bile from the gall bladder or cystic duct, let alone pancreatic fluid during its passage toward the duodenum, seems rather unreasonable. In fact, the presence of pancreatic fluid throughout the entire biliary outflow should not be overlooked.

Bile Flow.—We should not assume that the gall bladder and its duct empty themselves at one stage before the hepatic bile comes down from the liver for it may develop that these organs never entirely empty themselves or if they should, may do so in a rather sluggish manner.

Where then, does the bile flow initiated by the magnesium sulphate solution or other substances originally begin and of what bile does it in the main consist? Does the bile flow forth in the orderly sequence suggested by Lyon from the common duct, gall bladder and liver or does it all come directly from the liver, in spite of the variation in colors, or is it a mixture of all three biles in varying proportion throughout its transmission?

To my mind it seems that the greatest quantity comes directly from the liver itself and as it flows toward its outlet becomes admixed with the bile of the ducts and gall bladder in the proportion that these biles are present in the pathway of travel or as they are disposed to enter this pathway. To associate the bile with the different portions of the bile tract as Lyon has done is a beautiful way of trying to view the situation but requires further proof to justify the idea.

No doubt many of us are inclined toward the belief that the magnesium sulphate solution acts either as a hormone, reflexly or through osmotic influence, and we can hardly be discredited for such an opinion. May we not properly presuppose that the magnesium sulphate solution stimulates liver secretion just as bile salts are claimed to stimulate liver secretion, or just as food stimulates the secretion of gastric juice, except that in addition we have the hypertonic influence of the salt solution? In other words, as we may have a digestive hypersecretion so may we have a liver hypersecretion or pancreatic hypersecretion if the proper stimulus is applied, and it is not unlikely that the outpouring of bile after the magnesium sulphate treatment is due to liver hypersecretion principally rather than to a simple evacuation of the contents of the gall bladder and ducts.

Quantity of Bile.—The question of the quantity of bile is another interesting point for consideration. The amount of bile secreted during a day in the average individual varies, according to Copeman and Winston,[10] between 500 and 800 c.c. This

was an estimation made through the medium of a biliary fistula. The rate of the secretion varies considerably during the different hours of the day. It is greatest following a meal and least during the period in which the stomach is empty.

It is taken for granted by most physiologists that the secretion of the liver is a continuous procedure but that its rate of secretion can be either reduced or increased. Starvation reduces it, whereas the administration of food increases it. According to the above estimate the average amount of bile secreted is from approximately 20 c.c. to 35 c.c. per hour except during those days when great quantities of food are eaten when the quantity of bile is considerably increased.

The magnesium sulphate treatment for administration and response on the part of the patient varies as a rule anywhere from 10 or 15 minutes to an hour for completion, with probably 30 minutes as the average. During this time according to Lyon, the A bile in the normal individual amounts from 10 c.c. to 20 c.c. in quantity and the B bile no greater than 75 c.c. in quantity. From this would it not seem logical for us to conclude that the magnesium sulphate solution stimulates an increased liver flow similar to the effect produced by foods? Are we not impelled to lean toward the principle of biliary secretion coming from increased hepatic activity rather than a mere emptying of the gall bladder and ducts?

I have also noted that in a patient who had her gall bladder removed about four years ago, the amount of bile thrown out after treatment with magnesium sulphate varied upon different occasions, but at all times large quantities were obtained. During the period of drainage which took up anywhere from 20 minutes to an hour or more, from 75 c.c. to as much as 200 c.c. of biliary material was eliminated. Usually, it was found that from 60 c.c. to 100 c.c. wandered forth within the first half hour. This large amount of socalled bile, of course, did not come from a gall bladder and therefore must have come from some other source and that source very likely is the liver except for whatever quantity may have arisen from the pancreas.

From the observations made, I am not inclined to look with great favor upon the presumption that large amounts of dark bile bespeak a gall-bladder atony but would rather lean toward a diagnosis of liver hypersecretion, by which is meant an increased flow of bile established through the principle of nervous, hormonic, or osmotic influence. However, in spite of my opinion in this matter, it is not to be absolutely denied that such rare conditions as hydrops of the gall bladder or gall-bladder atony, if such latter condition exists, may have some bearing upon the emission into the duodenum of large amounts of dark bile. How much bile during a treatment passes through the intestinal tract by evading our duodenal tube? If this amount of bile should prove considerable, we may feel urged to discount the assumption that the bile eliminated following a treatment is mainly from the gall bladder and ducts but rather from a secretory source such as the liver and possibly to a certain extent the pancreas.

Recently in private and clinic work a series of cases were studied and it was discovered that the quantity of biliary material ejected varied with different people as well as with the same individual on different examinations. It was observed that by simply passing the duodenal tube through the fasting stomach into the duodenum, without the administration of magnesium sulphate solution, a flow of biliary material was established and this flow would continue more or less constantly for hours. Quantities varying anywhere from 20 to 300 c.c. were obtained and took from 20 minutes to 2 hours or more for accumulation. Generally, the longer the tube remained *in situ*, the greater the accumulation. This material was distinctly viscid biliary fluid and varied in color from a pale lemon yellow of thinner consistence to a deeper dark yellow or brownish yellow of thicker, more viscid consistence. Upon two occasions there was noted very dark brown bile and a heavy gritty, dark brown or black sediment. Of course, some of this total emission probably contained duodenal secretion and gastric secretion but the distinct biliary quality predominated from a physical point of view.

These findings were all made without the introduction of magnesium sulphate and after the stomach had fasted a number of hours. They seem to be at variance with the statement of Bruns' "that no bile appears in the duodenum as long as the stomach is empty." Just what influence the presence of the olive tip within the duodenum or the body of the tube within the stomach has upon the secretion of bile or the relaxation of the papillary sphincter is for us to determine. Later in all of these cases the magnesium sulphate treatment was given and then usually there occurred after ten to fifteen minutes the flow of lighter bile, to be followed afterward by a darker bile and then later the light yellow bile again.

From observations upon these cases I have been led to conclude that what the duodenal tube gives us without magnesium sulphate in a longer period of time, the injection of magnesium sulphate gives us in much shorter time. It seems to me that the tube alone within the duodenum collects a bile slowly being secreted from the liver in addition to whatever other biliary material may ooze forth from other portions of the tract. After magnesium sulphate, a liver that has been actively stimulated gives expression to larger quantities of bile and this outpouring we gather up within a comparatively short period.

Color of the Bile.—The color of the bile will also vary at different studies upon the same individual. It will not always show precisely the same conditions, although as a rule following magnesium sulphate a darker bile followed a preliminary lighter outflow. How shall we account for this? Is it possible that at first, the initial flow assumes a thinner consistence therefore a lighter color and later a concentrated character, therefore, a darker color? Has the magnesium sulphate solution through its hypertonic nature osmotically solicited a watery outflow at first and later before the osmotic relations are normally reestablished caused a concentrated biliary outflow? After all, are we correct when we attempt to lay important significance upon varying biliary colors?

Force of Bile Flow.—Though there may possibly

be moments when the gall bladder contracts or when, through an increase of muscle tension, it tends to urge its contents forward, it does not seem necessary for this organ to be concerned in arousing or maintaining a bile flow. It appears that when bile flows into the duodenum the force of the flow has its inception in the activity of the liver. As it is secreted, it continues to flow onward and the simultaneous relaxation of the papillary sphincter encourages the flow by removing a natural obstruction. As the flow continues it is very likely that from time to time portions of bile that had accumulated in the gall bladder and cystic duct, as a result of back pressure due to a former closure of the papillary sphincter, may join the main flow of bile and continue on its way. Therefore, it seems that the impetus for the flow primarily originates in liver secretory activity and either through a transference or transmutation of force continues to urge the accumulating bile along the path of least resistance. Relaxation of the sphincter papilla removes an obstruction and thus augments the rate of flow.

Another principle which may enter into the facilitation of the flow is the aspiration influence on the part of the active bowel below the level of the sphincter opening. It can readily be appreciated how a peristaltically active bowel with a movement of air and intestinal contents analward may through the medium of aspiration and an open Oddi's sphincter continue to aid in the elimination of bile from the bile tract.

In a recent paper by Aaron,[1] mention was made of the fact that the coloring agent phenoltetrachlorphthalein—which was given intravenously to normal patients—was shown to have been eliminated by the liver through the medium of the bile and appeared at the external end of the duodenal tube within fifteen minutes after the injection had been made. This alone, indicates that the liver is a very active organ and fosters an energetic bile flow.

Bile Constituents.—Since it appears that the so-called bile which enters the duodenum, with or without magnesium sulphate treatment, may come from a number of sources as the liver, hepatic ducts, cystic duct, gall bladder, pancreas and pancreatic ducts, it also seems impossible to definitely and correctly associate any of the finer findings of this bile with distinct portions of the tract. Very often the constituents of the bile present ill-defined characteristics which can have no significance. Neither should such recognizable elements as erythrocytes, leucocytes, mucus, bile salt deposits, etc., be definitely ascribed to certain portions of the tract. One may assume that some of these elements, because of their association with quantities of formed elements (epithelium), indicate disease at the site which corresponds to this epithelium but the possibility of error is always attached to such an assumption. Exfoliated epithelium is a common accompaniment of all excretory material and it is not unlikely that any of the constituents may have either gravitated or been wafted down from above prior to the magnesium sulphate treatment. Consideration of the bacterial content or bacterial potentiality of the bile is purposely avoided because of the great doubt expressed by most students of this subject regarding the significance of its application to diagnosis of disease of this tract.

Therapeusis of Magnesium Sulphate—In a recent interview with Lyon the fact was ascertained that *cholecystectomized* patients to whom he had given the magnesium sulphate treatment evidenced greater and more marked improvement than the *cholecystotomized* patients. Would this result not be accounted for simply upon the basis that the cholecystectomized patients were receiving a more thorough biliary cleansing from above down than the cholecystotomized cases? In the latter type of case a diseased gall bladder, like a diseased diverticulum, was too far removed from the avenue of cleansing, the common duct and since the gall bladder was unable to adequately express or rid itself of its diseased contents, the patient continued to suffer manifestly.

One thing, however, is certain and stands out most prominently and that is the fact that subjective improvement following magnesium sulphate treatment is a reality. This alone will, for some time to come, give the duodenal tube and magnesium sulphate solution a place in the treatment of biliary disease. Just how to account for this decided improvement in the subjective condition of the patient is for us to determine, but it seems that the biliary "housecleaning" instituted by the magnesium sulphate is responsible for it. This biliary cleansing that follows the intraduodenal application of magnesium sulphate solution seems to correspond very much to the Carlsbad cleansing that patients experience at the Carlsbad springs or at other springs where similar water is imbibed. Constantly drinking this spring water throughout the day results in the probable stimulation of liver and bowel glandular activity as well as an outpouring of fluids because of osmotic variations and in consequence the patient feels subjectively improved. We are all well aware of the great improvement that many socalled indigestion cases, liver and gall bladder patients, and constipated individuals experienced after taking the Kur at Carlsbad. When we give patients the intraduodenal magnesium sulphate treatment, are we not simply applying the Carlsbad or French Lick Springs treatment in a different manner?

Conclusion.—In conclusion, the following points must be borne in mind:

1. That studies of the biliary tract through the medium of expression of biliary material into the duodenum open up a new field of investigation for which Lyon is responsible and deserving of great credit, although the principles upon which his studies are advised are open to attack.

2. That to recognize by this method the existence simply of disease within the biliary tract, without specifically confining the diagnosis to any special part, is warranted.

3. That to diagnosis the existence of disease in the gall bladder alone, to the exclusion of disease in other portions of the tract, through studies of the quantity, color, consistence and constituents of the biliary outflow does seem somewhat unjustifiable. It is not unlikely that in those cases, where disease existed within the gall bladder, it also in most instances existed within other portions of the tract.

4. That the performance of cholecystectomy in the past most likely resulted in failure from the standpoint of subjective improvement because of the fact that disease which usually coexisted within other portions of the tract was not removed but remained to continue its ravages upon the remainder of the tract. It is not improbable that the disease very often profoundly established itself within the smaller hepatic ducts.

5. That conservatism must be practiced not only regarding the performance of surgery in biliary tract diseases but also regarding the continuation of the use of this latest biliary drainage method. No doubt that biliary drainage will benefit us a great deal but like every new idea is very often enthusiastically misapplied. In spite of the progress made surgery of this tract will for some time to come receive the indorsement which indications shall warrant. Medical cases will be favorably influenced by drainage but we can hardly look to drainage for the cure of a surgical condition.

VITAMINES IN INFANT FEEDING.

BY F. TWEDDELL, M.D.,
GREAT NECK, N. Y.

WE have been hearing a great deal about vitamines during the last few years, but I have noticed that not much use has been made of these most necessary and vital food ingredients in infant feeding. In the early months of life, the proper feeding of infants, even of healthy ones, at times taxes all our resources. In difficult feeding cases we are up against it, and often we do not know what the outcome will be; it is in fact a matter of life or death for the baby.

Any method of feeding or any food ingredient which helps towards overcoming stationary weight or loss of weight in infants, should be most welcome to those of us who take care of these helpless mites. For this reason I wish to report a new method of treating these cases. Some six years ago I attended a baby seven weeks old with bronchopneumonia. The mother had pulmonary tuberculosis and the father was not quite right mentally, for he attempted suicide the year before and succeeded a year later. The family history was therefore bad. When nine weeks old the baby was convalescing but not gaining in weight, which was seven pounds. Just about that time I had heard a good deal about vitamines and decided to try them in the shape of the yolk of a raw fresh egg, beaten up in the milk mixture. The baby gained steadily in weight and at six months of age was a normal healthy child. I lost track of it then. I gave no further thought to this matter until the fall of 1919 when two feeding cases came under my care. Both were eight weeks old and weighed eight pounds apiece. One of these was nursed for only two weeks and then its food was changed and modified every few days because it would not gain and vomited once or twice a day. On inquiry I found that the vomiting was projectile in character and had no reference to the food. There was constipation but it was not very marked. Here then was a case of pylorospasm, which had been overlooked. I put the child at once on appropriate doses of atrophine sulphate and noticing marked improvement after three days, I began feeding it on the yolk of a raw fresh egg beaten up in the milk mixture. This child gained in weight by leaps and bounds, never less than 12 ounces a week, often 14 ounces and once 16 ounces in a week. At four months of age it weighed 15¼ pounds, gaining 7¼ pounds in less than two months. As the egg agreed it was given every day so that at nine months the baby weighed 20 pounds and at 12 months, 24 pounds. A big baby, perfectly well, with firm flesh—nothing flabby like one gets with proprietary foods. Now at 22½ months, weight 31 pounds, height 36¼ inches, head 19 inches, chest 20¾ inches.

The other infant weighed at birth 9¼ pounds and was nursed until eight weeks old, but was not doing well and weighed then only eight pounds. The mother was a nervous woman, very much under weight. I put this infant on the yolk of a raw fresh egg and at four months it weighed 14¾ pounds. A few days later I noticed that the baby had lost his appetite, was cranky, and that the stools were gray, almost white. I concluded that this was fat indigestion, both from the milk and the egg. The parents kept Jersey cows and the milk was exceedingly rich. The baby was put on skimmed milk alone for a while and the yolk of an egg given only occasionally. When 12 months old he weighed 25 pounds and now at the age of 21 months, weighs 29 pounds, half a pound more than his sister, who is 13 months older. This sister was fed according to the usual method. This baby, now 2 years old, weighs 32 pounds.

There is no need to cite other cases, they are very similar. Vitamines alone are responsible for this amazing gain and improvement, for nothing else could have brought this about. Then why not give eggs? Most pediatricians do not give eggs until babies are about 12 months of age, as Holt and Howland,[1] some not till 18 months of age, as Morse and Talbot.[2] When I reported these cases at a medical meeting, it was remarked that this was a very risky thing to do. This is not a matter of daring, it is a matter of common sense.

The reason why I did not give a coddled egg or a soft boiled egg, as is the custom, was very plain. I consulted a gentleman farmer in my neigh-

borhood, a graduate of Harvard, who informed me that when eggs in incubators are heated over 108° F., or 110° F., for a few minutes, they are spoiled. A chemical change has taken place. Why should I change the chemical nature of a raw egg? I consider a coddled or soft boiled egg not as digestible as a raw egg, and a hard boiled egg would be out of the question altogether; this is self-evident. The yolk of a raw egg contains all the mineral matter necessary to form a chick: the bones, muscles, nerves, etc., and all these minerals, such as iron, sodium, potassium and what not, are in colloidal combination with ample vitamines, both fat soluble and water soluble. I never thought it necessary to give the white of the egg, as this is only a protein and of this we have plenty in the milk. Besides it is very difficult to mix the white with the milk.

The food is prepared as follows: Make up the milk mixture for the whole day, say 40 ounces of a 7 in 20 mixture, *i.e.* 14 ounces of milk to 26 ounces of water or barley water, and the necessary amount of sugar. Pour 8 or 10 ounces into a bowl, drop the yolk of a raw fresh egg into it and beat it up with an egg beater. Then add this to the rest of the milk mixture in a pitcher and stir thoroughly and place this in the ice box. At no time must the yolk be put into the milk when it is over 100° F., nor should the egg and milk mixture ever be heated above this temperature.

Of course before feeding a baby on this egg mixture, it is well to test the baby and find out if the egg will agree. A few infants cannot take eggs. The test is made as follows: Half an hour before the next feeding when the stomach is likely to be nearly empty, give the baby half a teaspoonful of the white of a raw fresh egg. If it agrees, nothing will happen. If it disagrees, the baby will vomit, or it may have sudden diarrhea and feel sick for a few minutes, and a rash may appear all over its body resembling "Liberty" measles (rubella). These apparently alarming symptoms disappear in a few minutes. A better and more satisfactory test is to inject the albumin intradermally similar to the tuberculin or Schick tests. If there is no reaction, eggs can be safely given.

As the yolk contains 25 per cent. fat it is advisable to watch the stools for fat indigestion as shown in one of the cases cited above. The eggs shou'd be fresh, not more than a few days old, preferably obtained from a neighbor or a farmer. Don't take chances.

What are we to give to the few babies who cannot take eggs? I had often thought of this and would have given yeast a trial on account of the water soluble vitamines which it possesses. But yeast contains ferments and other undesirable ingredients which could not be suitable for an infant a few weeks old. Fortunately I have discovered that various manufacturers are now making vitamines which can be used in those feeding cases when eggs do not agree, and I shall take the earlist opportunity to test these vitamines.

The ordinary milk mixture for infants is so much diluted, pasteurized and boiled, that it cannot contain much in the way of vitamines, and one wonders how infants gain at all. I hope therefore that this new method of feeding will help towards solving this difficult problem.

THE DIAGNOSIS OF VARIOLA BY INOCULATION OF THE CORNEA OF THE RABBIT.*

By W. H. HOFFMANN, M.D.,
HAVANA, CUBA.

For many years a great number of investigators have been spending much time and labor to find the cause of smallpox; but up to the present date this question cannot be considered as settled, although many organisms have been described as the causal agent. Among these assumed organisms special attention must be awarded to the so-called Guarnieri bodies. As far back as 1892 Guarnieri used the cornea of the rabbit for inoculation with variola virus, and found this to be a suitable means for studying the changes produced by that virus in the infected epithelial cells on the surface of the cornea.

If we produce small superficial lesions on the cornea of the rabbit and infect them with the virus from cases of variola or vaccine, there will appear from 24 to 36 hours later a proliferation of the epithelium at the site of the inoculation. This proliferation progresses rapidly, extends to the surrounding tissues and is followed by an epithelial desquamation in the central parts.

In microscopical sections through the altered tissues there will appear in many of these proliferated epithelial cells, and included in their protoplasm, small, round bodies, which are generally situated on or near the nucleus. These bodies stain intensely by the ordinary stains used for nucleus staining, such as hemotoxylin, and are often surrounded by a plasmatic zone, which appears in sections as a bright, transparent halo. Guarnieri considered these bodies, at first, to be the microorganism of variola, and so called them *Cytorrhyctes variolæ-vaccinæ*. These organisms which are found in the infected cornea of the rabbit in great numbers are of the same type as the organisms located, but not abundantly, in the epithelial layers of the skin of men suffering from variola.

Later investigations proved Guarnieri's theories to be only partially correct. Other investigators considered these bodies, or organisms, to be, not the causal agents of variola, but simply products of degeneration of the disease, including the cellular reaction on corpuscular elements, which may be specific for the variola-vaccine process. Recent researches tend to corroborate this last theory according to which these bodies are the product of a pathological increase and changed function of the formative cells. The *epitheliosis variolosa* produced in the inoculated rabbit cornea may be considered as a specific process of proliferative and degenerative reaction to the toxin of the virus of variola.

Paschen was the first to describe the minute,

*From the Research Laboratory, Las Animas Hospital, Habana, Cuba.

ultramicroscopical, filterable elementary bodies, which may be considered as the probable causal agent of variola. It is known that the pathogenic effect of the secretion from variola vesicles is not altered, is not changed in character, when passed through bacteria-proof filters.

Dr. Paul, employing these histopathological facts just described, succeeded in working out a simple, practical test for the diagnosis of variola.

The populations of Polonia, Russia, and Asia Minor have long been victimized by epidemics of variola for which no preventive or prophylactic vaccination has ever been used. On this rich field German scientists, skilled in both preventive and hygienic medicine, have tried the test of Paul for its diagnostic value. The additional advantage of the value of this test was worked out at the same time in the Robert Koch Institute in Berlin under exact laboratory observations.

During the past year variola of a very mild type has been brought into Cuba from Haiti and Jamaica. It is also frequently found in the United States, but it is of such a mild character as to create much difference of opinion among the medical profession as to the degree of virulency or the relation of this form of variola to smallpox. Diagnosis in these cases has often been extremely difficult, or overlooked, especially where single cases of the abortive type occur in areas hitherto free from the disease. From the sanitary standpoint these types of cases are of the greatest medical importance since the difficulty of diagnosis favors the propagation of the disease and interferes with the proper and necessary sanitary measures to be employed by the health authorities.

Dr. Guiteras, one time director, now secretary of health, Cuba, has shown great interest from the beginning in the application of this diagnostic test of Paul's, as a preventive measure against the spread of variola in Cuba, the danger of which seemed imminent for some time.

In the research laboratory in Havana this diagnostic method has been employed in a great number of such suspicious cases which, through their mild and uncertain symptoms, offered the greatest difficulties for diagnosis. The diagnosis in these cases has been supported almost regularly by the results of the inoculation of the cornea of the rabbit followed by histological examination of the same. Included in these mild cases were several which had recently arrived by steamer from the neighboring islands and which might possibly belong to that group of diseases often designated by the name of alastrim.

So from the sanitary and preventive standpoint just these mild cases are of the greatest scientific and practical interest, for they present the greatest danger and offer an avenue for the spread of the disease and the increase of its virulence if they are overlooked or improperly diagnosed. Therefore, medical practitioners, who, in the country, are most apt to meet the initial cases of mild variola, should fully realize their responsibility and should take immediately all prophylactic measures to prevent the development of small endemic foci. It is in such doubtful cases that the test of Paul can be so aptly applied and with the best results.

In the following account I shall give briefly a description of the method, or test, of Paul for the diagnosis of variola. It is so simple that it can be universally used since little more is required than a rabbit for inoculation and a few instruments usually possessed by every medical practitioner.

The positive reaction obtained through this test is diagnostic of variola infection, and the variola virus gives a positive reaction in 90 to 95 per cent. of suspected cases. Varicella does not give a similar reaction, as we found in Havana. The reaction of vaccine virus is also somewhat similar, but usually shows more diffuse and confluent proliferation. A negative result of the inoculation, however, does not change a diagnosis of variola if it has been based on sound clinical observations; nor should it contraindicate variola in a suspicious case.

This test of Paul brings out one essentially new point, namely, that for the practical purpose of determining the diagnosis of a suspicious case the Guarnieri bodies need not be demonstrated under the microscope. Macroscopical methods are sufficient to establish a diagnosis. Infected foci in the rabbit cornea inoculated with variola virus are not very marked. However, if the eye be enucleated and placed in a solution composed of 4 gm. of sublimate, 30 c.c. of 98 per cent. alcohol and 60 c.c. of distilled water, the infected foci will stand out completely transparent, clear and plastic.

The practical procedure used in a suspicious case is as follows:

A small quantity of the secretion from a suspicious pustule is removed by a small knife or needle, previously sterilized in the flame, and placed on a sterilized slide, cleansed by alcohol. The slide is put in a Petri dish and allowed to remain for some time. The dried secretion may be used for the test, as it has only to be moistened at the moment of inoculation of the animal, and for which either Ringer's solution or a few drops of a 50 per cent. glycerine solution in water may be used. Because of the employment of the dried secretion for this experiment the slide holding the material may be sent to a laboratory for further investigation if necessary or more convenient.

The rabbit to be used may be of any kind or size. The cornea may be anesthetized by a cocaine solution, but it is not absolutely necessary. The animal may be wrapped in a towel, all but the head, to insure greater ease in technique, and then held down on the table by two of the operators.

With a small, sharp steel needle, previously sterilized by flame, there are made from 3 to 5 superficial horizontal incisions across the epithelium of the cornea of the eye, and as many in a vertical direction, crossing the first group of lines. It is not difficult to hold the eye open and fixed with the left hand, while with the right hand the above-described operation can be performed in a few seconds. Following this, a quantity of the secretion to be tested is then placed on the surface of the cornea with a small, blunt, properly sterilized instrument, and thoroughly distributed by a closing movement of the eyelid. The inoculated animal is then placed in a cage and treated as a highly contagious case.

If no specific, variolic infection of the cornea has taken place, the small traumatic lesions will be healed in twenty-four hours; and after forty-eight hours the cornea will appear absolutely clear and without

irritation. If, however, the eye has become infected with variola virus, there will appear on the cornea, from thirty-six to forty-eight hours after injection, certain lesions which may be visible to the naked eye, but are much more clear under a low power lens. A definite irritation of the eye and some slight grayish epithelial prominences will be seen on the surface of the cornea.

Forty-eight hours after inoculation the rabbit is killed by a blow in the neck in all cases, irrespective of reaction. The eye which has been used for the experiment is enucleated with great care by the method used in ophthalmological work, cutting through the external muscles and the optic nerve. The bulb is immediately placed in the alcoholic sublimate solution already detailed, and fixed for from one to two minutes. Then the cornea is separated from the eye in a line near the limbus with a small Graefe knife or fine, sharp, irridectomy scissors. Any pressure on or lesions to the corneal tissue should be avoided.

The cornea, lying in the solution, may then be inspected with a lens. If infection has taken place there will appear along the criss-cross lines previously made small, isolated circumspect prominences of a porcelain-white color, and which contrast sharply with the rest of the cornea which presents a diffuse grayish opacity. The prominences may be confluent when a secretion of great virulency has been used for inoculation.

The virus of varicella does not produce such an infection of the epithelium. Similar lesions can be produced only when vaccine virus has been used; but the vaccine virus produces a broader, more extensive and more confluent proliferation of the epithelium, which presents a different aspect.

Forty-eight hours after infection has taken place, there will be found in the center of the variolic proliferation, which is still progressive in the peripheral parts, a desquamation of the epithelial cells; and after ninety-six hours there will be developed a round crateriform depression with a very sharply-defined rim. This type of proliferation is pathognomonic of variola. These macroscopical lesions are so characteristic of variola that they allow of an undisputed diagnosis of this condition. For scientific purposes, however, the diagnosis can be confirmed by the histological examination.

In sections there is to be seen a proliferation of the epithelium of characteristic form, beginning from the rim and slowly and regularly increasing to the center. This proliferation is caused by an increase in number, and a swelling of the infected epithelial cells. The hydropic degeneration of these cells appears at first, and most marked, in the cells of the basal parts near the Bowman membrane. Here the cells appear larger and broader and by their irregular shape are more or less separated from each other and do not keep their regular conformation. Later a similar hydropic inflation and dislocation is seen in the upper layers of cells. The degenerated and proliferating epithelial cells also penetrate into the small lesions which have been made by the needle in the connective tissue of the cornea, and fill them completely. The swelling of the epithelia gradually passes into a complete hydropsy of the cells.

In the central parts of the proliferation are to be found the oldest epithelial cells, and therefore the most advanced and marked. It is in these older cells that the Guarnieri bodies are first seen and in the greatest numbers.

Though the histological examination is not absolutely necessary for diagnosis of variola, this method tends to confirm and to increase the confidence of the scientific worker in Paul's proceeding for diagnosis of this disease.

I obtained satisfactory results through the use of preparations made after the following method:

The cornea of the enucleated eye of the rabbit showing the typical macroscopical lesions of variola infection is fixed in the alcoholic sublimate solution for 10 minutes. Thereupon the cornea is placed for several minutes in 98 per cent. alcohol to which have been added one or two drops of tincture of iodine, making the solution the brownish color of cognac. The iodine removes the mercury from the preparation. Then a five minutes' bath of alcohol solution, 98 per cent., and changed several times. With necessary caution in order to avoid all pressure and production of lesions, small pieces of tissue, 3 to 5 mm., containing the foci of the proliferation, are cut out of the cornea for histological study. These pieces of tissue are passed for five minutes in absolute alcohol, changed several times; five minutes in aniline oil, changed twice; five minutes in xylol, changed several times to wash off all of the remains of the aniline oil; five minutes in xylol paraffin, then five minutes in paraffin of 56° to 60° melting point. Place in paraffin, mount the pieces on blocks and make thin sections with the microtome.

The sections are fixed on the slide by removing them from the surface of warm water and drying them in the incubator for some hours, after the well known laboratory method.

Pass them through xylol and alcohol of decreased strength, then into water. Stain for five minutes with a regular hemotoxylin solution. For differentiation use a one per cent. solution of hydrochloric acid in alcohol, 90 per cent., until the sections show a red color. Wash in water made slightly alkaline by the addition of a very small portion of sodium carbonate until the sections have obtained a pure blue color. This usually requires about a half-hour, perhaps a little longer. The sections may be left in this water over night.

Then counterstain with an alcoholic solution of eosine; one minute in absolute alcohol, changed several times; one minute in a mixture of xylol and crystalline phenic acid; one minute in xylol, cover specimen with Canada balsam and apply coverglass. The histological details can be distinctly studied by lower power lens. To demonstrate the Guarnieri bodies, the objectives Nr. 6 and 7 b, of the Leitz microscope are used. It will not be necessary to use the oil immersion.

I have made some microphotographs of my sections. The first shows at low power the characteristic histological lesions of epitheliosis variolica of the cornea of the rabbit. The other microphotograph shows at high power, Nr 7 b, a number of Guarnieri bodies in the swollen epithelial cells of the cornea of the rabbit forty-eight hours after inoculation with the contents of a pustule from a case of variola.

THE THERAPEUTIC VALUE OF THE TRAINING CENTER AT ST. ELIZABETH'S HOSPITAL, WASHINGTON, D. C.*

By WILLIAM M. KENNA,

WASHINGTON, D. C.

P. A. SURGEON (R.), UNITED STATES PUBLIC HEALTH SERVICE.

As the writer, in the capacity of medical advisor, has been assigned to take an especial interest in the Vocational Training Center of this hospital; and as vocational advisement is frequently asked of the conference when patients are presented before its members, it occurred to him that a few remarks concerning this project might be acceptable, since they relate more or less to the question of the therapeutic value of the center in the treatment of its members. Although the plan of this feature of the Federal Board for Vocational Training is both prevocational and vocational in type, yet it would appear that it has demonstrated itself to be a valuable therapeutic measure as well.

The idea is founded on the conception that patients during their stay in the hospital may be properly surveyed and, in a preliminary way, trained along lines of future economic helpfulness subsequent to their discharge from the hospital.

That a certain material percentage of the war risk beneficiaries will eventually be discharged as recovered, as social recoveries, or at least as much improved, is to be taken for granted and, generally speaking, these patients of necessity will have to make their own living without supervision in the future. It was with these conditions in mind that the idea was conceived of instituting training centers in the field so that constructive work in the proper teaching and placing of these men might be accomplished; that round pegs in square holes might be avoided; that patients might be helped to rehabilitate themselves and also to readjust in a suitable environment; and, finally, that time might be saved during the period of rehabilitation for at least a certain percentage of War Risk beneficiaries.

The selection of a right vocation in any sphere of life is a highly important matter, and its importance is being more and more recognized by educational and industrial leaders throughout the country. If this be true of normal individuals, how much more so must it be of psychotics with their unstable constitutions and weak resistive powers. Dr. Treadway of the Public Health Service in a recent paper on mental hygiene gave a happy example of this in relating an instance of readjustment. He referred to a corner newsman of his acquaintance who, though paranoidal in his makeup and positively anti-social in his views and expressions, was coordinating sufficiently well to make a livelihood in spite of his conflicts. This same man placed in a highly organized industrial relationship, for instance, would indubitably have succumbed to the stress of his surroundings.

The aftercare of patients who have been discharged after being hospitalized for phychoses, has long been an acute problem for those who are engaged in psychiatry. As a rule, when a patient leaves the hospital, he goes into an atmosphere of fairly consistent disinterest and enters a social environment where a process of economic attrition is again resumed. Here and there some effort at post-hospital assistance is made; but it is mostly of an advisory nature; and mere advice in this world of constant financial strife is not accepted as a substitute, or as collateral, for that mystifyingly evasive substance termed "coin of the realm."

Congress in its liberality passed the law under which the Vocational Board is active; and its provisions were made in appreciation of the important part our men played in winning the war and in making our country safe for democracy. It showed its willingness to give financial assistance to those who needed and deserved it during their term of rehabilitation. It evidenced its desire not only to furnish adequate hospitalization as long as necessary, but to render financial aid to those who were eligible for training after their release from hospital supervision. And as a further measure of interest and help came the institution of the training centers in the various hospitals.

It may be pertinent to recall here that post-hospital eligibility for training comes under two heads: Class 2 and Class 3.

Class 2 training includes maintenance and support for the man and his dependents, the allowance ranging from $80 to $150 per month according to the number of dependents.

Class 3 training allows no maintenance or support but provides for instruction, books and supplies without cost. So-called "placement training" comes under Class 2 and in this phase, the man is given employment in his chosen sphere, meantime remaining under the supervision of the board. It is the present policy of the board to encourage patients not only to take training while in hospitals but to continue it after their discharge.

The personnel of the training center of this hospital now consists of the director, the assistant director and sixteen instructors. More recently a purely occupational unit devoted to war risk beneficiaries has been instituted and from the above staff five members have been assigned to duty in this section. Dr. Noyes is quoted as expressing the opinion that probably three hundred of the present war risk patients not now enrolled in the vocational center will be available for enrollment in this occupational class. It is hoped that in the occupational section there will be developed a sufficient number who will take up the vocational work later on. By this means it has been planned to have points of contact from the purely occupational work, through the prevocational center to the subsequent training after discharge from the hospital, in order to stabilize the later attempt at social adjustment.

This program may seem too ambitious and idealistic. The question is: Is it of practical therapeutic value? And if it is a beneficial asset in the treatment of the psychoses is it sufficiently valuable to justify the expenditure involved, from an economic and from a financial aspect? Taking also into consideration the future welfare of the patient, is it worth while?

The training center was instituted about July 1, 1920, and has been in operation nearly ten months. It would seem that an opinion as to its

*Read before the Clinical Pathological Society, April 12, 1921.

therapeutic value from an observation of its workings might well be expressed.

Personally, the writer considers the plan a valuable therapeutic agent; that in reality it is an economic measure. It appears to be not only of benefit in helping a certain number of patients to readjust themselves, but, in so far as it relates to the subsequent health of the patients after their discharge from the hospital, it must accomplish much in fortifying them against another mental collapse, since it endeavors to develop them along lines of work for which they show natural aptitude, in which they evince an interest, and, finally, in placing them in vocations where the stress will not be too great.

The teaching staff of the training center can be said to be of the highest type. It is marked by the pleasing personality of its members who have shown an enthusiastic interest in the welfare of the patients and in their progress. Likewise they have demonstrated tact in the handling of the patients; they have shown unswerving loyalty to the hospital and its officers; and they have uniformly recognized the necessity for medical guidance in the performance of their tasks.

Medical advice with reference to a patient's possibilities and to the pitfalls against which he very properly should be guarded forms a part of the procedure. There is always the danger that the program outlined may be too ambitious in scope and that misguided enthusiasm may stimulate him to efforts which in themselves might act as causative factors in a return of his psychosis.

For example, a patient who was recently discharged by the conference had, of his own initiative, formulated the idea that he must have a career, must "amount to something," to use his own expression—and glibly announced to the conference that after leaving the hospital he desired to continue vocational training and aspired to become a lawyer or a physician. Here was an individual of quite limited education and of unstable makeup who was shooting above the mark. The matter was afterwards carefully gone over with him, his limitations were pointed out, and an attempt was made to show him where his best possibilities lay. He was lithe and slender, naturally alert and quickly absorptive, of agreeable personality and rather scrupulous in the care of his dress and person. Moreover, he had flexible hands, had shown decided manual dexterity and had evidenced a decided interest and a definite ability in typewriting and kindred subjects. So the inadvisability of trying to carry out the plans he had formulated was pointed out to him and the incongruity of such a procedure as he had outlined was dilated upon. Emphasis was placed on the handicap for academic work which he must necessarily have because of his limited and meagre education, should he make attempt to obtain a professional degree. He was therefore advised that the safer plan, both from the standpoint of his health and from that of a successful economic adjustment, would be for him to engage, if possible, in some form of office work which was really to his liking and in which there would be not too much mental stress.

An opposite type was that of another patient who upon entering the center was tried out in school work. He had been improving slowly but at the time was rather too indifferent to express a desire for any special kind of work. After a short period it was observed that he was obviously disinterested in the class-room details and apparently chafed under them. Later, as he became more accessible and communicative, it was learned that he possessed a strong mechanical bent; that, as a boy, he enjoyed tinkering with such things as a bicycle, frequently taking it apart and reassembling it. He was of the robust, muscular type with large, squarely-shaped, strong hands. He was relieved from class-room work and was sent to the blacksmith shop where he plunged with energy and enthusiasm into the work and simultaneously began to show mental improvement by leaps and bounds. He now plans to take a course in automechanics, an occupation which will not only be lucrative but which will, no doubt, afford him happiness and contentment because he will be in an environment which he enjoys and for which he is naturally adapted.

In enrolling candidates for the training center a survey of patients is made with certain well-defined features in mind. These may be classified under five heads:

1. Interest. Is the patient interested in taking up training of any kind?
2. Health. Is his condition such that the proposed training will be beneficial or harmful?
3. The utilization of his past experience as a basis.
4. Building on his previous education.
5. The selection of a vocation financially attractive. All these features should be considered before the enrollment of the patient in the training unit is made.

From July 1, 1920, until April 1, 1921, the training center has had a total enrollment of two hundred and ninety four patients, all undergoing instruction. Of these fifty-six have been discharged, six of this number having been transferred to other hospitals. A critical and unprejudiced analysis of the fifty patients who were discharged to their homes classifies them as follows: Twenty-five were considered as fairly good material for subsequent training and would probably be highly benefited. Nine were thought to be doubtful. Four were absolutely not available for training of any type. Twelve were intermediate; that is, they were thought to be in a class between the accepted doubtful ones and those who were fairly sure of taking the advantage of training.

The attendance has varied in percentage during the different months from 5 per cent. of the total number of war risk beneficiaries last July to 17 per cent., which was the percentage enrolled in February, 1921. The percentage of the available patients enrolled from the number assigned for training has varied from a low of 67 per cent. to 100 per cent. in different months. The writer feels that the percentage of enrollment of the total war risk population should be and can be increased materially in the near future.

Briefly, the courses offered are as follows:

1. Prevocational training which includes arithmetic and English.
2. Trade and industrial training, comprising cement work, drafting, carpentry, etc.

3. Agricultural training, including farm crops, animal and poultry husbandry.

4. Business and commercial training, which includes typewriting, stenography, salesmanship, etc.

5. Occupational crafts of a miscellaneous kind.

Unfortunately, owing to the congestion which exists in the hospital and the resultant lack of space, it has been necessary to group with the enrolled members many patients of a semi-disturbed type who, in their restless condition, are not available for training. It is felt that their presence has a more or less deterrent effect upon the more comfortable patients, some of whom have expressed their dissatisfaction with this situation at different times. To be consistent it would seem that a training center of this nature should certainly have an atmosphere of calm and repose. The influence of idlers and of objectors to training upon those who have become interested in the work should also be neutralized to the greatest possible extent in order that the necessary morale may be preserved.

It would appear that more benefit is to be gained from the industrial, mechanical and agricultural courses of training than from the purely class-room or intellectual types. When we take into consideration that the ex-service men have had, as a rule, very meager educations, this is quite readily understood. They have failed to go through school originally because of backwardness, lack of interest, or financial stress or illness. Now that they have matured, it is not surprising that many of them revolt at the idea of taking up school work again. The suggestion is repellent to many patients and the benefits to be derived are either ignored or refused because of this repugnance to the atmosphere of a schoolroom. On the other hand, class work associated with the industrial and agricultural courses is more gracefully accepted because, apparently, of the appeal which the practical application of their studies makes to these men.

The industrial branch of the training center has done some very capable constructive work. With the aid of the enrolled patients it has erected the new dental clinic which is practically completed. There has also been constructed a frame chicken house 16 ft. x 36 ft., and a concrete incubator cellar. The drawings for these latter were prepared by some of the men in the school drafting class.

Another project well under way is a trades shop consisting of a main portion with two wings. When completed, this building will have the machinery and equipment of a modern wood-working, machine, and automechanic shop, as well as a drawing room. The program embodies a course in which it is hoped to carry a man from the drawing room through the various processes of shop work to the completion of articles. He will be started on the drawings, taught the method of calculating costs as to material, labor and overhead, and then brought to the practical construction of the work at the bench and machine. In the automechanics branch an effort will be made to turn out men who will not only have learned the art of driving a car but, also, *mirabile dictu!* men who will be able to repair one as well.

After a patient has been discharged from the hospital the physicians of the Federal Board have the obligation of deciding definitely and finally whether he is entitled to training and whether such training is feasible. If no history is known of the patient's illness, the decision must rest upon a short examination or upon observation of the patient in another hospital for a period of time. Thus matters are delayed and the patient may suffer a hardship in the interim. To obviate this difficulty and to lessen the period of delay, brief reports concerning the patients are made by the writer to the educational director from time to time. Again, when a patient is discharged, the opinion of the conference, if expressed, is embodied in a letter to the director. Through this procedure immediate contact in a medical way is established and it redounds to the patient's advantage.

Up to the present time we have no definite data as to the progress of discharged patients in so far as it relates to vocational training. However, a followup system has recently been initiated and it will no doubt be fruitful and interesting to learn to what extent the prevocational training has been helpful to these men in their efforts at adjustment.

As stated before, the whole plan—the basis idea—is prevocational and vocational in scope. It is occupational, to be sure, but it is more than that. Its design is to give preliminary training to patients along vocational lines so that upon their discharge from the hospital they may, under the supervision of the Federal Board or "on their own," pursue a gainful occupation to which they are adapted and fitted and in which there will be sufficient freedom from stress to allow them to make a contented, peaceful and successful social adjustment. Contrary opinions to those expressed by the writer as to the therapeutic value of this unit may very likely be held. His own opinion has been formed with a total lack of prejudice and with an unbiased feeling of detachment. Moreover, it is based upon the results of work already done and is formulated with the possibilities of the future firmly fixed in mind.

STAMMERING AND LEFT-HANDEDNESS.

By ERNEST TOMPKINS, M.E.

PASADENA, CAL.

A MUCH discussed feature of stammering is its alleged connection—in one way or another—with left-handedness. One authority says that stammering is prevalent among left-handed children; another says that to make the normally left-handed child use the right hand makes him stammer; another says that stammering being prevalent among the normally left-handed children and feeble-mindedness also being frequent among them, therefore, the stammerer is presumably feeble-minded. This alleged feeble-mindedness is an attenuated form of the ancient superstition that the stammerer was insane, a revival of which we find in the occasional statement that he is psychopathic. But the object of this discussion is not to consider ancient superstitions, but one which is largely due to a misconception arising from the discovery of Broca's center.

The physician is apt to have put to him the question: "Will my left-handed child stammer if we require him to write with his right hand?" Or, "Is my left-handed child more likely to develop

stammering than if he were normally right handed?" Will the answers be reliable? Or will they support popular misconceptions? This article is designed to enable the physician to do himself credit by his answers.

What is handedness? The reader of discussions which involve it would get the impression that a right-handed child either has no left hand or that its left hand is paralyzed. But any person who has two healthy hands uses one to an extent quite comparable to the use of the other, the difference being that one hand is used preferentially for certain performances. It is beyond the scope of this article to consider whether a preference is inherited. But social competition impells desistance from equal training of both hands, and convention dictates the training of the right hand for writing and other uses involving more or less skill. Indeed, custom keeps the right hand in advance. It is extended for greetings, because the proffer of the left hand is considered a slight; it is extended at entrance and exit because door handles are placed conveniently for the right hand; the scissors are made so that use by the left hand is extremely inconvenient; and the list might be lengthened to a tiresome extent. In short, whatever the inherent tendency, if any, necessity dictates the preferential use of one hand, and custom dictates that use for the right hand. But it is obviously erroneous to think that the nonpreferential hand is not used or is not skillful. For instance, an expert carpenter holds the nails in his left hand, "fingering" them—to use the trade term —so that a new nail is, head up, in position for driving as soon as the last blow has been struck on the preceding nail. In this case the dexterity required of the left hand far exceeds that of the right; but the man is called right-handed. In other similar cases the left hand is deprived of credit which is due it. We may liken the relation of the two hands to that of two partners in business for mutual benefit. For the sake of efficiency they divide the labor, one taking the shop management and the other the office management. The latter gets the credit for being the head of the concern because his labor is generally regarded as more intricate and he is more in evidence; but the preference which he enjoys is not proof that his partner could not perform the office duties provided he had the training for them. So it is with the hands. The left hand in a normally right-handed person does much skillful work, and my own experience in educating my left hand indicates that it is capable of just as much dexterity as the right hand. It is safe to say that the alleged intrinsic superiority of one hand over the other is largely or entirely mythical and that the difference observed is due to the difference in training given them.

Now there would be much more stammering than there is and much more left-handedness, if both habits were not checked by parental care. What more hackneyed instructions are there than "Stop talking that way or you will never get over it," and "Hold your pencil in your right hand"? Some authorities—and they are evidently well sustained —state that practically every child goes through a stage of stammering; and anyone who has grown up in a large family knows how incessant was the correction of incipient left-handedness. But not all parents are careful, so it necessarily follows that, purely as a matter of neglect, both stammering and left-handedness will remain as collateral characteristics of some individuals.

Before we leave the above explanation of the occasional coincidence of stammering and left-handedness, let us consider it. Suppose we submitted it to the editor of a popular journal as a scientific deduction. He would turn up his nose—rather turn down the manuscript. His idea is that nothing is scientific if it is not mysterious or involved and he wants his scientific material to smell of test tubes and other laboratory apparatus. He is not alone in his beliefs and predilections: these misconceptions of science are general. So in order to obtain consideration for our observation it is necessary to explain that science is a method of procedure designed to enable us to understand natural phenomena, and one of the rules of that procedure is that between two descriptions of a phenomenon, the complicated description is to be rejected and the simple one retained. Therefore, the description already given of the coincidence of stammering and left-handedness is to be retained until a simpler or more accurate description is presented.

We have to consider two propositions. The first one is that there is a cerebral connection between stammering and left-handedness. What does it rest on? On two sets of observations. One set is the occasional coincidence of stammering and left-handedness. The other set is the frequent coincidence of aphasia and paralysis of the right hand subsequent to injury or lesion of the left side of the brain; the reasoning being, since a cerebral injury is manifested coincidently by a speech defect and disability of one hand, then there must be a connection between stammering and "handedness." That sounds reasonable. But consideration shows it to be not only unreasonable but untenable. Aphasia is not stammering. Except that both are disorders of speech they are entirely different. Aphasia is a central deficiency; stammering is peripheral obstruction. Aphasia is not intermittent; stammering is. Aphasia is due to a lesion; none has ever been demonstrated for stammering and all reason is against one. Aphasia is almost never free from complication with other affections; stammering (except for some inducing causes) is free from complications. Aphasia is not subject to quick changes; the changes is stammering are as quick as thought. Aphasia appears most—except by accidental causes—in advanced age; stammering originates in childhood and never in advanced age. One might continue giving the antithical characteristics of the two disorders; but enough have been given to convince any fair-minded person that the two affections are totally dissimilar. From this it follows that, although under some circumstances a central connection between the use of the hand and aphasia has been established, this connection is not an acceptable indication of any such connection between stammering and the use of the hand, because stammering is totally different from aphasia.

This alleged central connection of stammering and handedness is negatived by other considerations, among them the only valid theory of stammering, the speech-interference theory. Most of us

remember that during the war the government was pestered to accept motors alleged to develop more energy than they consumed, and a portion of the popular press denounced Congress for not recognizing these wonderful inventions. But all the people who understood physics said to themselves at once: these schemes are contrary to the law of the conservation of energy, and wasted no further thought on them, except possibly to notice with an "I-told-you-so" air that when Congress finally did investigate the schemes it had to reject them. Just so, we have a general law of stammering which bars out the alleged connection of stammering and handedness. This law says that stammering is panicky, conscious interference with normal speech; that the stammerer has perfect speech ability; that his central organs and his vocal organs are all right. But an accident or incident induces him to begin the conscious efforts after his speech is newly acquired, and the ridicule visited on the failure of these original misdirected efforts prompts him to continue making more of them. It is demonstrable in numerous ways that if he desists from his impeding efforts his speech comes fluently, but after years of indulgence in this most tenacious habit it is difficult for him to desist. From this speech-interference law it follows that the only elements involved in stammering are the inducing accident or incident, normal speech, the fear of speech disability, and impeding conscious effort. Handedness does not enter in, so it is forever cast out. In short, there is no valid reason for believing in a central connection between stammering and handedness, and there are many reasons why we should not believe in it. The view, in the present state of knowledge, is a superstition.

The remaining view to be considered is the very popular one, unfortunately frequently advanced in our medical press, that discouragement of the preferential use of the left hand causes stammering, and the still more ridiculous view that return to the use of the left hand cures the stammering alleged to have been caused when that use was abandoned. The argument is that a cause operative at the left hand is transmitted inward via one neural path, centrally to another neural path, and then outwardly to the vocal organs where its effect is stammering. Now consider this argument. Take the cause, which is so inocuous as slighting the left hand by giving preference to the right. The left is not injured—it is merely neglected. Next consider the allegation that this mere slight to the left hand is transmitted inward with damaging effect. What evidence have we that any treatment of the hand is so transmitted inward? None whatever. Only a few days ago I was in the company of a man who had had part of his hand burned away by contact with an electric wire. No damaging effect had been transmitted inward to deteriorate his brain, much less to be transferred to another neural path and then outwardly to affect his speech. If this burn had no such effect, how could a mere slight to the left hand have such direful effect as to cause stammering by the devious route described? Finally consider the alleged connection of the inward and outward neural paths. There is an old saying that a chain is no stronger than its weakest link. Then this chain of transmission has no strength, for the connecting link is missing altogether. It has already been shown that there is no central connection. But, if the hand were injured (but it is not) and if the injury were transmitted inward (but it is not), and if there were a central connection (but there is none), then the effect would be aphasia, *and not stammering!*

If we need more proof of the falsity of this dextro-sinistrality cause of stammering, it is readily supplied. J. E. Wallace Wallin in his "Report on Speech Defectives in the St. Louis Public Schools," shows the view not to be sustained by the facts, and Ballard himself, after disseminating the superstition, says now, "I regard my investigation as more or less preliminary and suggestive rather than conclusive. . . . I only examined left-handed children and did not in any way test the right-handed children. It is probable that if I had done so and had tested their speech I should have rated the percentage of stammerers higher than the casual observers did, and thus reduce the difference between dextrals and sinistrals. At any rate, I now feel that the subject demands a much more careful and detailed investigation before any very definite conclusions can be arrived at." (Quoted by Wallin in the above report.) Ballard is mistaken in the last sentence; no investigation is needed. The view is so contrary to experience that an investigation is a waste of time.

Conclusion. There is no connection between stammering and the use of the hands.

174 South Bonnie Avenue.

PERITONITIS ACUTA CIRCUMSCRIPTA CATARRHALIS.

A NEW DISEASE.

By E. Palier, M.D.,

New York.

Under this heading I desire briefly to describe an affection that I have met with within the last two years, which greatly puzzled at first, and I am unaware that it has ever been described before. I will relate facts, and they will speak for themselves. The first case occurred in myself.

One morning nearly two years ago, in the late fall, I began to feel an uneasy sensation in the left iliac region. There was a sensation of fullness, discomfort, and pain on deep pressure. The bowels were costive, and there was slight nausea. Thinking it to be a case of intestinal indigestion I paid little attention to it. A few days passed without improvement setting in. The bowels remained costive in spite of an anticonstipation diet and the taking of laxatives, which ordinarily would be more than enough in my case to cause copious movements of the bowels, as I seldom resort to laxatives, getting good results from an anticonstipation diet alone. The pain became more localized and defined. It was in an area of about two to three inches in diameter, just above Poupart's ligament, between the anterior border of the ilium and the rectus muscle—rather nearer to the former. It was a slight, dull pain, aggravated on deep pressure, on walking or exercise, and relieved on lying in a horizontal position. About eight days thus passed, and in spite of careful attention to the bowels, there was no improvement. An examination of the stools did not show anything to incriminate the intestines. Had the affection occurred on the right side it would have worried me greatly for fear of appendicitis.

Then I felt some itching in the throat, some pain on

swallowing, and there was slight elevation of temperature. I took salicylates for this trouble. To my great surprise after two days of the exhibition of the salicylates the abdominal affection greatly improved, and a few days later entirely disappeared, the bowels becoming again normal, not requiring any laxatives.

I dismissed the disappearance of the abdominal affection as a mere coincidence, and did not consider it of any significance.

A few days later a little school girl, aged 11 years, was brought to me by her mother. The little patient complained of pain in the left iliac region, her bowels, which had previously been normal, became costive. The patient claimed that she was too sick to go to school and stayed at home.

On examination, I found a small, sensitive area near the anterior left iliac border near the anterior inferior spine of the ilium. I took it for a localized colitis. Indeed, I have often elicited pain in this region, and in some cases I could feel a small, soft, sausage-like tumor, which disappeared after appropriate treatment.

My treatment of the little patient in question was directed to her bowels. But the patient was under treatment for about twelve days without any improvement. The mother, who was an intelligent woman, remarked that if the trouble had been situated on the right side she would have feared for appendicitis.

On examining the patient again, I found the sensitive area increased, and corresponding nearly to the area in my own case as described above. This patient's stools did not reveal anything either to incriminate the intestines. There was also a slight elevation of temperature and a small increase in pulse. Then I thought of my own case and put the patient on salicylates. In a few days the child completely recovered.

The third case is of still greater interest; as the trouble occurred on the right side in the area corresponding to the McBurney point.

Patient, male, 35 years old, came to me complaining of pain in the right side of abdomen, from which he had suffered for about eight weeks, and had been treated at a clinic without any benefit. The history showed that the ailment began with a "cold." On examination, there was tenderness with increased pain on pressure in the area corresponding to the McBurney point, the pain radiating upward towards the ribs. The diagnosis of appendicitis, of course, suggested itself. The bowels were costive. An examination of the chest, however, revealed fine râles in its lowest portion on the right, in the area between a line drawn from the nipple and the axillary line. The chest affection, which I will omit discussing here, as it does not enter within the scope of this article, suggested to me the nature of the abdominal malady. The latter I considered as a complication of the former, and the patient was treated accordingly. In about three weeks the patient recovered.

I will now describe a fourth case where the affection occurred again in another spot, thus illustrating how it can occur in various localities and under various conditions.

This patient, male, age fifty, was suffering from pulmonary tuberculosis. The physical signs in the lungs and the subjective symptoms were slight, but the sputum was positive. He came to me complaining of pain in the left side. The pain and tenderness on pressure were located in the left side of the abdomen, just below the ribs, between the nipple and the axillary lines. On questioning the patient, I again elicited the fact that he had had a "cold" a few days previously, and since then the trouble had commenced. The administration of salicylates gave good results. This case was seen by me with Dr. Jos. S. Glickman, of New York City.

I have seen some other cases coming under this heading, but I think the four cases described sufficiently illustrate the malady in question.

Now, gastrointestinal disturbances in grippal affections or in "colds" are common. Some years ago, in a grip epidemic, I had under treatment a case which simulated diffuse general peritonitis, with hardly any lung trouble, but with congestion of the upper air passages. As the case occurred during an epidemic of grip, I treated it as such, and the patient made an uneventful recovery.

But localized pain in the abdomen is quite another matter, something I had not met with till about two years ago, or if I had met with, I had been unable to diagnose it.

I have named this affection acute circumscribed catarrhal peritonitis. The word catarrhal is, of course, very vague. But any other definition would be as vague, and still more hazardous, such, for instance, as grippal or rheumatic. As none of the cases, fortunately for me not my own case either, came to the operating or to the autopsy table, their exact pathology and etiology cannot be known. I have described the cases as I saw them clinically. Now that attention has been called to them, the opportunities for their further study by others may present themselves.

As to the treatment of these cases, I found the salicylates—I prefer strontium salicylate—acting almost as a specific. I will not enter into a discussion why this is so, and as to whether the salicylates act something like a specific in grip and in colds generally. This does not enter within the scope of the article. Here I simply report clinical facts the way I observed them.

There is no need to emphasize the interest of such cases, particularly with reference to the right side of the abdomen.

151 East Eighty-ninth Street.

CONCERNING THE THERAPEUTIC VALUE OF SILVER ARSPHENAMINE.

By OSCAR BERGHAUSEN, B.A., M.D.,

CINCINNATI, OHIO.

THE clinician is still confronted with the probability of reactions following the intravenous administration of arsphenamine and neoarsphenamine. The immediate and slight reactions which follow are common experiences; the later but more severe reactions are much less common but numerous enough to demand our attention. Many more fatalities have occurred than are reported in the medical literature. The writer knows of two which have not been reported: the last one following the intravenous administration of 0.6 g. neoarsphenamine, supposedly a conservative dose.

We are in need of a preparation possessing the highest chemotherapeutic index, by which is meant the ratio of the maximum amount of the drug tolerated to the curative dose; one with which subsequent reactions are slight, never serious, but yielding superior clinical results. The latest modification which has been placed upon the market is silver salvarsan, the sodium salt of silver-diaminodihydroxyarsenobenzene, in which the silver is in non-ionizable form. By recording our experiences it will be possible to determine its therapeutic value. Already the idea has been expressed that the clinical results are not equal to those obtained

with the older products, chiefly because of the fact that reactions do not occur. It may be desirable to obtain reactions in certain chronic latent syphilitics, but this should never be desired unless the clinical condition of the patient has been thoroughly investigated and unless the patient's tolerance for smaller doses has been previously determined.

Diagnosis	Number of Cases	Number of Injections	Number of Reactions	Result	
				Imp.	Same
Congenital Lues	2	9	1	2	..
Lues	13	53	0	13	..
Cerebrospinal Lues	14	44	1	11	3
Tabes dorsalis	8	24	0	4	4
Paresis	2	3	1		2
Total	39	133	3	30	9

In the above table the results obtained in treating advanced patients are listed. In this type of case severe reactions should be avoided because of the mental as well as deleterious effects which may be produced. In my own experience it has been found more advisable to repeat small doses than to risk the marked reactions which may follow the administration of larger doses, unless the tolerance of the individual has previously been determined. In the 133 injections, mostly containing 0.2 gm. and 0.3 gm. each, only three reactions were obtained, two of them were slight, and the other accompanied by loose bowels in a paretic who was unable to tolerate the older arsenic preparations as well as mercury. The initial dose was usually 0.1 gm., followed by 0.2 gm. injection in 4 or 5 days, and then by 0.3 gm. in case no reaction occurred. Improvement occurred very readily in those suffering from lues, congenital lues, and cerebrospinal types of lues; some improvement was noticed in 50 per cent. of the tabetics. In two cases the intravenous injections were followed by intraspinous injections according to the Swift-Ellis technique, with no reactions.

The patients all express a willingness to take another injection because no severe headaches nor gastrointestinal disturbances follow. Those who previously had been unable to take arsphenamine or neoarsphenamine without the production of symptoms, could readily take this newer preparation and suffer no ill effects. Improvement in the clinical condition was as marked as when the older preparations had been used.

The Wassermann reaction, using both cholesterinized and plain alcoholic antigens and the method of icebox fixation, thus far has been determined in only twelve cases before and after the treatments. These results show that in 3 of the 12 it was possible to change the reaction from distinctly positive to negative, in 2 it was made less intense, and in 7 of the 12, or 58 per cent., it remained unchanged.

19 West Seventh Street.

Protein Therapy in Malta Fever.—Ferro recently treated three patients with this disease, using intramuscular injections of sterilized cow's milk. In each case there was a severe general reaction, demanding the use of adrenalin and cardiac tonics. Two patients appeared to recover at once following this reaction, but the third showed a relapse on the sixth day.—*La Presse Médicale.*

Medicolegal Notes.

Medical Opinion That Accident Could Have Caused Injury.—The rule in the Missouri courts in personal injury cases is that expert testimony that the injury "might, could, or would" result from the supposed occurrence is equivalent to testimony that such occurrence was sufficient to cause the injury, and the quoted words are the proper ones to be used by counsel and physicians in asking and answering hypothetical questions.—Keith v. Kansas City Rys. Co. (Mo. App.), 231 S. W., 1046.

Ohio Limited Practice Act Held Valid and Constitutional.—The Ohio Supreme Court holds that the measure of the police power of the State is the measure of the public need, limited only by the State and Federal constitutions. Public health is one of the most vital subjects for the exercise of that power. In the conservation of the public health the legislature may require all those who may desire to practice the art of healing to furnish some substantial evidence, by public examination or otherwise, of qualifications to practice such art as a whole or in any of its branches. The statutory qualifications defined by section 1270, Ohio General Code, as preliminary to taking an examination of persons desiring to secure a license to practice the art of healing in Ohio, are reasonable and valid statutory provisions, and are in full force and effect in the Limited Practice Act until lowered by any rule or regulation of the Ohio State Medical Board, pursuant to the statute. Sections 1274-1 to 1274-7, General Code, further regulating the practice of medicine and surgery by authorizing the examination and registration of practitioners in the limited branches thereof, is a constitutional and valid exercise of legislative power. The court said: "If it be constitutional for the General Assembly to generally regulate the practice of medicine and surgery in this State, it would seem to follow that it had the same right to regulate any part and to provide in that regulation for a limited practice act. That is to say, that inasmuch as the whole includes all its necessary parts, what is constitutional as to the whole would have to be constitutional upon the same ground as to any one of the parts, unless such limited part for other reasons violated some constitutional provision."—Williams v. Scudder (Ohio), 131 N. E., 481.

Inference That Fall Resulted in Accident Cannot Be Built on Inference of the Fall.—In an action on an accident insurance policy, where the deceased was found at the foot of a stairway with a bruised forehead, it was held that a fall down the stairway was not a necessary conclusion. And with the positive and uncontradicted evidence of a diseased condition of the insured, and that an actual cerebral hemorrhage took place, it was held not proper to build upon the inference of a fall from the fact of a bruise the further inference that such fall was the result of accident rather than disease. There was evidence that a fall might have caused a rupture of an artery of the brain and brought about the cerebral hemorrhage. None of the physicians undertook to testify as a fact that the hemorrhage was produced by the fall. They simply said that it might have been so produced. No evidence of injury to the outer covering of the skull or to the skull itself, or to the dura mater or to the membranes covering the brain, or to the brain itself was found by the physicians. It was in evidence that a jar, not sufficient to injure these parts, could still be heavy enough to rupture a blood vessel in the brain of one in the condition of the insured, or that the effort expended by him in attempting to avert a fall might produce the same result. But a finding that a fall caused the death was, after all, an inference. And inference cannot be built upon inference to establish a fact necessary to be proved.

The advanced stage of the sclerotic condition of the insured's arteries, the undisputed evidence of cerebral hemorrhage causing death, the positive proof that there was not the slightest evidence of external violence causing any injury to skull or brain covering were held to argue just as strongly that the insured's fall, if he did fall, was caused by disease, as that it was caused by accident. That the fall was caused by accident was speculation. It certainly was nothing more than mere inference. The defendant's demurrer to the evidence should have been sustained.—Phillips v. Travelers' Insurance Co., Missouri Supreme Court, 231 S. W., 947.

MEDICAL RECORD.

IMMEDIATE DEATH OF HEREDITARY SYPHILITIC INFANTS.

HEREDITARY syphilitic infants may die immediately after birth, and this *immediate* death does not belong exclusively to debilitated premature infants, as it may occur in well developed babies born at term. The frequency of immediate death in syphilitic infants cannot be exactly given, as precise statistical figures are not at present attainable. The mothers in these cases rarely present manifest syphilitic lesions at the time of the birth. On the other hand, the history of the mother will not always give a clue to the diagnosis, but in many instances the young age of the mothers, who are usually primiparæ, will be noted. Other than hydramnios, there is nothing in the ovum that could possibly indicate the lesions offered by the infant. During the entire pregnancy the fetal heart-sounds and beats remain normal so that they do not offer any prognostic indications as to the precocity and rapidity of the death which will follow the infant's birth. Examination of the placenta almost always shows a considerable hypertrophy, it being about one-third of the weight of the fetus of six to eight months and one-fourth that of the infant at term.

By the term "immediate death" is meant death occurring two to three minutes after birth, the infant dying after having cried and taken several spontaneous inspirations. In some cases the infant may struggle for life a little longer. Among the organs involved the brain, heart, kidneys, and thymus are those less usually the seat of morbid changes. The lungs are frequently the seat of inflammatory changes, while the liver and spleen are rarely intact. Ascites is generally present. There are some cases in which the most careful necropsy has failed to reveal any determining cause for the sudden death.

The theory of "inaptitude for life" maintained by Fournier can be applied only to those infants in which autopsy has failed to reveal any organic lesion, but the discovery of the *Spirocheta pallida* has made these cases very exceptional. The theory of "occlusion of the portal vein," put forward by Gaston, which is based on clinical and experimental data, and which he regards as capable of explaining sudden death in hereditary syphilis, does not seem to be applicable to infants who die immediately after birth. Bonnet believes that the real cause of this immediate death is the impossibility of the lungs to expand, on account of the hypertrophy of the abdominal viscera, and so to dilate sufficiently for the entrance of air, and he concludes that these subjects die because the respiratory functions cannot become established. All his autopsies showed that the lungs were in a state of atelectasis. He also points out that the specific lesions in the infants examined postmortem by him were sufficiently apparent to eliminate any accusation of criminal attempt on the infant's life. Although absolutely negative findings have resulted in other reported cases, from the viewpoint of the cause of this sudden death, it is none the less true that nearly always a careful examination of the patients will reveal evidences of syphilis, no matter how hidden they may be.

CONSTITUTIONAL SYMPTOMS OF PROSTATIC HYPERTROPHY.

UNTIL quite recently the generally accepted view of hypertrophy of the prostate has been that formulated by Guyon long ago, namely, that enlarged prostate is a phenomenon of senility of which arteriosclerosis is the dominant condition. At the present day this view is held with considerable reserve or regarded as wholly erroneous. In an article appearing in *Le Bulletin Médical* for July 20-23, xxxv, 20, Pousson endeavors to introduce quite a different conception of the disease founded on endocrinopathic developments. The enlarged prostate, like the enlarged thyroid, he says, pours into the blood an excess of its proper internal secretion and sets up a status that could be designated "hyperprostatism," after the analogy of hyperthyroidism. This picture must be kept quite distinct from another with which it may coexist, to wit, chronic infection from a prostatic focus. Both pictures in turn may be confused with the results of back pressure due to prostatic obstruction, so that the conquences of enlarged prostate may be very complicated. The author gives an outline of the results of back pressure which are of course well understood and which coincide in part with those of chronic nephritis when the kidneys are compromised. Is the hypertrophy of the heart with heightened blood pressure, which is so common in the prostatic subject, always or usually motivated by secondary nephritis? This conclusion would be absurd, for some elevation of blood pressure—which subsides after prostatectomy—is almost always present.

Along with the circulatory anomalies we see peculiar digestive and nervous symptoms, which do not at all agree with those of minimal uremia. Among the former are habitual thirst due to lack of saliva, betrayed also by difficult mastication and swallowing and even articulation. Similar troubles of the other digestive fluids may be established clinically. Under nervous symptoms should be mentioned nervous depression. Animal experiments with prostatic

extract show that the latter has both a physiological and toxic action. In the clinic it is not always or often possible to obtain a clearly defined picture of hyperprostatism because of the coincidence of back pressure symptoms. In addition to hyperprostatism we have to bear in mind the possibility of a "dysprostatism." The consequences of prostatectomy cannot be made to throw light on the individual case, for it often happens that well-marked nephritis with its secondary symptoms will apparently recede after excision of the gland. If we grant that most of the severe symptoms are due to back pressure, there is a residue which cannot be thus explained and which can hardly be due to any cause other than a toxin of a neurotropic character. There is a large and increasing list of cases of mental disturbance which have improved strikingly after prostatectomy. Ordinarily these would be set down to senescence—naturally, of course, if no operation were performed, but the surprising mental recovery after prostatectomy shows that there could have been no primary mental failure.

THE MIRAGE OF URINARY ANTISEPSIS.

FROM the days when Lister filled his operating room with carbolic acid spray down through the long succeeding line of experiments with all varieties of antiseptics, physicians have had ever before them the ideal of perfect asepsis, or, failing that, of complete antisepsis. Enthusiastic physicians have seen just ahead of them the abolition of nearly all disease by the application or administration of appropriate germicides.

One of the primary obstacles in the road toward such a goal, however, was the fact that the usual antiseptics, in strength sufficient to be germicidal, were altogether too irritating to be applied to such areas as mucous membranes or the interior of viscera. In the face of this undoubted fact, compromises were made. Thus we had substances which would gradually liberate antiseptics which, mingling with the natural fluids of the part in question, would be mildly antiseptic. Of this nature were the various intestinal antiseptics which began to flood the market, lozenges which, dissolving slowly on the tongue, were presumed to inhibit the growth of oral bacteria, and so on.

The advent into therapy of hexamethylenamine was naturally the occasion for rejoicing among the devotees of this doctrine. Here was a substance which when taken internally resulted in formaldehyde being excreted in the urine, the bile, cerebrospinal fluid, middle ear, and possibly other places. This at once gave rise to many schemes of therapy, as, for example, the treatment of general paresis by sterilizing the spinal fluid. Many English psychiatrists seriously recommended the drug in this disease, published case reports showing apparent improvement in patients treated with it, and even put the method into textbooks.

The most obvious use for the new drug, however, was as a urinary antiseptic. But as the years go on, it becomes increasingly evident that it must be relegated to a position but little, if any, higher than salol, boric acid, and ammonium benzoate. The mirage of a perfect urinary antisepsis still lures us on, but fades on our approach. Aside from the difficulties necessarily involved in finding a chemically stable substance which will pass through the kidneys in sufficient quantities, which will be nontoxic, and which will be sufficiently antiseptic in large quantities of urine of any reaction, we have the frequent presence of a chronic source of reinfection with which to contend. In the presence of such things as retention, a stone, or a neoplasm such a drug as hexamethylenamine is by no means specific, in fact, we are coming more and more to believe that its chief value is as a prophylactic. The ideal urinary antiseptic is then still to seek, and we must regard it as one of those problems such as the search for a specific for tuberculosis and a treatment for paresis, which continue to fascinate investigators.

SKIN CHANGES IN CHRONIC INTESTINAL STASIS.

THERE is no doubt that there is a distinct relationship between certain skin affections and gastrointestinal disorders, probably a more intimate relationship than is commonly imagined. In a way this connection is more or less easy of explanation. If the gastrointestinal tract is in a disordered condition, toxins are apt to invade the circulation when certain skin complaints may follow.

Of all the disorders to which the alimentary tract is subject, none is perhaps more frequent and none is more liable to bring about intestinal autointoxication than intestinal stasis. Moreover, intestinal autointoxication means that the entire system may and often does become infected, with the result that one of the symptoms is the supervention of certain skin affections. Sir Arbuthnot Lane has been for long the chief apostle of the doctrine that a large number of the ills to which human flesh is heir are due to an accumulation of the contents of the large intestine, which after a time produces injurious effects on the alimentary tract and a general infection. In the endeavor to adapt itself to the circumstances changes take place in the gastrointestinal tract, of which one result is the formation of evolutionary bands, which secure the intestine in its normal position, but which later tend to constrict the lumen of the bowel and increase the stasis. In a paper contributed to the *Medical Press and Circular*, October 26, 1921, Sir Arbuthnot Lane points out that the above is an illustration of a law that he formulated, namely, that every change that arises during the lifetime of the individual to enable him to accommodate himself more efficiently to his surroundings tends to shorten his life.

So far as the effect of chronic intestinal stasis on the skin is concerned, it is noted that pigmentation is the most marked change. This change is said to be owing to degenerative changes in the

adrenals consequent on the excessive strain experienced by these organs because of the presence of the toxins in the blood. Profuse and offensive sweating is another skin symptom, and abnormal growth of hair and premature appearance of wrinkles are others. Again, the temperature and color of the skin afford evidence that the toxins in the circulation are giving warning that something is decidedly wrong with the state of the blood. The temperature is subnormal and the skin is a bluish livid color or bloodless and pallid.

While the writer does not tabulate the various affections of the skin which in his opinion arise from intestinal stasis indirectly, he draws attention to the fact that owing to the lowered vitality and resisting power of the several structures composing the skin, due directly to autointoxication or to changes in the ductless glands produced by it, the skin is liable to be invaded by organisms which are able to secure a foothold in it and to form inflammatory changes constituting disease. He ends by saying that the dermatologist is no longer satisfied to treat these skin conditions empirically by external applications, supplemented by drugs by the mouth, but first investigates the condition of the gastrointestinal tract, studies the several factors which prejudice the health of the tissues generally, as well as of the skin, and endeavors to deal with them, while at the same time he attacks the disease directly with suitable germicidal agents.

While many do not go so far as the British surgeon in attributing to intestinal stasis the disastrous sequelæ which he enumerates, there are few now who do not indict the gastrointestinal tract as a factor in the causation of several diseases and minor maladies directly or indirectly. To what extent the skin is prejudicially affected by chronic intestinal stasis is a question. It certainly is true that if the gastrointestinal tract is not in proper working order, it puts the entire system out of gear, and if long continued, as in the case of chronic intestinal stasis, may lead to very serious conditions. The moral is to prevent it from becoming chronic by treating any slight digestive troubles by dieting, exercise, and so on, but never by the use of strong cathartics.

More Vicious Legislation

The so-called Sheppard-Towner maternity bill, which passed the Senate last July, was passed in amended form by the House of Representatives on Saturday of last week, and is now in reference committee. That the measure will finally become a law, unless the President in his superior wisdom disapproves of it, is practically certain, for the vote in the House was 279 to 39, showing that the vociferous lobbying of the women advocates and the chronic congressional itch for squandering the people's hard earned money have together been too much for the practically unanimous opposition of the medical profession and that of those old-fashioned folk who still have a liking for the doctrine of States' rights. The bill provides for the spending of a million and a quarter dollars of government funds annually for the alleged "public protection of maternity and infancy," whatever that may mean. This public protection is to be effected by the Children's Bureau of the Department of Labor, with an advisory board consisting of the chief of the Children's Bureau, the Surgeon General of the United States Public Health Service, and the United States Commissioner of Education. The money is to be spent in the employment of "assistants, clerks, and other persons in the city of Washington and elsewhere," in the purchase of "such supplies, material, equipment, office fixtures, and apparatus" and in the payment of such travel and other expenses as the Children's Bureau may deem necessary for carrying out the purpose of the act, and to pay for instruction to the residents of the various States in the hygiene of infancy and maternity. Any State that wants this federal gift must match it with an equal sum, which means that its helpless citizens will be doubly taxed to pay for "instruction in the hygiene of maternity and infancy through public health nurses, consultation centers, and other suitable measures" approved by the chief of the Children's Bureau. As Senator Reed of Missouri pointed out in a speech last summer opposing the bill, the chief of the Children's Bureau and all her subordinates, with one exception, are maiden ladies whose knowledge of maternity and infancy is purely theoretical.

Sudden Death in the Puerperium from Acute Hepatic Insufficiency.

Accoucheurs are familiar with certain aspects of the toxemia of pregnancy which terminate fatally, including pernicious vomiting, eclampsia, and acute yellow atrophy in some of their more atypical forms. The so-called hepatic form of eclampsia in which the kidneys are intact and the so-called eclampsia sine eclampsia are among the rarer forms of acute toxemia of pregnancy and may destroy life rapidly. A case reported by Couvelaire and Aubertin in *Le Bulletin Médical* for September 7-10, 1921, xxxv, 37, is a good example of very rare and atypical toxemia which did not supervene until after delivery. The patient had gone through four gestations without any disorder and the fifth was also normal until after labor. There was a mere trace of albumin a few days before term. The vascular tension had been normal. Labor was normal and the puerperium banal for a time, but in two hours after expulsion the woman was dead. The earliest symptom was cyanosis followed by profuse sweating and rapid pulse. The suspicion was of concealed hemorrhage, but autopsy showed that none had occurred. The liver was found to be profoundly altered to the microscope. The diagnosis was dissociating hepatitis with atrophy and fatty infiltration of the cells, especially in the center of the lobules. In discussion various opinions were expressed. Potocki was certain that the lesion of the liver was of long standing. Several spoke of obstetrical shock as the determining cause of death, but it was objected that the labor was mild and relatively short. Sudden deaths of similar type have occurred not so very infrequently in women who appeared to be in every respect normal.

News of the Week.

The American Public Health Association held perhaps the most notable meeting in its history in New York City during the week of Nov. 14, under the presidency of Dr. Mazyck Ravenel. The activities of this, the semi-centennial meeting of the organization, were ushered in by sermons on health subjects from many pulpits in the Greater City. Grand Central Palace housed the largest health exposition ever held, from which no educational feature in the drive for better health was omitted. In connection with the exposition there was a baby contest, a search for the most perfect foot among women and for the most perfect set of teeth among children, and there were obesity reduction contests for both men and women. In the background and overshadowing all other features of the celebration was the figure of Dr. Stephen Smith, founder of the association and father of public health propaganda, who is ninety-nine years young and still actively engaged in public health work. A banquet in his honor was given in the grand ballroom of the Hotel Astor, at which he addressed the audience with the vigor of a man of sixty. He made several other addresses during the week, in which he delivered the message that there is no reason why man should not extend the span of life by thirty years, and demonstrating on biological grounds that the natural span of human life is one hundred years. One of his outstanding declarations was that "Few, if any, persons die of too much work, while thousands lose health and life by the slowly disintegrating process of idleness." President Harding sent a message to Dr. Smith congratulating him upon his health and his splendid work and adding good wishes for the testimonial banquet.

During the conference the American Public Health Association adopted the report of a committee, composed of representatives of the Foods and Drugs, Public Health Administration, and Laboratory Sections, recommending that the group of drug addicts spoken of as "criminals, degenerates, and feeble minded" be kept under official control and declaring that the control of this group is a police problem. The group of addicts who suffer from physical conditions necessitating an indefinite continuance of their use of drugs constitutes a medical problem, in the opinion of the committee. The committee's report said that so far as prevention of new cases of drug addiction may be considered a public health problem there are two points that the committee would urge — first, that international measures leading to the reduction of uncontrolled supply of drugs be taken; second, that the importance of the education of the physician as to the dangers of inducing addiction through medical practice and as to the best methods of avoiding such dangers be emphasized. The committee also recommended the appointment of a research committee of clinicians, biochemists and psychiatrists with official sanction to investigate all phases of the narcotic drug question and to make an authoritative pronouncement on the medical problem involved, and that this committee be authorized to cooperate with other official bodies. The Association also endorsed the movement to establish the Gorgas Memorial Institute of Tropical and Preventive Medicine in Panama City, in memory of the late Surgeon General William Crawford Gorgas. A committee was appointed to represent the Association in furthering the memorial.

The following officers were elected to serve for the ensuing year: *President*, Dr. Allan J. McLaughlin, Assistant Surgeon General, United States Public Health Service; *Vice-Presidents*, Dr. Haven Emerson, formerly Health Commissioner of New York City; Dr. Alfonso Pruneda, head of the National Department of Health of Mexico, and Royal S. Copeland, City Health Commissioner; *Executive Secretary*, A. W. Hedrich; *Treasurer*, Dr. Roger I. Lee, Harvard University.

Doctors' Fees and the Workmen's Compensation Laws.—The Committee on Medical Questions of the New York State Department of Labor, appointed to study the questions of medical care of injured employees, medical evidence and the manner of presenting it, method of selecting physicians and payment of medical expenses, hospital service and costs, has been holding hearings on these subjects. Thus far several hearings have been held in New York City, Buffalo, Rochester and Syracuse. Industrial Commissioner Henry D. Sayer states that the Department of Labor has had more difficulty over the medical situation than over any other question under the Compensation Law. At the conclusion of these hearings the Committee on Medical Questions will attempt to frame rules and regulations governing the medical practice and attendant problems.

County Medical Society Election.—The annual election of the Medical Society of the County of New York will be held on November 28. The only contest is for chairman of the Legislative Committee, Dr. Jacob Diner having been nominated in opposition to Dr. A. C. Prentice. Dr. Diner is the candidate of those who are in accord with the State Society in legislative policies.

Misinterpretation of the Harrison Law.—At a meeting of the Council of the Chicago Medical Society on November 8, the following resolution was adopted: *Whereas* Congress has passed a law to deal with the abuse of narcotics, called the Harrison Anti-Narcotic Act, and *whereas* reports are coming from various sections of the country which make it appear that the Bureau having to do with the administration of this act has apparently gone far beyond the intents and purposes of the act in its enforcement through arbitrary rules and unjustified interpretation, and *whereas* it appears that the rulings and acts of this Bureau are causing much intense suffering to many unfortunate addicts and are hampering physicians in their honest endeavor to properly assist these victims, and *whereas* it appears that many purely scientific and medical questions bound up in this Harrison Act are being interpreted and decided by people of no medical training; *Therefore Be It Resolved* that the Chicago Medical Society appoint a special committee to look into the workings of the Harrison Act from every standpoint and to make such recommendations to the Society as will in its opinion secure due recognition of the medical side of the narcotic problem and lead to governing rules that will have the sanction of the organized medical profession.

Pasteur's Centenary Observed.—In connection with the centennial celebration of the birth of Louis Pasteur in France during the week of Nov. 21, it has been revealed that John D. Rockefeller recently provided funds for the purchase of the great scientist's birthplace at Dole in the Jura. It will be transformed into a museum in which will probably be housed an extensive medical aad surgical library, with all the authentic documents of the French savant.

Druggists May Sell Medicinal Beer.—Telegrams were sent on Nov. 17 by Commissioner Blair to all prohibition directors authorizing them to amend the permits of retail druggists to allow them to sell beer for medicinal purposes. Telegrams were sent to retail druggists who have made inquiries regarding permits, advising them that the proper procedure in order to enable them to sell beer for medicinal purposes was to apply to the State Director.

Annual Report of United Hospital Fund.—This report shows that of the money contributed to New York hospitals belonging to the United Hospital Fund, ninety-three cents out of every dollar contributed to the United Hospital Fund last year was spent on patients in the fifty-seven non-municipal hospitals. The operating costs of the fifty-seven united hospitals, exclusive of new construction and improvements, were $14,836,466 last year, caring for 188,532 hospital patients for an average of sixteen days each, and also for the treatment of 628,732 out-patient cases. The average daily number of employees was 10,363, of whom 4,018 were nurses. Visiting and attending staffs of doctors, who care for ward patients and dispensary cases practically without charge, numbered 3,457. From nineteen hospitals in 1879 the organization has grown to include the present fifty-seven. The number of persons cared for has increased from 8,688 in 1879 to 188,532 in the last year, the number of hospital days from 177,692 to 3,010,699, and the receipts from $26,455.07 to $710,773.04.

Unique Volume for Medical Society.—A single volume giving the records of the Hennepin County (Minn.) Medical Society, the preparation of which has taken four years and cost nearly $800, was presented to the society at its meeting on Nov. 8. Dr. A. E. Benjamin, who headed the committee of nine who prepared the book, made the presentation. The volume is bound in morocco and printed on Japanese parchment in its original color, and is designed to withstand the wear and tear of a hundred years.

Seven Counties Favor Tuberculosis Hospitals.—All of the seven Pennsylvania counties that held referendums on Nov. 8 on the question of establishing tuberculosis hospitals voted in favor of the project. The vote was favorable in spite of the fact that loans in several of the counties were defeated. The counties voting for tuberculosis hospitals are Delaware, Montgomery, Berks, Luzerne, Lackawanna, Cambria and Beaver.

Hospital Notes.—The Norwegian Deaconesses Home and Hospital, Brooklyn, N. Y., will conduct a campaign during the week of Nov. 27 to raise a fund of $75,000.

A special tax has been levied to raise funds for a tuberculosis hospital to be erected in Des Moines, Ia., at a cost of $100,000.

The Brooklyn Hebrew Maternity Hospital, at Lincoln Place and Eastern Parkway, opened its doors on Nov. 12. The hospital has a capacity of 200 beds.

A new hospital to be known as the Broadview Healthatorium is to be erected at Wichita, Kan., at a cost of $100,000. The new institution will be built of the cottage plan and will be prepared to care for expectant mothers and patients on diets, rest cures, etc.

Ground was broken for the new Baptist Hospital to be erected at Little Rock, Ark., at a cost of $300,000, on Nov. 7. The hospital will have a capacity of 300 beds. Only the central wing of the hospital, costing $100,000, is to be erected at the present time.

The Thompson Memorial of the Riverside Infirmary, Charleston, S. C., which is to be operated under the direction of the Medical Society of the State of South Carolina, was formally opened on Nov. 10.

"Prevent Disease" Drive.—Resolutions have been adopted by the Medical Society of the County of Kings inaugurating a campaign in preventive medicine. The medical societies of the other boroughs of Greater New York have been invited to join the Brooklyn physicians in their movement to inform the public on "Social Diseases and Degeneration and Waste of the Money and Man-Power of the State." A committee of five has been appointed to confer with similar committees from other medical societies on the preparation of a plan for lectures to be given with this end in mind. The public is to be warned against the "nature and probable effect of threatening or pending vicious public health legislation." The resolution was introduced by Dr. John J. A. O'Reilly.

Dr. Adolf Lorenz of Vienna, Austria, reached New York on the French liner *Paris* on Nov. 19. He will work for a time at the Post-Graduate Hospital.

Dr. Kennon Dunham has been appointed head of the Department of Tuberculosis of the Medical College of the University of Cincinnati and director of the tuberculosis service of the general hospital.

Dr. James S. Danceker has been elected president of the Providence Floating Hospital Association for two years.

Dr. Mendonca and Dr. de Lima, who came to this country to attend the meeting of the American Congress of Surgeons, were the guests of honor at a dinner recently given by the Rockefeller Foundation at the Hotel Commodore, New York.

Charitable Bequests.—Under the will of Ernest Ryle of Paterson, N. J., the Paterson General Hospital receives a bequest of $5,000; the Paterson Eye and Ear Infirmary and the Children's Day Nursery each receive bequests of $2,500.

Drive to Raise Funds for a Medical College.—A campaign has been planned by the trustees of the University of Cincinnati to raise $400,000, the amount still necessary if the gift of $700,000 to the medical college from the Rockefeller Foundation is to be assured.

The New York Academy of Medicine will hold a stated meeting on Dec. 1, under the auspices of its Public Health Committee. A summary of the

committee's findings in a year's study of the hospital situation in New York City will be presented by Dr. E. H. Lewinski-Corwin, Executive Secretary. Dr. George B. Wallace will discuss "The Recording of Hospital Case Histories"; Dr. S. S. Goldwater will discuss "The Private Room and the Ward," and Dr. Gilman Thompson "The Function and Need of a Central Hospital Bureau."

Vacancies for Bacteriologists.—A vacancy is announced for a bacteriologist at the State Hospital for Incipient Tuberculosis, Ray Brook. The duties of the position include experimental studies in tuberculosis, routine laboratory work, and directing activities of technicians. Candidates must have had thorough training in bacteriology and at least three years' experience on problems in tuberculosis. The salary is $2,000 and maintenance. A vacancy is also announced in the position of Laboratory Assistant in Bacteriology, Division of Laboratories and Research, New York State Department of Health, at a salary of $1,500. Candidates must have had a college education or equivalent training in chemistry, physics and bacteriology and have had one year's experience in laboratory work. Application forms may be had by addressing the State Civil Service Commission, Albany, N. Y. Forms may not be sent out after Nov. 28 and may not be accepted after November 30.

Medical Society Elections. — THE SOUTHERN CALIFORNIA MEDICAL SOCIETY, at its sixty-fifth semi-annual session held in Los Angeles, Nov. 4, 1921, elected the following officers for the ensuing year: *President*, Dr. William Duffield, Los Angeles; *First Vice-President*, Dr. Robert Pollock, San Diego; *Second Vice-President*, Dr. H. A. Johnston, Anaheim; *Secretary-Treasurer*, Dr. Egerton Crispin, Los Angeles.

Obituary Notes. — Dr. JOHN J. ROBINSON of Plattsburg, N. Y., a graduate of the University of Vermont Medical College in 1885, died suddenly of heart disease in Albany, N. Y., on Nov. 2, at the age of sixty-five years.

Dr. PHILIP RANKIN KOONS of Mechanicsburg, Pa., a graduate of Jefferson Medical College, Philadelphia, died of heart disease on Oct. 31, at the age of seventy years.

Dr. D. WEBSTER B. KUPP of Reading, Pa., a graduate of the University of Pennsylvania School of Medicine, in 1882, died from cerebral hemorrhage on Oct. 30, at the age of sixty-four years. He was formerly secretary of the Board of Pensions Examining Surgeons.

Dr. CHARLES A. LONG of Muhlenberg, Pa., a graduate of the College of Physicians and Surgeons, Columbia University, in 1887, died after a prolonged illness on Oct. 31, at the age of sixty-one years.

Dr. VILMAS CONDORY, regimental surgeon of Roosevelt's Rough Riders during the Spanish-American War, retired from active practice, died suddenly in San Francisco on Oct. 28, at the age of eighty-four years. He held medical degrees from several European universities.

Dr. CAREY BRECKINRIDGE GAMBLE, the oldest alumna of the University of Maryland, died at his home near Elkridge, Md., at the age of ninety-seven years. He served in the Confederate Army as post surgeon under General Braxton Bragg.

Dr. FREDERICK EDWARD EASTON of Syracuse, N. Y., a graduate of the Long Island College Hospital, Brooklyn, N. Y., in 1884, died suddenly of apoplexy on Nov. 12, at the age of sixty years.

Dr. ROY L. BARR of Gowanda, N. Y., a graduate of Hahnemann Medical College and Hospital, Chicago, in 1908, died suddenly following a surgical operation in Rochester, N. Y., on Nov. 6, at the age of thirty-seven years.

Dr. RUPERT A. FOLGER of Whitestone, Long Island, N. Y., died from pneumonia on Nov. 13, at the age of forty-six years. He was graduated from the Long Island College Hospital in 1898. He was visiting physician to the Flushing Hospital.

Dr. JACOB NEHRBAS of Brooklyn, N. Y., died of heart disease on Nov. 14 at the age of sixty-six years. He was graduated from the College of Physicians and Surgeons, New York, in 1880.

Dr. THOMAS MILLMAN of Toronto died suddenly on Nov. 15 at the age of seventy-three years. He was a graduate of Trinity Medical College, Toronto, in 1873; the Royal College of Surgeons, England, in 1876, and the Royal College of Physicians, Edinburgh, in 1876. He was supreme physician of the Independent Order of Foresters.

Dr. JOHN J. NEWPHER, a graduate of Bellevue Hospital Medical College in 1881, died at his home in Lancaster, Pa., on Nov. 9, at the age of sixty-seven years. He was consulting physician to the Lancaster County Hospital and Deputy Coroner for many years.

Correspondence.

LETTER FROM SWITZERLAND.

(From Our Own Correspondent.)

GENEVA, Nov. 1, 1921.

Encephalitis Epidemica.—I am able to give authentic data received from an absolutely reliable source concerning encephalitis lethargica as it has so far appeared in Switzerland. The first case of encephalitis was observed at Bâle in 1917 and no other case was reported until the end of 1919, when some isolated cases developed in Geneva and Neuchâtel. But during January, February, and March, 1920, there was a rather severe epidemic which began to subside after the middle of March so that by the end of June it had disappeared. The epidemic of 1920 amounted to 984 cases, 850 of them having been reported in January, February, and March, showing the predilection of this disease for cold weather.

The following table shows the absolute proportion of encephalitis per 10,000 persons in relation to sex and age:

Age	Males	Females
Under one year	0	0
1–4 years	0.6	0.9
5–14 years	2.2	1.7
15–19 years	4.2	3.6
20–29 years	3.5	3.5
30–39 years	3.5	3.1
50–59 years	3.6	2.0
60 and over	2.9	1.8
Totals	2.8	2.5

The age at which one is most prone to contract the disease ranges from 15 to 49 years and in this respect is similar to influenza.

The number of deaths positively known to be

due to the disease was 290 out of a total of 984, making a mortality of 29.4 per cent., there being 162 males and 128 females. Contrary to what was noted in other countries the death rate of males was higher than that of females. During January, February, and March, 1921, 28, 49, and 36 cases respectively were reported, with 9 in April, 8 in May, 2 in June, 5 in July, and 2 in August, thus making a total of 139, and as compared with the epidemic of 1920, that of this year appears to have assumed a less serious type.

The contagiousness of the disease in Switzerland was not at all evident; nearly everywhere the cases developed sporadically, but some familial epidemics were noted which would seem to leave no doubt as to the contagious nature of encephalitis lethargica. The virus of this disease, like that of epidemic cerebrospinal meningitis and acute anterior poliomyelitis, so far appears to possess only a very slight power of propagation. But this does not mean that this factor should be regarded as negligible because, as in cerebrospinal meningitis, the virus of encephalitis may become suddenly intensified from unknown causes, so that a real epidemic explosion may ensue.

In Switzerland, as elsewhere, encephalitis has presented an accentuated polymorphism. Its proteiform aspects have notably differed from what was observed in former epidemics and the clinical triad—ophthalmoplegia, somnolence, and meningism—described by Economo for making a sure diagnosis, has been partially destroyed. In not a few cases there was restlessness instead of somnolence and the disease was one of insomnia. Delirium, similar in type to delirium tremens, has been noted.

Ophthalmoplegia has often been absent and when it did exist it was sometimes incomplete, fleeting, and alternating, the paralysis passing from a muscle to its homonym on the opposite side. As compensation, algias, often of a very obstinate kind, have been observed along with myoclonus and the myoclonic synchrome of the limbs and abdomen has sometimes assumed such intensity as to resemble electric chorea. The syndrome of paralysis agitans has likewise been encountered, as it has been in England and elsewhere. Nystagmus is also frequent. In some cases a true infectious exanthema has been noted, and the rise in temperature is constant.

At first it was stated that encephalitis lethargica was characterized by the absence of meningeal reaction, but the work carried out in Swiss clinics during the epidemic of 1919-20 by Turrettini, Bauer, and Stähelin has shown that this opinion should be revised. An early lymphocytosis has been found, especially marked in the oculolethargic forms of the process, moderate or even nil in the myoclonic or nervous types, and rapidly diminishing with the retrogression of the symptoms. Whether or not the tension of the cerebrospinal fluid remains normal is yet a moot subject. While Turrettini maintains that it is normal, Bauer noted a moderate increase in most of his cases. A partial or total hemorrhagic state of the cerebrospinal fluid has occasionally been found whose content of glucose is likewise increased (hyperglycorrhachis).

Briefly, it would seem as if the clinical picture of encephalitis at first was limited to a localization of the virus in the mesocephalon and then as the epidemic continued the virus, for unknown reasons, progressively invaded other portions of the cerebrospinal axis. As to the gravity of the various forms of the process, Cramer of Geneva has remarked that the types with insomnia have a much more serious prognosis than the lethargic forms, and death occurred in his cases only in the former. From a study, especially on his own cases, Bauer has attempted a classification which is interesting to refer to because in a way it is a summary of the cases as they occurred in Switzerland. He distinguishes four types of encephalitis: (1) The cortical type, with acute delirium simulating delirium tremens, general paralysis, and other psychoses and typical Jacksonian epilepsy or aphasia of Broca's type. (2) The classic mesocephalic, myoclonic, and lethargic types as well as alternating paralysis in which the Parkinsonian type may perhaps be included. (3) The meningeal type, very difficult to distinguish from the tuberculous variety. (4) Forms with an unrecognized localization, simulating hysteria and other neuroses. There is, of course, the entire scale of fleeting, abortive, and aberrant types, which is not included under the headings of the above classification.

For reasons too numerous to discuss, the opinion of the Swiss profession becomes more and more inclined to regard influenza and encephalitis lethargica as two distinct morbid processes. Their coincidence may be explained by the interference of certain factors whose action has as an effect to activate their respective viruses simultaneously. It is evident that this explanation is very hypothetical, so that the question is still moot.

7. Pessary Worn Without Removal for Twelve Years. Charles J. Kickham.

1. Surgical Aspects of Intraabdominal Tuberculosis in Infancy and Childhood.—Charles G. Mixter bases this paper on a study of 120 cases of tuberculous peritonitis, chiefly from the surgical service of the Children's Hospital. He groups tuberculous peritonitis into three types, namely, the miliary type, the ascitic type, and the adhesive or plastic type. He believes these various types to be different stages of the same process. A family history of tuberculosis or known exposure was elicited in only 12 of the 120 cases. This point is suggestive evidence that tuberculous peritonitis is one of the most frequent varieties dependent on the bovine bacillus, as is also the fact that the relative number of such cases has apparently decreased during the last decade, coincident with more adequate supervision of the milk supply. The *x*-ray is of no value in clearing up an obscure diagnosis in cases of abdominal tuberculosis, except in demonstrating calcareous glands, or

revealing a spasm of the ileocecal valve. As to the treatment, where practicable in cases of mesenteric adenitis, excision of the tuberculous focus and correction of the cause of ileal stasis is indicated. Operation should be advised in any case of the ascitic type, where improvement does not take place after a fair trial of medical treatment. Laparotomy has frequently marked the turning point toward convalescence in a patient who has been progressing unfavorably under hygienic measures. The causative factor has never been proved, though it is generally considered that the hyperemia produced by the withdrawal of the fluid and the entrance of air into the peritoneal cavity is responsible. Working on this supposition, seven years ago, the writer began the introduction of nitrogen into the peritoneal cavity after the evacuation of the fluid. Later air was used in place of nitrogen. The results thus far obtained suggest that air injection may give more beneficial results than simple laparotomy. In the plastic type of the disease, operation is of no value except in meeting complications of the disease. The hygienic treatment is of paramount importance. Surgery should only aid and never supplant it.

5. Squamous Cell Carcinoma of the Antrum. Report of a Case, Treated with Radium Alone, That Is Free from Recurrence Twenty-two Months After the Last Application.—J. Harper Blaisdell describes the operative procedures that have been employed in the removal of squamos celled carcinoma of the antrum and the method of combining the actual cautery and radium, employed by New at the Mayo Clinic in eight cases, of which only three were alive and without recurrence at periods ranging from thirteen to seventeen months. The case reported by Blaisdell was a man 63 years of age who developed cancer following chronic tooth disease. At the time he came under observation the mass in his cheek was large enough to push the nose well over to one side; there was obstruction and discharge from the affected nostril. No glands were palpable. Under ether anesthesia an incision was made into the antrum through the canine fossa and the radium introduced. This consisted of 50 milligrams of radium element, screened with 0.5 millimeters of silver and 1.0 millimeters of brass. It was left in place twenty-four hours, giving a dosage of 1200 milligram hours. The immediate effect was excellent. About a month later a second application of radium was made, using double the dosage above mentioned. Three weeks after the last treatment three months of extreme suffering began. The few remaining teeth on that side came out; the hard palate up to the median line and the alveolar processes sloughed away. The constitutional reaction was most striking. There was a mental dulling and complete physical failing. Pain was so extreme as to demand morphine over several weeks. The man's weight fell from 180 to 130 pounds, and a fatal termination seemed the only possible outcome. Finally a very large mass of sequestrum came away, and from that time the patient improved rapidly. Within a few weeks he was back at work and felt as vigorous as he had been all his life. His weight returned to 185 pounds. The final result was complete removal of the antrum and its surrounding structures from the mouth to the orbit. No recurrence has appeared in the twenty-two months that has elapsed since the second radium treatment.

6. Monitor Ventilation.—Walter A. Griffin points to the failure of the usual methods of ventilation now in use and describes the monitor system which has been in use for two years at the Sharon Sanatorium and has proved so highly satisfactory that they would not construct a building ventilated in any other way. The principle of the monitor system is exemplified in the Indian wigwam, built in the shape of a cone with an opening at the apex. In order to remove the vitiated air from a room most thoroughly there should be not only an opening in the ceiling but the ceiling should be raised at its center to a peak like the attic of a house. With this system the air inside the buildings is seemingly as pure as out-of-door air. When used in schools the results are practically as good as in an open-air school, and far less rigorous for the pupils. With it there are no perceptible drafts. Its disadvantages are that it presents some architectural problems where a more than one story building is to be erected, but these are not insurmountable. It might also be objectionable in certain noisy or dirty places in the city. A school in Canton, Mass., is ventilated in this way, and all of the teachers are exceedingly enthusiastic. They state as their impression, though no data have been collected, that the incidence of respiratory disease among the pupils is much less than in an ordinary school room.

1. Protein Hypersensitiveness and Its Importance in the Etiology of Disease.—Warfield T. Longcope reviews the history of the subject of hypersensitiveness in man, and adds certain new observations. He states that a certain proportion of individuals possess a peculiar idiosyncrasy to some substance or substances that usually are proteins, or contain proteins, but that may be of a non-protein nature, such as certain metals and drugs. Contact with these substances under certain conditions may cause hay fever, asthma, gastrointestinal disturbances, eczema, urticaria, or other cutaneous manifestations. As a rule the symptoms of these diseases appear early in life and may be observed the first time the patient comes in contact with the substance to which he is hypersensitive. There is undoubtedly a definite tendency toward the inheritance, not of a specific hypersensitiveness, but of a quality of tissues that allows of the development of idiosyncrasies; and this may be dependent on a condition of the body fluids or of the cells which permits of a ready union of foreign protein with them. The peculiarity of the patients is that the skin reacts by the formation of an urticarial wheal to the application of the substance or substances to which they are hypersensitive. Though these reactions are highly specific, they may be multiple and produced by a large variety of proteins. Normal individuals who have had subcutaneous or intravenous injections of horse serum show a measurable difference in their susceptibility to serum disease. This does not depend upon the amount of serum, but on the condition of the tissue cells and fluids of the body which, in susceptible individuals, allows of rapid union of the foreign serum with the cells of the body. The writer's observations suggest very strongly that the susceptibility of certain individuals to serum disease depends upon the readiness with which the cells of the body unite with the circulating horse serum to form antibodies. Should this preliminary union be interfered with, the subsequent reaction is very slight, and if the union of the circulating horse serum and the cells of the body is by any means completely prevented, there will be no formation of antibodies, and no manifestation of serum disease. It is impossible to say at present whether this protection against the foreign protein is due to some quality of the serum which stands as a barrier, so to speak, between the cells of the body and the foreign protein, or whether the protective mechanism resides in the cell itself, which for some reason is impermeable to horse serum. It seems possible that sensitization of the human being may well depend upon two factors: (1) The permeability of the tissue cell to the foreign protein, and (2) the formation of antibodies within the cell. That many of the characteristics of the symptoms and reactions that occur in the hypersensitive patient may be produced in normal individuals by chemical substances is well known. It seems highly probable, from all the evidence that can be col-

lected, that proteoses, or the toxic amines such as histamine, may be absorbed from the intestine and cause disturbances not only of nitrogenous catabolism, but also temporarily of renal functions, but without anatomical lesions in the kidneys that can be demonstrated by our present methods. To explain satisfactorily the clinical manifestations of the idiosyncrasies and allied disturbances, one must, therefore, consider two factors: (1) The possibility of a specific hypersensitiveness toward some protein or chemical substance; and (2) the possibility of a direct intoxication by some poisonous derivative of the protein molecule. How nearly related these are and what part the second plays in causing symptoms in the hypersensitive individual, it is impossible to state at the present time.

2. The Pirquet System of Nutrition and Its Applicability to American Conditions.—William E. Carter describes the Pirquet system for determining the nutritional index of a given subject, based on the belief that the sitting height furnishes a more accurate basis for estimation of the nutritional state than the standing height. It was demonstrated that the cube of the sitting height in centimeters is approximately ten times the weight in grams of the normal person. When the sitting height and the weight are known the formula is simply ten times the weight divided by the cube of the sitting height equals 100 per cent. To designate this percentage of nutrition, Pirquet coined the word "pelidisi" (*p*ondus, *e*decies, *l*inear, *d*ivided by *s*itting height). In actual practice, the pelidisi of a well-nourished normal child is close to 100 per cent; an obese child may go up to 110, while thin children will run between 88 and 94 per cent. Instead of the calory, Pirquet prefers a nutritional unit based on the food value of 1 c.c. of milk. This unit he calls a "nem" (*n*utritional-*e*lement-*m*ilk). The physician and dietitian have to deal with a populace to whom milk is familiar and who can readily visualize a unit of food measured in terms of this common article of diet, while the calory suggests nothing concrete to one unaccustomed to thinking in terms of physics. The fact that there are about 667 calories in 1000 c.c. of milk further complicates the system. With Pirquet's method 1000 c.c. of milk equals 1000 nem. The nutritive value of any other food can be readily expressed in nem simply by comparing its food value with that of milk. Pirquet also estimated the needs of the individual for basal metabolism and for varying degrees of activity. The writer believes the Pirquet system is applicable to American conditions, especially those under which it may be desirable to feed children in considerable numbers. It provides a simple, accurate, and rapid method of estimating the nutritional status easily grasped by workers even without medical training; it reduces the prescribing of the requisite food intake to a simple formula; it makes it possible to use a single word to make a record of the child's nutritional state which may serve for comparison with the results of future examinations; it eliminates waste and at the same time supplies the child with an adequate amount of food and by its very operation it secures the actual ingestion of the food; it serves as a selective agent, at once segregating children into various groups —those with a moderate need, those with urgent need, and those without need of additional food. The Pirquet system has been applied in the children's wards and in the out-patient department of the University of California Hospital, and has been found applicable, easy of accomplishment, and extremely popular among all who work with it. It has been applied to the examination of children in several schools and brings out the fact that many of our own children, judged by the same standard employed by the American Relief Administration, are in need of supplemental food.

5. Tumors of the Pancreas.—Charles D. Lockwood discusses the diagnosis of pancreatic tumors and reports a case of sarcoma of the tail of the pancreas, a condition which is exceedingly rare. He says the diagnosis of pancreatic tumors is exceedingly difficult; there are, however, certain symptoms common to all tumors of the pancreas. These are: (1) Pressure symptoms exerted by the tumor upon surrounding structures. Tumors of the head of the pancreas by pressure on the large vessels or the common duct may produce edema, ascites, or persistent jaundice. Pressure on the renal veins has produced marked hematuria as reported by Ransohoff. Pressure on the stomach and duodenum causes distention and apparent filling defects simulating tumor of the stomach on the roentgenogram, as was shown in the writer's case. Pressure on the solar plexus produces epigastric pain. Tumors of the tail of the pancreas give rise to fewer pressure symptoms, owing to the large space offered for growth in this location and the freer mobility of the tail. Tumors of the tail, however, closely simulate those of the kidney and spleen. In addition to pressure symptoms there are: (2) Fatty stools due to closure of the pancreatic duct. The failure of the pancreatic juice to enter the duodenum may be determined by the administration of salol, the so-called "Signe de Sahli." Undigested muscle fiber in abnormal quantities has also been reported by a number of observers. (3) Sugar in the urine has been reported infrequently. (4) One of the most characteristics symptoms is rapid emaciation with cachexia and weakness. Dr. Joseph Bloodgood, after examining a section of the tumor from the case reported, stated that it was a sarcoma. Dr. E. R. LeConte of Chicago questions the possibility of this being a primary sarcoma of the pancreas; he thinks it may be a lymphosarcoma originating in the retroperitoneal tissues.

2. Hunger-Osteomalacia in Vienna, 1920. I. Its Relation to Diet.—Elsie Dalyell and Harriette Chick have made this report to the Accessory Food Factors Committee appointed jointly by the Lister Institute and the Medical Research Council. Briefly, they find that the occurrence of "hunger-osteomalacia" in Vienna during the period of greatest food deprivation, its incidence among the poorest inhabitants, and the beneficial effect of improved diet without any other form of treatment, suggest that the disease is of dietetic origin. The disorder affects chiefly middle-aged and old people of both sexes. The characteristic symptoms of the condition are pain on body movement, difficulty in mounting stairs, severe pain in the sacral region on pressure or movement, a waddling gait, and pain in the ribs on compression of the thorax. Tetany may occur in association with the disease. Forty-eight cases were treated by making additions to the patients' diets in the form of carbohydrates, cereals, and fats of various kinds. Little improvement could be demonstrated after the addition to the diet of sugar or cereals (*i.e.* extra calories without fat), although in many instances the previous diet had been very scanty. Recovery followed the addition of either cod-liver oil, butter, oleomargarine containing 80 per cent. of animal fat, or olive oil. The beneficial influence was in the order named above, cod-liver oil being by far the most effective. Some of the severer cases did not improve until cod-liver oil was given. The relative therapeutic value of the fats used corresponds roughly to their content in fat-soluble A vitamine. This is regarded as significant. It is also possible to interpret the remission of symptoms of "hunger-osteomalacia" in summer and their relapse in winter as due to varying supplies of vitamine A in the diets, for, during summer, inclusion of green vegetables in the diet provides a valuable source of this vitamine. One attempt, however, to cure a severe case with a fat-free diet, rich in green vegetables, was not successful. More observations are needed on this point. The increase in Vienna of rickets in children and of late rickets in young adults, simultaneously with the occurrence of "hunger-osteomalacia" suggests that the three disorders may be due to the same cause.

2. II. Comparative Treatment of Cases of "Hunger Osteomalacia" in Vienna, 1920, as Out-Patients with Cod-Liver Oil and Plant Oil.—E. Margaret Hume and Edmund Nirenstein, out of 177 cases of hunger-osteo-

malacia treated as out-patients in Vienna, selected 130 as suitable for this experiment. About one-third of the number was treated with a plant oil (subsequently identified as belonging to the rape oil group) containing phosporus, the other two-thirds with cod-liver oil. Most of the patients made progress, but some of the patients on plant oil had to be transferred to cod-liver oil, and some of those on cod-liver oil had to have the dose increased before good progress could be made. The results fall into a series; doses of about 100 c.c., 150 c.c. and 200 c.c. of each of the two kinds of oil were given. The smallest dose of plant oil gave the worst result and the largest dose of cod-liver oil the best; the smallest dose of cod-liver oil was better than the largest dose of plant oil. Once a good improvement was set on foot it could not be detected that the rate of progress on the different doses varied much. It is provisionally concluded that cure of the disease was due to addition of vitamine A rather than of fat as fat to the diet. The relation of hunger-osteomalacia to the osteomalacia of pregnancy is regarded as quite uncertain.

3. Practical Points in the Treatment of Plague.—Wu Lien Teh (G. L. Tuck) traces the beginning of the bubonic plague of 1920-21 in the Transbaikal district of Siberia toward the end of the summer. During a stay at Hailar he was able to follow it through its evolution from bubonic, through the septicemic into the pneumonic form, after which it became most infectious and dangerous. Fortunately, owing to the early preparations made by the Manchurian Plague Prevention Service and the splendid co-operation by the authorities of the Chinese Eastern, South Manchurian, and Chinese Government Railways, as well as by most classes of people, the epidemic did not reach the colossal dimensions of that of 1910-11. For instance, the whole of the Changchun district only claimed 77 deaths from plague, and Mukden only four deaths, as compared with 5000 deaths in each city during the epidemic of ten years ago. Whereas at least 50,000 plague deaths were recorded in 1910-1911, only 8500 persons died in the epidemic of 1920-21. The Plague Prevention Service made and distributed 60,000 anti-plague gauze masks and 8000 doses of anti-plague vaccine from their laboratory. In addition to their routine work, the staff took advantage of the occurrence of this rare epidemic to perform a series of important bacteriological investigations. Experiments performed ten years ago at Mukden, and repeated this time at Harbin, show that the infection is transmitted in droplet form, and that the droplets seldom travel more than three feet. If a way can be found to allow persons to sleep as well as work out in the open air, however cold, infection will not take place and pneumonic plague will lose its dreadful character. The cotton and gauze mask is apparently efficacious against the plague, though it was considered best for those in immediate contact with patients to wear, in addition to the mask, a head covering made of cloth with an extra piece of silk before the nose and mouth. Experiments indicated that air of the sick room was not nearly as dangerous as might have been expected. It was found that the clothing from plague victims was highly dangerous and should be burned with the dead bodies. Over 400 experiments were carried out with the best known antiseptics, and it was found that the plague bacilli were extremely resistant to their action, and more concentrated solutions for longer periods than usually recommended are necessary to destroy the bacilli.

1. The Harveian Oration on William Harvey, Obstetric Physician and Gynecologist. Herbert R. Spencer.
2. The Physiological Cost of Muscular Work: A Reply to Objections. A. D. Waller and G. DeDecker.
3. Glycosuria of Malarial Origin. G. A. Harrison.
4. Over Five Hundred Gallons of Fluid from an Ovarian Tumor. John D. Malcolm and G. A. Gibb.
5. A Method of Skin-grafting. Samuel Samuel.

3. Glycosuria of Malarial Origin.—G. A. Harrison notes that in referring to several textbooks on medicine no mention of glycosuria of malarial origin could be found. Castronuovo, however, regards malaria as important in the etiology of some cases of diabetes mellitus. (*Medical Science*, iv, 6, 497, September, 1921.) The case reported is that of a Jewish merchant, 32 years of age, who went to Bombay in 1919; in 1920 was in bed three weeks with dysentery and colitis, and a little later developed malaria. Parasites were found in the blood. During the following six months he had a number of relapses, and in March, 1921, sugar was found in his urine, and a diagnosis of diabetes mellitus was made. Carbohydrates were reduced; the glycosuria decreased considerably, but was present in May, 1921, when the man left India. In June sugar was again discovered, but in July Sir Charlton Briscoe found no trace. There was a family history of diabetes which should make it instructive to keep in touch with the case for several years. The writer speculates as to the site of action of the malarial toxins—whether the glycosuria may have been due to diminished glycogenic function of the liver and other tissues. Presumably the urobilinuria resulted from the destruction of red blood corpuscles by the malarial parasites, but, in part, at any rate, may have been due to the effect of their toxins on the liver. The islands of Langerhans may have suffered from the toxic action, so that the supply of internal secretion was insufficient to prevent glycosuria on a full diet. Against this is the fact that all the pancreatic tests performed in this case were negative. Owing to toxic action of the kidneys their "leak point" temporarily may have been lowered. The type of blood sugar curve gives some slight support to this hypothesis, since four days after evident glycosuria the curve should have revealed some degree of hyperglycemia unless the glycosuria was of the renal type. Lastly one may picture a toxic influence on several of the ductless glands, so that the balance between their secretions was upset in such a direction as to cause glycosuria. There is always the possibility of two or more of the above causes being at work. Such theorizing suggests possible lines of research in malarial patients that might be of interest if not of real value; for instance, (1) examination for glycosuria before treatment, and (2) blood-sugar curves to decide, among other things, if the glycosuria is renal in origin. As in two cases previously published, so in this instance the glycosuria cleared up with quinine in the absence of dietetic treatment; in fact, sugar was deliberately included in the diet throughout the patient's stay in the hospital.

4. Over Five Hundred Gallons of Fluid from an Ovarian Tumor.—John D. Malcolm and G. A. Gibb state that the cyst from which this fluid came was noticed in 1893, and the abdomen was tapped the first time in the autumn of that year. In 1899, after about six years' tappings, the late John Langdon tried, and failed, to remove the tumor. On July 20, 1906, John D. Malcolm tried again, with the same result. Almost to the last the condition of the patient was fairly good. She was up and about and ate enormous quantities of food, except just before tappings, when she suffered from nausea and vomiting. On June 30, 1921, when a tapping was about due, the patient was seized with pain and vomiting, and was tapped without relief. She died on July 6, at the age of 67. There were some 368 tappings in all, by which 506 gallons of fluid, which would weigh two tons, were removed.

5. A Method of Skin Grafting.—Samuel Samuel describes a method of skin grafting by which the grafts and area to be covered are prepared in the ordinary way, and the grafts are applied to the skin-free area in the usual manner. Silk threads are then carried from one side of the surrounding healthy skin over and through the graft and into the underlying granulation tissue and then through the healthy skin on the opposite side. The grafted area is then covered with perforated protective, preferably the transparent variety. On top of the protective is placed a thick layer of sterile gauze damp with the physiological saline or artificial serum, and a final over-all dressing, consisting usually of a thin layer of dry sterile gauze. The silk threads are then utilized for anchoring all the dressings, the silk being finally threaded through thin rubber tubing and then knotted on the tubing to prevent cutting. By this method the grafts can be easily and frequently fed. The threads not only carry the feed, but drain away the discharge which forms around the granulations. By this method it is not necessary to

disturb the grafts and the dressing affords means of applying firm gauze pressure, which is so essential for insuring success and for keeping grafts and dressings in position in cavities and hollow surfaces and in convex areas. The use of splints, strapping and the application of collodion is thus done away with. The only disadvantage is the little extra time required in doing the operation.

September, 1921, clxii, 3.

1. Diagnosis and Clinical Manifestations of Cardiospasm Associated with Diffuse Dilatation of the Esophagus.—Frank Smithies during the past seven years has observed 76 cases of cardiospasm associated with diffuse dilatation of the esophagus. The tabulated records of 47 of these cases were available for study. Of the 47 cases there were 25 females and 22 males. This equality in the sex ratio is rather striking in view of the prevalent opinion that females are more likely to be affected than males. The average age of the series was 39.2 years, the majority of instances occurring between 25 and 35 years. Occupation seems to play a very small part as an etiological factor, but the ailment seems to be relatively common in those individuals who are very active physically and mentally. Temperament, it would seem, has been rather unduly emphasized in its relation to the initiation of cardiospasm. Ailments previous to the onset of the cardiospasm, with a few exceptions, appear to have little bearing with regard to causing the affection. Excessive smoking, particularly of cigarettes, was noted in five cases, and offers an interesting etiological suggestion to those who attribute cardiospasm to vagus malfunction. In but 17 instances the affection with the associated dysphagia was acute in its inception. The average duration of symptoms in this series was 5.6 years, and ranged from three months to twenty years. Dysphagia was not commonly painful. It is of diagnostic significance to know that liquid foods are more prone immediately to bring about distress than are solids. In this way the type of dysphagia differs strikingly from that common to various forms of anatomical stenosis. A fairly characteristic and differential feature of the vomiting is that it is usually sudden, frequently explosive, and very often occurs shortly after the ingestion of food. Regurgitation, without actual vomiting, was especially annoying in 15 of these patients. Other symptoms are loss of weight, poor appetite, anorexia, and constipation, largely due to insufficient amounts of food. Roentgen examination is of great aid in diagnosis, but the evidence which it supplies is not infallible. Roentgenograms should be made with the patient in the semilateral or "quartering" position as well as in the anteroposterior. Inasmuch as in certain cases of cardiospasm the initiating fault lies in an esophageal lesion it would appear to be a proper procedure to examine by sight the entire esophageal mucosa from pharynx to cardia, provided one is familiar with esophagoscopes and knows the significance of what he sees. If the affection is properly managed, there is clinical and functional recovery in about 70 per cent. of even well established instances of cardiospasm; improvement occurs in about 20 per cent., and about 10 per cent. of the patients are not permanently benefited by any form of treatment at the most expert hands. In these unfortunates gastrostomy may be required to save or prolong life.

2. The Spleen and Digestion.—William DeP. Inlow reviews the literature and various theories that have been advanced in regard to the function of the spleen, and presents an experimental study of the effects of splenectomy on dogs, which he summarizes as follows: (1) Removal of the spleen causes a diminution of the proteolytic power of the gastric juice (Tarulli and Pascucci, Gallenga, Betti, Gross, Rusca, Soler, and Madero). (2) Injection of splenic extracts (Tarulli and Pascucci, Soler and Madero) and of leucocytes and of extracts of lymph glands (Soler and Madero) increases the proteolytic power of the gastric juice of splenectomized animals. (3) Removal of the spleen causes an augmentation of the proteolytic power of the gastric juice (Silvestri, Tini). (4) Removal of the spleen has no effect whatever on the gastric secretion (Trampedach). The chief theory put forward by the first group of investigators has been that the spleen gives the blood stream during digestion a substance which activates or leads to the further elaboration of the gastric enzymes, especially pepsin. In the writer's experiments on three dogs with accessory stomach pouches (secretory meal of meat), and on two similar dogs serving as controls, removal of the spleen caused no noteworthy changes in gastric secretion except a slight diminution of the gastric juice obtained. From these experimental inquiries and a critical review of the literature Inlow is led to the conclusion that a definite pepsinogenic function of the spleen has not been demonstrated and that the relation of the spleen to gastric secretion is probably merely vascular, the diminution in the amount of juice secreted after splenectomy being attributable to decreased gastric blood supply from injury to the gastrosplenic circulation.

4. The Relative Value of Laboratory and Clinical Methods of Study in the Diagnosis of Tuberculosis.—F. M. Pottenger shows how advantageous it would have been had clinical observation kept pace with laboratory research during the period of development of our knowledge of tuberculosis; and that with our knowledge brought up to its present state, the one outstanding cry is for more thorough clinical study. It now offers the greater and apparently more fruitful field. Starting with the conception that tuberculosis is an infectious inflammation, chronic in nature, which (1) disturbs the nerve and endocrine balance of the patient, and particularly produces sympathetic effects by toxins which are liberated from the diseased areas, and in this manner produces general symptoms, and (2) irritates nerve endings in the lungs and thus produces reflex symptoms, we have a basis for explaining two groups of common symptoms found in this disease, the toxic and the reflex. To these one more is added in early tuberculosis, in which those symptoms are placed which are incident to the disease itself; and still another in advanced tuberculosis in which are placed symptoms and syndromes which result from the disease. After discussing these four groups of symptoms, attention is called to a tendency in examining chests to direct attention too much to the changes in the lung. While these are what we wish to determine, we must not consider that we can auscultate and percuss the lung alone. Percussion examines the skin, subcutaneous tissues, muscles, bony thorax, lung and all adjacent structures which modify the impulse. The tension of the soft tissues as revealed, especially in the degeneration of the subcutaneous tissue and muscles and the increased muscle tone, often make up most of the departure from normal in the percussion note. This is particularly true in percussion over the apices from the second rib upward in early tuberculosis. When active tuberculosis is present the scaleni, the sternocleidomastoideus and the pectoralis all show increased tension, and so produce a fixing of the upper portion of the chest wall. Percussion through this fixed area and through the tense muscles must of necessity produce greater changes in the percussion note and percussion resistance than can possibly be produced by the few tubercles in the lung. This the writer believes causes the major portion of the percussion changes that we have been ascribing to the infiltration in the lung in early tuberculosis. He goes on to show that increased muscle tonus, particularly as detected on

palpation, and the lessened respiratory movement, are just as much symptoms of physiological disturbance as are the symptoms which he details under clinical history. They are the most evident and therefore the most dependable symptoms indicative of active inflammation in the lung; and because of their localization in definite groups of muscles their presence suggests pulmonary disease.

6. Classification of Râles: A Plea for Simplification.—J. Birnie Guthrie, after discussing the various classifications of râles, suggests the simple heads: (1) Crepitant or vesicular; (2) mucous or tube; and (3) cavernous. Under these he says we shall be able to place every râle we hear except pleuritic friction sounds, which are perhaps best excluded from this category. He argues that he is not perverting the meaning of the word mucous, since, whether fluid or tenacious, the basis of the mechanism which produces them is mucous. The classical terms subcrepitant, sonorous, and sibilant may be used as subdivisions of the mucous. Nearly all of the half a hundred of varieties described by various authors would be subvarieties of the mucous râle. *Cavernous* might also be included within the category of mucous râle, which would be a further and desirable simplification.

7. Diagnosis of Lung Tumors.—A. S. Blumgarten confines his remarks to the medical diseases of the lungs which are amenable to surgical treatment. He states that primary lung tumor is one of the most difficult pulmonary lesions to recognize early. This can only be done with a fair degree of certainty. If we wait until we can do so positively the patient is beyond our therapeutic reach. Consequently, when the condition cannot be recognized definitely an exploratory thoracotomy should be performed whenever there is a reasonable suspicion of a primary tumor of the lung. If such a lesion is present it can be removed at the time when the operative risk is at a minimum and the chances of recovery are at their height. Clinically two types of primary lung tumor may be recognized, the pleural and the hilus type. The pleural type is most amenable to surgical treatment. A reasonable suspicion of the presence of the pleural type of primary lung tumor is based upon the occurrence of a one-sided pleural effusion, with or without bloody fluid, in the absence of definite signs of tuberculosis. The roentgenograms of the chest taken when the pleural cavity is inflated after removing the fluid is one of the best methods to demonstrate the mass in the lungs. The most important indications of the presence of the hilus type are the persistence of chronic bronchitis in the absence of tuberculosis, with evidence of blood-tinged sputum and the subsequent evidence of a mediastinal mass with pressure symptoms. In these cases bronchoscopic examination is of the greatest diagnostic value and gives the earliest evidence. The careful study of many cases of recurrent pleurisy and chronic bronchitis will probably reveal that primary lung tumors are much more common than we have heretofore believed.

Diagnosis of Threatened Perforation of Gastric Ulcer.—Ryser wrote a paper on this subject in 1913, and since has had eight additional cases in his practice, with a total of fourteen. In the last series he was able in two cases to make the correct diagnosis of threatened perforation from the telephone summons alone, so typical was the syndrome. Naturally the patients were under his care at the time for ulcer of the pylorus. The author narrates four of his cases to bring out the syndrome in question, which is in part as follows: The patient is seized with severe pain with or without hematemesis. It is likely to occur when the patient is off the ulcer diet and up and about, but when these measures are begun or resumed the pain does not improve as is the case in simple ulcer pain. The anteperforative pain persists for several days before perforation occurs, thereby giving the surgeon an opportunity to operate before this crisis. In the author's experience this latent interval is always present. If operation is not performed after the onset of these symptoms perforation inevitably occurs. The pain is not entirely peritoneal, being associated with simple ulcer pain. In the absence of a correct diagnosis an unnecessary operation may be performed. The fact that the pain is refractory to treatment is of value in diagnosis. The diagnosis of pyloric ulcer is also of value as in this locality perforation is most likely to occur. When the surgeon is summoned for the first time the diagnosis of ulcer must be first made, before the pain can be interpreted correctly. History of stomach troubles with remissions and exacerbations, examination of stomach contents, localization in the pylorus, etc., should enable the surgeon to make this diagnosis in season to avert perforation.

The "Doll's Eyes" Phenomenon.—Cantelli applies this nickname to a phenomenon which, according to him, has never before been recorded. There is a dissociation between the movements of flexing the head and lowering the gaze, and those of extending the head and raising the eyes: as a result of which flexion and extension of the head are not accompanied as usual by the proper movements of the eyeball. This dissociation he has seen after epidemic encephalitis, and attributes to focal lesions in the mesencephalon which may be unilateral or bilateral. The author mentions but two cases, and gives no detailed account of them. The eye mobility was in all other respects normal. He was struck by the resemblance of the behavior to that of the movable eyes of dolls in which forward inclination of the head is not followed by downward turn of the eyeball. The author goes extensively into the normal and pathological movements of the head and eyeballs in the attempt to account for this behavior of the eyes by the above-mentioned localization of mesencephalic lesions. His article is partly designed to anticipate priority as the discoverer of a new phenomenon.

La Presse Médicale.

September 21, 1921, xxix, 76.

Suppurative Orchitis in Mediterranean Fever.—Lombard and Béguet of Algiers first mention the benign inflammation in the male gonads, seen in a small percentage of victims of this acute affection. Suppuration is a termination wholly exceptional, although there may be atrophy of the testicle or persistent nodules in the epididymitis as sequelæ. The *Micrococcus melitensis* is notoriously nonpyogenic, so that suppuration should in theory denote a mixed infection. The authors can find record of but five cases of testicular abscess, one of which is personal and moreover studied under complete bacteriological control which was evidently absent in two of the others, while in a third results of examining punctate were negative and in a fourth there is no mention of finding the micrococcus in the testicle or punctate—although a histological examination was made of the ablated organ. The authors found the micrococcus in the pus from the testicular abscess, but nothing in sections of the ablated testicle. The absence of any of the pyogenic organisms, banal or rare, appears to show that in very rare cases Bruce's organism can itself be pyogenic. This patient was a man of 56 who had suffered from both malaria and dysentery. His orchitis was a late complication which appeared three months after the onset of Mediterranean fever, but this attack passed off and the suppuration developed during a late relapse which appeared four months after the original lesion. Castration became necessary in another three months, the testicle then being as large as an egg, although with its proper tissue nearly destroyed. There is no mention of orchitis on the opposite side, but there was a resolved epididymitis. The patient was laid up altogether about a year and it was of course necessary to exclude banal affections of the testicle, as syphilis, tuberculosis, and some mycosis.

Surgical Intervention in Status Epilepticus.—Picqué cites a case in an ex-soldier, in which craniectomy was performed on the third day of serial and overlapping attacks. Dural adhesions were freed and patches of leptomeningitis found but the suspected abscess of the brain was not present.—*La Presse Médicale.*

Book Reviews.

THE MEDICAL RECORD VISITING LIST OR PHYSICIANS' DIARY FOR 1922. Revised. Price, $2.00. New York: William Wood and Company.

EVERY physican must use a visiting list. The present volume is well known, and has long enjoyed a well deserved popularity among the members of the medical profession. It contains the customary blanks for names of patients with dates for services rendered, and special blanks for consultation practice, obstetric engagements and practice, vaccinations, register of deaths, addresses of patients and of nurses, and cash account. At the beginning of the volume there will be found much miscellaneous information. The paper and binding are all that can be desired; and the book is of convenient size and is handsomely bound.

HUMAN PHYSIOLOGY. By Prof. LUIGI LUCIANI, Director of the Physiological Institute of the Royal University of Rome. With a Preface by J. N. LANGLEY, F.R.S., Professor of Physiology in the University of Cambridge. In Five Volumes. Vol V. Edited by M. S. PEMBREY, M.A., M.D., Professor of Physiology, University of London, and Lecturer in Physiology, Guy's Hospital. Metabolism—Temperature—Reproduction, Etc. Price 30 shillings. London: Macmillan & Co., Ltd., 1921.

THE present volume brings to a close the English edition of Luciani's magnificent work. It includes a chapter on Metabolism, which, though brief, is a useful résumé of what is known on the subject. The bibliography at the end of the chapter is mainly useful for the indications to more complete lists of the literature. The greater part of the volume is taken up with the physiology of the generative system. It comprises three chapters, and is probably the most complete exposition of the subject in any book on physiology in the English language. The volume closes with two important chapters on The Stages of Life and Death and The Human Races. The former of these is most valuable, and discusses (among other things) the theory of growth, the periods of virility and maturity, the critical age in woman and in man, theories of senility and of death. This chapter (with its bibliography) is most interesting, and the reader will find herein a great deal of information which is ordinarily only to be found scattered in various periodicals. This work, now completed, is the standard work on physiology in the English language; it is to the present generation what Foster's great work was some thirty years ago. It is written with the same grasp of material and in the same philosophic spirit as Foster's book, and it is far more readable than Foster's treatise, in spite of the fact that we are reading Luciani in a translation.

TEXTBOOK OF TRACHEO-BRONCHOSCOPY (Technical and practical). By Sanitätsrat Dr. M. MANN, Senior Physician to the Department for Diseases of Ear, Nose and Throat, in the Municipal Hospital, Dresden-Friedrichstadt. Translated by A. R. MOODIE, A.M., M.D., Ch.B. (St. Andr.), F.R.C.S. (Edin.). With 50 Illustrations and 5 Plates in the Text, 10 Colored Plates in the Appendix Price $9.00. New York: William Wood & Co., 1921.

OUR rapidly growing literature on direct examination and treatment of the air passages has been considerably enriched by the appearance of the English version of Mann's well known textbook of Tracheo-Bronchoscopy. This infant specialty, barely a quarter of a century old, is making great strides toward becoming a firmly established method of both diagnosis and treatment in certain conditions of the respiratory tract that were until its advent a veritable noli me tangere on the part of even experienced laryngologists; these are now being attacked with success and life-saving results by skillful operators. And as the scope of its application enlarges its practice will of necessity require a broad knowledge of general medicine and a thorough grasp of various methods of clinical investigation. To be sure it requires a certain dexterity and peculiar inborn skill to become a complete master of laryngo-tracheo-bronchoscopy, and so far there are but a select few who devote themselves to it; it is hoped, however, that in the not distant future the methods and the instruments will be so evolved as to place them within the grasp of every more or less skilled and apt laryngologist. The work before us is surely one of the means to advance knowledge on the subject as much as it is humanly possible to do so in a book.

The subject proper is introduced by a chapter that contains, among others, a short history of the method that is as fascinating as any novel, where the achievements of that master mind Kilian, but recently deceased, are dwelt upon at some length, and where due recognition is accorded to some of the American pioneers in the field. The first part of the work is devoted to the technique of the procedure, including both upper and lower tracheo-bronchoscopy, and everything pertaining to the operation is gone into most minutely and conscientiously. The second part is taken up with (1) The extraction of foreign bodies, of which the clinical histories as culled from the literature of the world, are presented and thoroughly discussed by the author; (2) The diseases of the trachea and the bronchial system, such as bronchiectasis, gangrene of the lungs, and pulmonary abscess, bronchial asthma, tuberculosis and tumors, both benign and malignant; (3) Diseases of the neighboring organs, such as the thyroid, thymus, spinal abscess, tuberculous glands compressing the trachea and bronchi, mediastinal tumors, aneurysms, and so on. All these conditions are illustrated by an array of clinical cases that present a wealth of information and instruction that should be perused with care and attention by every worker in the field. The plates of Part III, presenting pathological conditions and bronchoscopic pictures, serve to illuminate cases in the body of the book. The translation is done creditably, and both the bookmaking and the plates are of good quality.

PATHOLOGISCH-ANATOMISCHES PRATIKUM. Von Prof. Dr. RICHARD OESTREICH. Zweite verbesserte Auflage. Price 54 marks. Berlin and Vienna: Urban & Schwarzenberg, 1921.

THE first edition of this volume appeared in 1913, so that there has been much new matter to incorporate. The number of pages is now 316. A work on this subject, without a single illustration of any kind, suggests a book for the student for quick reference or memorizing, like our quiz-compends. In his first edition the author designates it as a pocket companion. He also regards it as an introduction to the study of the subject, hence the omission of illustrations.

LEHRBUCH DER GESCHLECHTSKRANKHEITEN FÜR AERZTE UND STUDIERENDE. Von Prof. Dr. MAX JOSEPH. Achte Auflage. Price 54 marks. Leipzig: G. Thieme, 1921.

THE seventh edition of this work appeared in 1915 and contained 515 pages, so that the present volume of 217 pages represents a cutting down of nearly 50 per cent. The author's design was to enlarge instead of curtail the work, but the price, it was feared, for such a volume would have been prohibitive. The present is, therefore, rather a guide than a treatise to the subject of diseases of the sexual organs.

AIDS TO ELECTRO-THERAPEUTICS. By J. MAGNUS REDDING, F.R.C.S., Surgical Radiographer, Guy's Hospital; Late Assistant in X-Ray and Electro-Therapeutic Departments, Charing Cross Hospital, etc. Price $1.75. New York: William Wood & Co., 1920.

THIS is the latest addition to the well-known "Students' Aid Series," and it is a useful guide to electrotherapy. The book is not burdened with too much theoretical matter, but it contains a sufficient description of the apparatus used and of the methods of employing the same. A valuable feature is the indication of the various conditions in which electrotherapy is not available or is not likely to be productive of much benefit. The book is well and clearly written; and the student will find in it a useful summary on galvanism, faradism, ionization, sinusoidal currents, high frequency, diathermy, radiant heat, ultraviolet rays, *x*-rays, radium, and electrodiagnosis of nerve lesions and myopathies. The work closes with a brief index of treatment, in which the various pathological conditions are alphabetically arranged with an indication of the various lines of treatment which are available in each case.

Society Reports.

FIRST DISTRICT BRANCH OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Fifteenth Annual Meeting, Held in South Nyack, N. Y., October 19, 1921.

THE PRESIDENT, DR. GEORGE A. LEITNER OF PIERMONT, IN THE CHAIR.

Hay-Fever and Pollen Therapy.—Dr. RALPH OAKLEY CLOCK of Pearl River presented this contribution, in which he asserted that about 1 per cent. of the population of the United States was susceptible to hay-fever. Because of the large number of people affected, hay fever prophylaxis merited the attention and serious consideration of the medical profession. The fact that hay fever was caused by the inhalation of windborne pollens only, eliminated certain insect pollinated plants such as the rose, goldenrod, honeysuckle, chrysanthemum, lily-of-the-valley, and daisy as an important factor in hay-fever. Although hay-fever might be caused by pollens of hundreds of different plants, investigations had shown that most of these might be divided into four biological groups, namely, using the common names, grasses, chenopods, ragweeds, and wormwoods. In addition to these four groups, the pollens of certain trees were a local cause of hay fever in certain parts of the United States. This biological classification was important, because the similarity of the pollens from a biological standpoint made it not only possible but also practical to use desensitizing treatment with pollen extracts. Furthermore the large majority of persons who were sensitive to one pollen were sensitive in varying degrees to other pollens of the same biological group. After discussing the different seasonal types of hay-fever and their causes, Dr. Clock said that practically all observers who had worked with pollen extracts had concluded that there were only two or three pollens which were responsible for the large majority of cases of hay-fever; namely, timothy which was the cause of spring hay-fever in the East; sweet vernal grass and June grass which had been found to be the cause of spring hay-fever in the Middle West; and, finally, ragweed which was the cause of fall hay-fever. For practical purposes, therefore, in the East at least 90 per cent. of the cases might be treated with two extracts alone, namely, timothy for the spring type and ragweed for the fall type. When skin tests showed multiple sensitization, more satisfactory results were usually obtained by treating the patient with extracts of all the pollens that gave a positive reaction. Koessler, who first reported detailed methods of preparing pollen extracts, emphasized the fact that the aqueous pollen extract was not stable and that it rapidly deteriorated in potency after three or four weeks. It appeared, therefore, that extracts of pollen could not be generally used by the practising physician unless some method of extraction could be devised which would insure a uniformly stable product. With this end in view they had extracted pollen by various methods and had succeeded in preparing a stable pollen antigen by extracting the dried pollen in 66 2/3 per cent. glycerol and 33 1/3 per cent. saturated sodium chloride. They had been able to standardize the antigen with accuracy against antipollen serum by means of the complement fixation method, whereby the amount of antigenically active protein in the extract was accurately determined, thus making it possible to establish a uniform and accurate dosage which insured the maximum degree of protection with the minimum of reaction. The glycerolated antigen was prepared in concentrated form so that 0.1 cc. would contain the required number of pollen units for a given dose. This plan permitted of diluting the antigen, just before its injection, to 1 cc. which made the final percentage of glycerol about 6 2/3 per cent., an amount readily absorbable by the tissues. The scheme of dosage which they had adopted for the glycerolated pollen antigen consisted of fifteen doses of a gradually increasing number of pollen units. The dosage began with 2½ pollen units which were contained in 0.1 cc. of a 1-400,000 dilution of a pure soluble pollen protein, and progressively increased up to 1,000 pollen units corresponding to 0.1 cc. of a 1-100 solution of the pollen protein. The antigen was administered subcutaneously, preferably in the arm over the insertion of the deltoid muscle. The interval between doses was usually 48 hours. It thus required about five weeks to compete the preseasonal treatment of 15 doses usually given. Preseasonal pollen treatment yielded by far the most satisfactory results, although treatment with pollen antigen during the pollinating season had often proven beneficial. Desensitization in hay-fever was not permanent or stable. Freedom from symptoms lasted only as long as the antigen remained in combination with the tissue antibodies, probably only a few weeks after the completion of the antigen treatment. The records of 1,578 cases treated by the glycerolated pollen antigen by physicians in various parts of the United States had been collected, and showed a remarkable uniformity of favorable results in each year from every locality. The average protection or relief from symptoms for the 1,578 cases reported during the five years was 84 per cent. By favorable results was meant that the persons taking this treatment at least six weeks before the hay-fever season either did not have hay-fever or if hay-fever did occur, the symptoms persisted for only a few days and were mild in character. Favorable results were also manifested in the possibility of the patient remaining in his home town and at his usual work for the first time in years. Another evidence of favorable results was in the decided relief from asthmatic symptoms which were associated in 50 per cent. of the hay-fever cases. In view of these results it seemed only fair to state that the method of giving prophylactic injections of the glycerolated pollen antigen early in the season offered the best means of any method thus far advanced for the preventive treatment of hay-fever.

Dr. S. W. S. THOMS of Nyack asked Dr. Clock if he had not mentioned hay-fever due to golden rod, which for the past month he had seen a good deal of. The symptoms were a little different from those of hay-fever due to ragweed. There was intense distress, some dyspnea, and the eye symptoms were severe in nearly all cases. He had had some experience with the Lederle vaccines but not as a prophylactic. In every case in which he had used them this summer there was marked relief. The point had been reached where it was realized that hay-fever was more than a neurosis, yet it was difficult to understand why some patients not exposed much to the chance of irritation or infection should have the condition. He had one such patient with an indoor occupation who suffered tremendously. That he had been unable to determine, but treatment with the vaccines had given him marked relief.

Dr. JAMES B. LANSING of Tenafly, N. J., told of one patient in whom he began treatment four weeks before the expected attack. She received the full course of fifteen injections, and during the hay fever season had experienced only about one hour of suffering. Previous to this season her asthmatic symptoms had been very severe. He cited several other cases in which the usual attack of hay-fever was greatly alleviated or the onset postponed.

Dr. GEORGE B. STANWIX of Yonkers asked Dr. Clock the maximum dose that he gave as a prophylactic and also the maximum dose that he gave at the time of the attack. He stated that he had had considerable experience in the treatment of hay fever and had met obstinate cases that did not yield to treatment. In such cases he had found that there was almost always a pathological condition in the sphenoid cavity which produced a vasomotor reflex. When one was able to determine the exact pollen that was causing the hay-fever the patient should be sent to the rhinologist to find if there was deviation of the middle turbinate. Frequently amputation of the anterior turbinate and clearing out of the ethmoid cells would add materially to the comfort and happiness of the patient.

Dr. CLOCK, in closing the discussion, said he was glad Dr. Thoms had brought up the question of golden rod. He was sorry to be compelled to differ with him as to golden rod being a direct cause of hay-fever. With the cooperation of the American Hay-Fever Prevention Association glycerine plates had been exposed in the vicinity of hay fever patients, and they

never were found to contain golden rod. However, if the patient was sensitive to the compositae groups it was possible to have an acute attack after exposure to golden rod used in room decoration, etc. Golden rod was an insect pollinated plant, so it was not the direct cause of hay-fever. The symptoms that were observed from August to October in this part of the country were usually due to ragweed or cockle-burr and in the West to wormwood. As to the dosage, for prophylaxis the maximum dosage was 1,000 units. For an acute attack the dose depended upon how ill the patient was. He usually began with $2\frac{1}{2}$ units of the pollens and gradually increased the dose giving in all up to 1,000 units, though usually 600 or 800 units were sufficient. One of the speakers had cited a case in which the patient was tested with extract of long ragweed and later reacted when the short ragweed was given. He would explain that on the hypothesis that the patient had been sensitized to the protein of ragweed when the first test was made and the injection of the extract of short ragweed had produced anaphylactic reaction.

The Diagnosis of Early Syphilis.—Dr. RAY H. RULISON of New York City presented this paper, in which he stated that from the time of Fournier, who estimated that 13 to 16 per cent. of adults were syphilitic, to the present day syphilographers had been trying to impress the profession with the commonness of this infection. The chairman of the Section on Dermatology and Syphilology of the American Medical Association, in his address at the Boston meeting in June of this year, estimated the *active* syphilis in this country at between 2,000,000 and 3,000,000. This estimate was based on late official reports from all parts of the country. If this disease was to be kept within bounds the general practitioner must apply these figures to his own practice and ask himself whether he was diagnosing his quota of cases and diagnosing them early. He must repeat to himself that 10 per cent. of *his* patients were luetic and that nearly one-third of this 10 per cent. were in the active stage. Speaking of the early diagnosis of syphilis by laboratory methods, the essayist pointed out the fact that we were told that spirochetes might be found in chancres, mucous patches, condylomata, in secondary skin eruption, and in material obtained by gland puncture. But lesions in the mouth and around the anus were almost sure to show benign organisms so closely resembling the pallida that a differential diagnosis was impossible. Their experience at Bellevue as regards gland puncture had not warranted enthusiasm so far and their dark field findings in primary lesions, even after repeated examinations, were only about 66 2/3 per cent. Spirochetes should be found in all chancres during the first ten days by the dark-field method, but at the Bellevue clinic the average duration of the sore at the time of admission was over twenty-four days; and many patients had applied some antiseptic powder or dressing, and often the lesion was a mixed infection. It was apparent that in many cases of primary syphilis the dark field either was not available or its findings were negative and that the Wassermann might remain negative for many trying weeks. It was in such cases that careful and repeated physical examination was most valuable. All chancres should be palpated as well as inspected and the presence of induration outside the limits of the sore was important; the presence of infiltration without acute inflammation in the sore, the efferent lymphatics and the regional glands would strengthen the probability of syphilis. Even more important to remember was the fact that fifty per cent. of soft chancres were really mixed chancres and even if the Ducrey bacillus was demonstrable the possibility of a hard chancre, developing more slowly and masked by the chancroid, must be kept in mind. A general examination of the body for evidence of possible secondary lesions should be made in every case and it was to one phase of this general examination that he wished especially to direct attention. There had been a failure on the part of teachers and writers to emphasize the fact that this disease from its incention to its extinction was essentially an infection of the lymphoid structures. Eighty non-syphilitic cases and 70 cases of primary syphilis were examined at the Bellevue Hospital clinic in syphilis and their superficial gland findings analyzed, as a result of which it seemed allowable to conclude as follows: (1) That an examination of all the superficial glands with a record of their palpability, repeated at frequent intervals during the early stage of syphilis, might give evidence of the presence of generalized infection at a time when neither the dark-field examination nor the Wassermann test were likely to be of assistance. (2) That palpable inguinal and anterior cervical glands had no diagnostic significance, since they were commonly enlarged in non-specific individuals. (It was of course understood that the important regional adenopathy accompanying the primary sore was not under consideration). (3) That enlargement of the epitrochlear gland and probably of other superficial glands occurred very early in the course of the disease. Like all clinical signs this one had its limitations; it would not be of service in every case and at times the findings might be puzzling; nevertheless the importance of an early diagnosis of syphilis to the individual and to society was so great that no means of arriving at it should be neglected, and in the presence of a history of exposure showing reasonable incubation period, followed by a suspicious sore, regional adenopathy and some evidence of generalized infection, such as the adenopathy referred to, one was warranted in making a diagnosis of syphilis and beginning treatment even without the aid of a confirmatory laboratory report.

Dr. JOSEPH B. HULETT of Middletown said he did not feel competent to discuss early syphilis since in recent years he had come more in contact with surgical cases and the treatment of early cases of syphilis was rather out of his line. However, judging from the number of cases of this disease which he saw in the course of his surgical work he thought the doctor was very conservative in his estimate of the number of cases in the United States. He believed it was a very important thing to hunt up cases of syphilis in good season, the earlier they were given treatment the better. He had studied under Dr. Otis who said the best way was to suspect every patient you saw. He believed this was a good plan to follow. He used to try potassium iodide on every suspected case, giving them whatever dose they were able to stand. It was astonishing the number of surgical cases the surgeon saw that would not heal up until put on antisyphilitic treatment. He believed there were more neglected cases of syphilis than we thought.

Dr. BENJAMIN S. BARRINGER of New York City called attention to a lessened incidence of neurosyphilis since the introduction of salvarsan as compared with that before this agent was generally employed. With salvarsan one man could handle a dozen cases in the same time that he could formerly handle perhaps one. Now an injection of salvarsan was given and the patient allowed to go home. Giving the injection was not a complex procedure. He felt that he could carry out the entire procedure in ten minutes if necessary. For the benefit of those comparing the incidence of syphilis in the city and in the country he would say that he was consulting surgeon to the McLillan Hospital at Cambridge, N. Y., and during the entire summer there had been only one positive Wassermann reaction among the patients in that institution. Two interesting points to which Dr. Barringer called attention were: (1) That there were two kinds of masked chancre, one merely within the urethra in which there was no induration, but merely a slight urethral discharge or a history of such discharge. There was a definite percentage of such cases with a history of specific or a non-specific urethritis in whom after a number of months the secondary manifestations of syphilis appeared or after years might become tabetic. (2) There were those cases in which the chancre on the head of the penis was masked by the foreskin. There is a peculiar bronzing of the penis. They usually got the rash about twenty-one days after the appearance of the sore plus a positive Wassermann some days earlier. Dr. Barringer said he was a great believer in the Wassermann test notwithstanding Dr. Symmers report. Dr. Symmers had not gathered all those statistics himself and he was not altogether convinced that they had been gathered accurately. He felt that the Wassermann was one of the most accurate laboratory tests we had.

Dr. RULISON, in closing the discussion, remarked

in connection with what Dr. Hulett had said of the use of potassium iodide, that this agent had fallen into unwarranted disuse. Dr. Wade H. Brown who was doing extensive experimental work in syphilis, had stated in conversation that the medical profession was working with the idea of killing the spirochete, but that until we had also developed some method of increasing the body resistance and body elimination we would not gain satisfactory control of the disease. Gougerot said that potassium iodide should be used in all stages of syphilis. The question of treatment was not taken up because, as Dr. Barringer had said, treatment was not difficult in the average case. Dr. Rulison said he might have given a wrong impression as to the frequency of positive Wassermann tests. Noguchi's figures were no doubt correct, but those were untreated cases. In general practice one did not get cases of the ideal type. He had had no intention of condemning the Wassermann test but was simply trying to bring out a rather neglected clinical point which was available to everyone and which might be an aid where the Wassermann did not become positive in a reasonable time.

The Etiology and Laboratory Diagnosis of Typhus Fever.—Dr. CHARLES E. KRUMWEIDE of the Bureau of Laboratories of the New York Department of Health presented this communication, in which he said that it was always possible that a case of typhus fever might escape into the community as had happened early last spring. That brought up the question of diagnosis. Then it was not only a question of imported typhus but we had Brill's disease which was sporadic in New York City. With reference to the etiology of typhus fever the point to be emphasized was that if one took an experimental animal and injected it with the blood of a patient ill with typhus fever, it would have a rise in temperature simulating that of typhus fever; following this that animal would become immune to injections of typhus virus. Many investigators thought they had succeeded in isolating the pathogenic organism of typhus fever. The question to be asked under such circumstances was whether after injecting an animal with these organisms the animal was immune to injections of typhus virus. If this was not the case the man had not proved that he had discovered the pathogenic organism of typhus fever. As to the pathology of the disease, there was an inflammatory reaction of the blood vessels of the skin and brain. This reaction was primarily a proliferation of endothelial cells which might go on to necrosis. Some of the blood vessels might close while others would rupture, and that was the reason of the petechial rash. In reply to the question as to what the laboratory could offer in the diagnosis of typhus fever, Dr. Krumweide stated that the laboratory took its correct place in that it could offer confirmation of the clinical diagnosis but it was not a substitute for clinical diagnosis. At quarantine they were using the Felix-Weil reaction. It had been found that the blood of typhus fever patients agglutinated quite a number of organisms. The organism best agglutinated was x-19, a strain of proteus. There was, however, not one iota of evidence that *B. proteus* had anything to do with the primary etiology of typhus fever. The Felix-Weil reaction could be carried out easily but had certain drawbacks. In only about 50 per cent. of the cases did a reaction occur which could be considered diagnostic before the fifth day; 90 to 95 per cent. gave the reaction up to the crisis, and the rest during convalescence. In a suspected case of typhus fever the proper course to pursue was to submit specimens of blood from the patient during the course of the illness until assured that the result of the laboratory tests was negative. The susceptible animals were the monkey and the guinea-pig, and further tests might be made by animal inoculation. The possibility of error here was that a temperature reaction might be set up by a simultaneous infection. If, however, the patient had typhus fever, a later injection of the patient's blood would produce no reaction in the animal. In obtaining a specimen for the laboratory, the blood should be kept from clotting by adding it to sodium citrate solution which was warmed to blood heat. The specimen should be kept warm and rushed to the nearest laboratory. The incubation period of typhus fever was from eight to ten days. Post mortem pathological examination was made by excising a specimen of skin or brain tissue, fixing it or delivering it to the laboratory immediately. On sectioning the specimen and examining it microscopically, if it was from a case of typhus fever one would find a peculiar endothelial cell proliferation. According to Wolbach only one other condition gave a similar picture, and that was Rocky Mountain fever, which was not encountered in the East.

The Relationship of the Medical Profession to the General Public.—Dr. JAMES F. ROONEY of Albany, president of the Medical Society of the State of New York, delivered a brief address, in which he said that his friend, Dr. Leitner, said he was going to speak on the relationship of the medical profession to the general public. This was a large subject and it must be understood that one could but imperfectly touch upon the essential points in the time he had allotted himself. The evolution of the practice of medicine in the last forty years had been much greater than in the preceding seven or eight centuries. The evolution of civilization and the complexity of civilization in that period had been correspondingly great. During this period civilized nations had changed from agricultural peoples to urban communities. The last census had shown that there were more people in towns of 10,000 inhabitants and up than in the country. With this change people had become accustomed to luxury, and not only that, but things formerly considered luxuries were now considered necessities. The type of physician and the type of medical service that forty years ago was satisfactory to-day was apparently not satisfactory. During this period, owing to the development of medicine, the field had become so wide that only a synthetic mind like that of Helmholz could compass it. Hence the profession of medicine had split up into a number of more or less (and sometimes one thought less rather than more) correlated groups, denominated specialties. With this there had grown up a demand on the part of the people for service bearing the hallmark "the best medical service." These demands were being made as a matter of right, that was it was being commonly said everywhere and had come to be taken as an aphorism or axiom that every person living in the community had a right to the best medical service. The only question that was left open for discussion was how the best medical service might be made available to all people, meaning this best medical service must be brought within the means of the least affluent of the public. Dr. Rooney declared that he did not believe this statement to be either an aphorism or an axiom. If one considered the corresponding profession of the law, it might be said that every man during his lifetime was only occasionally in contact with the medical profession, but every man and woman was continuously in contact with the law. Why, then, was there not a demand that the best legal service should always be at the command of the whole public? Why was there not a demand that the legal profession as a group should be subsidized by the State in order that we might have "state law" or rather the best legal service at the demand of everyone in the State? The reason, Dr. Rooney said, was quite plain. The medical profession was only a sort of lay priesthood. Primarily all physicians were priests and the priestly idea was still indissolubly an element in the teaching of every physician. The little priestly element that might be present in all of us was the little leaven that leavened the whole lump. The legal profession was originally also a part of the priesthood and early split away. Because the public had always had religion offered freely from the cradle to the grave to all alike and because medicine had always given its services freely, it was now proposed that the profession of medicine should be subsidized to the people and that physicians should become priests of the State and servants of the people. Sir John Moore, when he wrote Utopia, and Plato, when he wrote his Republic, had much this idea in mind and in the ideal state without question this plan would be feasible and proper, but we had just witnessed the failure of the attempt to put such a utopian plan into effect in Russia. When one group was subsidized to others a step had been taken on the way to slavery, and with it one must expect in the subsidized group the slave type of mind. What could be done to prevent the chaining of the chariot of medical progress to

the wagon of slavery. Thoreau said it was much easier to exact respect than it was to solicit it. He feared the medical profession was making the mistake of soliciting respect. There was one thing that must be done, and that was that the medical profession must unify and solidarize and demand from the public the respect that was due it. Unless the medical profession exacted the respect for themselves that the legal profession exacted, unless it developed the type of authority that the legal profession had taken in relation to its State and National bars it was merely a matter of time until it became submerged on the wave of false and untrue demands on the part of the public. He well understood that he might be saying things today that were apparently entirely different from the pronouncements of certain leaders of the medical profession, namely, that what the public demanded must be given them, that the medical profession as a profession had no rights except in so far as they advanced the interests of the community. There had also been false prophets. We had passed through an era of false prophets. It was only four years ago that they said it was useless for the medical profession to oppose a certain scheme which would have taken into the meshes of its net over 80 per cent. of the physicians in this State. Those false prophets had relented temporarily, but there were others. It was a peculiar phenomenon that the rank and file of the profession were directly against this doctrine. It had been given to the rank and file of the profession to see that all these propositions were marble columns erected on bases of sand. The same emergency would have to be met again. There were certain groups that were interested in subjugating the medical profession. He who was not willing to fight continuously for his rights in the end forfeited them. He who would not speak when he might, might not speak when he would. Finally Dr. Rooney urged the medical profession, when these various propositions were brought up for consideration and discussion, not to be overturned by sentiment but to decide for themselves the truth of the statements upon which these various propositions were based.

The Continued Use of Digitalis.—Dr. HAROLD E. B. PARDEE of New York City presented this paper, in which he stated that the two problems that always presented themselves in treating a patient with chronic heart disease were to decide *how long digitalis should be continued* and *what dosage should be used to obtain the best effect*. First and most important of all indications for the use of digitalis was the presence of auricular fibrillation. Patients with this condition must take the drug continually all of their lives. As long as they did this they were usually able to remain in a fair or even very good state of compensation, so that they were able to undertake the ordinary exertions of their lives without discomfort, and sometimes even rather extraordinary ones. Within *ten days or two weeks* of stopping digitalis these patients began to notice shortness of breath or precordial oppression or fluttering, after a smaller amount of exertion than would formerly have caused these symptoms. If digitalis was still withheld their exertions would become more and more restricted and more severe signs of cardiac failure would set in. Digitalis *slowed the rate of these hearts* by increasing the tone of the vagus. This in turn produced a depression of the function of the auriculo-ventricular bundle so that this did not conduct so many impulses from the fibrillating auricles to the ventricles, and the ventricular contractions were fewer—the heart rate slower. Coincident with the slowing the heart became less irregular, not because the fibrillation was in any way improved, but because the impulses from the auricles passed to the ventricles with less irregularity. The object with these patients was to keep the heart rate between 70 and 80 per minute when the patient was at rest. With this degree of digitalization it would be found that the rate did not usually increase inordinately with exercise. Occasionally a patient was found who maintained a heart rate of 70 to 80 per minute without the use of digitalis, in spite of the fact that auricular fibrillation was present. The heart rate of these patients usually could not be quickened by the use of atropine, so one could not consider that the slow rate was due to a vagus hyperactivity. It was felt that here there was disease of the auriculo-ventricular bundle so that its function of conducting impulses from auricles to ventricles was pathologically depressed. Digitalis would cause still further slowing in these patients, and dizzy spells or fainting attacks might result, so that they constituted an exception to the rule that every patient with auricular fibrillation should receive digitalis continually. Dr. Pardee referred to recent investigations showing that quinidine was useful in restoring auricular fibrillation to normal rhythm. It seemed surer in its action when the patients were well compensated, so they should first be given a course of digitalis and then tried with quinidine to see if normal rhythm could be restored. If this was successful the patient passed at once from the category of those who must receive digitalis continually, to that of any patient with cardiac insufficiency. Other forms of irregularity were not benefited by the continued use of digitalis and those with heart block or extrasystoles might even find their discomfort increased by any dosage large enough to produce a therapeutic effect. Such patients would only be harmed by a long course of digitalis, so that it was contraindicated for them. The mere presence of valvular disease, no matter how loud the murmurs, or without valvular disease the find of a rapid heart or an enlarged heart should not be considered to indicate digitalis therapy. The controlling feature was the functional capability of the circulation as a whole. The need for digitalis arose when the cardiac reserve became reduced so that the ordinary exertions of life, which the patient had recently been able to undertake without complaint, became a cause of symptoms. These were the cases whose hearts were in need of treatment and whom digitalis might be expected to benefit, no matter what the pathological condition that caused the failure of the circulation. When patients with regular hearts showed signs of cardiac overstrain on ordinary exertion, they should be treated for the degree of failure that was evident. If, after the patient had recovered his compensation, he again showed signs of losing ground, he should be given a course of digitalis combined with graduated exercises extending over a period of several weeks. Treatment might then be stopped, but if the symptoms reappeared it would be advisable to give the digitalis continually for some months. In discussing the guide to the patient's daily dosage, Dr. Pardee stated that different patients excreted the drug at different daily rates, but the average figure for excretion was about 22 minims per day of a tincture of average potency, or 2 1/5 grains of an average leaf, say 20 minims of the tincture or 2 grains of the leaf. The patient should first be brought to the point of therapeutic saturation, which was very close to the early toxic stage. It made no difference whether the drug was given in divided doses or in a single dose. The writer's preference, however, was for a single dose at night before retiring, because it seemed to be less often forgotten then. Over half of all patients had an exact dosage lying between 15 and 27 minims of the tincture daily; some could take but 10 minims, others as high as 40 minims of the same tincture. By trial one had to find the correct dosage for the individual. By the end of the second month one should have a fairly exact idea of the patient's daily needs. When one had determined the dose it would be possible to continue it indefinitely, but it was rarely necessary or useful to continue it over four or five months in patients with regular hearts. Figures were presented illustrating the varying dosage that could and must be given.

Dr. EDWARD C. RUSHMORE of Tuxedo Park read a humorous letter written by a man who had gone to Baltimore to have his case accurately diagnosed, and who described the way in which he was sent from specialist to specialist, in order to give an idea of the way the modern method of making a diagnosis looked to the average layman. So far as his personal knowledge went he said he could add nothing to what had been said. They all knew that digitalis was one of the most important drugs in the pharmacopeia. During the last few years much more had been learned about digitalis and diseases of the heart with the electrocardiogram than had been known before. It was formerly thought that digitalis was a drug with cumulative action in the body, but we knew now that we only got poisoning when it was given in excessive doses;

with proper dosage it could be given over indefinite perods. He knew of a case in which digitalis had been taken over a period of fifteen years with an occasional interval and with the possibility of the patient being ill if it was discontinued. Many took it for months and even for years, but proper testing was necessary to determine the dosage. One thing one should always be on the look out for in giving digitalis, that was in counting the pulse in patients with auricular fibrillation one must have the patient in a proper state of mind and in a proper degree of rest. If the patient was under excitement one would get pulse conditions that did not furnish proper guidance for treatment, although patients digitalized did not respond to emotional impulses as rapidly as those not so digitalized.

Dr. PARDEE, in closing the discussion, said that Dr. Rushmore's modesty was unnecessary, for he was sure Dr. Rushmore had seen more of the use of digitalis than he had. From the experimental side, it was noteworthy that these figures had been worked out without the use of the electrocardiogram on the patients themselves, and other figures worked out on the patients themselves with the electrocardiogram agreed with these. As to the question of intermission in digitalis treatment, patients with irregular hearts should never have intermissions of more than 48 hours unless they showed symptoms of digitalis poisoning or the heart was too slow. It was better to have daily intermissions twice a week than two days in succession. The tincture he used in these cases was one he had been using for months, and was the same for all the patients. In digitalis therapy two things were important. First, it was important to remember that a drop dose was not a minim dose. He has seen instances in which the drug had been prescribed as so many drops. It required almost two drops to make a minim, and varied with the dropper used and the person who did the dropping. He preferred, with patients outside the hospital, to give tablets. If one gave tablets and had the patient bring the bottle when he came to the office, one could tell just how many tablets he had taken. In the hospital they used the tincture because they had the nurses to administer it. If one gave the tincture to patients outside the hospital he should have them bring the bottle back with them to see how much was left. The second important point was the psychic factor, as true in patients with normal rhythms as in patients with auricular fibrillation. If the patient was under any emotional stress at the time of examination one was liable to reach very erroneous conclusions as to the patient's habitual heart rate.

Demonstration of Nervous Cases.—Dr. EDWARD LIVINGTON HUNT and Dr. ORRIN S. WIGHTMAN, of New York City gave this motion picture demonstration showing the diagnostic symptoms evinced in motion and gait. The pictures were made at the City Hospital. The demonstration included encephalitis, with the tremor, rigidity and Parkinson type of facies; chorea, and here it was mentioned that these patients did better without bromides and without arsenic; hydrocephalus; juvenile paresis; tertiary syphilis, with the ataxic gait, tremors of the tongue and hand; progressive muscular atrophy, locomotor ataxia; Charcot joint; Marie's cerebellar hereditary ataxia, Friedreich's ataxia, multiple sclerosis, etc.

(To be continued.)

The Schick Reaction in Measles.—Lereboullet and others tested 110 cases of measles in both latent and eruptive periods. They agree with previous workers in this field that the reaction is invariably negative, in the sense that the presence of measles has no influence upon it; the percentages of actual positives and negatives being the same as in non-rubeolous controls.—*Le Progrès Médical.*

Diabetes Following Mumps.—It has been surmised that certain cases of severe and fatal diabetes in childhood are due to atrophy of the pancreas following a metastasis to that organ, but as far as known no proof has yet been offered. Labbé and Débre have, like others, seen transitory diabetes after a diagnosticated mumps-pancreatitis, but it yielded promptly to diet.—*Le Bulletin Médical.*

Therapeutic Hints.

The Ether Treatment of Peritonitis.—Lienhardt sums up this treatment in the *Schweizerische medizinische Wochenschrift.* The combination of ether and camphorated oil has not made good in his experience, either in inhibiting infection or preventing adhesions. On the other hand the use of ether alone when poured into the peritoneal cavity exerts a favorable influence on the prognosis. The customary mortality of peritonitis in the clinic has been 27.7 per cent., while under the ether treatment it was reduced to 18 per cent. The action of the ether is chiefly local, since it contributes to the production of a reactive inflammation, exudation, and pouring out of increased immune substance with destruction of germs. The production of cold by the evaporation of the ether exerts a synergistic action by contracting the blood-vessels and inciting peristalsis. The bactericidal action of ether is not a direct one—it does not itself destroy microorganisms—but it is antibacterial because it stimulates the defense. Ether exerts a constitutional action based on its physiological activities when given for narcosis. It relieves pain, lowers temperature,(?) and stimulates general leucocytosis. The drug should not be used in routine, but reserved for severe cases as a special resource. So far from preventing adhesions it probably increases the tendency to adhesion formation. In fact, this property of favoring adhesions is the chief contraindication and only when this becomes relatively unimportant because life is threatened, should ether be used. The quantity of ether poured in at one time should not exceed 100 c.c. Too much will tend to favor paralysis of the intestine and collapse.

Vaccine Therapy for Whooping Cough.—Bloom and De Reyna employ in the St. Vincent's Foundling Orphan Asylum a mixed stock vaccine (recently prepared within one month), in the manufacture of which no preservative is used. Each cubic centimeter of the vaccine contains 5,000,000,000 Bordet-Gengou bacilli and 3,500,000,000 influenza bacilli. For infants under six months of age they use $\frac{1}{4}$ c.c., 3 doses, on alternate days. For infants from six months to one year, $\frac{1}{2}$ c.c., 3 doses, on alternate days. For children from two to six years, $1\frac{1}{4}$ c.c., 3 doses, on alternate days. In previous years not less than 50 per cent. of the entire number of children living in this institution contracted whooping cough. From the first week of May, 1919, to the first of January, 1920, there was not a new case of whooping cough noted in this institution. They consider that the prophylactic use of this vaccine has untold possibilities in the prevention of whooping cough in asylums, schools, and public institutions, and in limiting disastrous epidemics.—*New Orleans Medical and Surgical Journal.*

Nerve Sedative.—Ammonium bromide, 5ii; aromatic spirit of ammonia, 5i; water, q.s. ad 5iv. Two teaspoonfuls to be taken three or four times a day.

For Bleeding from Superficial Cuts.—The local application of dilute acetic acid, it is said, will arrest bleeding from hemorrhoids or superficial wounds.

Medical History.

CRITICAL AND DESULTORY REMARKS IN THE LIGHT OF ANCIENT MEDICINE.

By JONATHAN WRIGHT, M.D.,

PLEASANTVILLE, NEW YORK.

I.

It was said by an eminent histopathologist in the early days of the now rapidly fading optimism in cancer research that we would never know the cause of cancer until we discovered the origin of life itself. In the pessimism which has followed in the wake of the war, but which so far as the cancer problem is concerned had already set in before it,* despite the fact we know more about the mechanism of germ cell division than ever, this view, so far as I have observed, has at least gained no ascendency over many other factors which may enter into its etiology. We have hitched up the chromosomes with some success to the manifestations of the dynamics of heredity. When we were especially interested in the phenomena of mutation in plants and animals it was at the back of many a mind, busy with histological research, that cancer was essentially a mutation of the heredity of the somatic cell.[1] How much of this prepossession persists in the minds of men I do not know, probably not much, assaulted as we have been by the clamor of Mendelism and its relation to the phenomena of germ-cell division.

Still the mystery eludes us and the cure of cancer too is as far off as ever, though, however deep our pessimism it would be foolish to deny we have gained no ground since the cancer campaign opened with all the élan of a decade and more ago. To have become imbued with an appreciation of the size and scope of the problem is something, if only in the way of a chastening of the spirit. In this most modern of all scientific illusory searches, we have left out of account, in fact it has been entirely ignored, that it began almost with the beginnings of medicine. The thing that will impress us the most when we turn to see what Hippocrates says of it, is the pessimistic turn which his thoughts also took. "It is better to give no treatment to persons affected with hidden cancer, for if you treat them they quickly die; if you do not treat them their life is prolonged."[2] Cancer of the breast and of the uterus were well known to the Hippocratic writers. Their course is traced with some accuracy in one of the spurious books,[3] but not with this flash of meaning we recognize in the more genuine discourse of the Aphorisms. It pierces our consciousness across the ages as we think of some of the deep and organic cancers and of the meddlesome rather than of the radical surgery, of the superficial growths, of the dalliance with *x*-ray and radium, escharotics, and local applications. If not early, quick, wide incision—indeed their life is not prolonged and it is better often to give no treatment. This is not far from the state of mind of the majority of modern medical men. Puttering discourse as to etiology as well as the paltering with treatment in some of the Hippocratic writings,[4] is noticeable, but as to the latter chiefly in those books, having an affiliation or rather apparently a direct descent from Egyptian medicine, found in the Kahun and other papyri. As to the etiology it is not at all certain that Galen's idea had a Hippocratic origin, although possibly it was derived from something in the Master we cannot perceive now. I cannot see that Hippocrates flatly asserts as does Galen:[4] "Black bile without ebullition," Kühn renders it in Latin and so the Greek text seems to warrant, but evidently *boiling* is not the meaning, "black bile without ebullition causes cancer," and so it remained for more than 1500 years. Paulus Aegineta, as Adams[5] translates him, says "by overheated black bile"—evidently derived from Galen, but what the text is in Paulus as to the heating, I do not know. We cannot escape the translation of Kühn for Galen if we accept his text, but that is immaterial, black bile alone is sufficiently astonishing. I do not propose here to go in detail into the hints warranted in widely separated phrases we get for the conjecture that the ancient mind was supported in this etiological idea by the dusky hue of subepithelial cancer, especially of the female breast. Bile in the ancient humoral theory was apparently split up into yellow and black to make the trinity of bile, blood, and phlegm into a tetrarchy. Sometimes urine was added to the three in order to conform to the four square cast of the Egyptian mind. At any rate we can easily imagine the vogue the idea had of splitting bile into the yellow and black (bilirubine and biliverdine is the modern bow to color) when it was new. In this state of mind no wonder the dusky hue of the malignant tumor, as contrasted with more benign growths, was sufficient to throw a "flood of light" on the progress in ancient cancer research. Boiling we can let pass. It probably had something to do with the theory of the coction, but so the biliary theory of cancer came down to us through the ages, through the Arabians and van Swieten with the sympathetic comments of Adams even in the 19th century. It probably is responsible for some of the dietary notions as to treatment, ancient and modern.

The dietary cuts a not unimportant part in many ancient authors in the treatment of cancer, vegetable usually; arsenic applications were recommended by Scribonius Largus, the Roman, and Avicenna, the Arab, approved of a vegetable and milk diet. We can find them all, except *x*-ray and radium in ancient literature, but the knife, the last choice of them all when medicine was an Egyptian and Mesopotamian hierarchy, steadily has grown in repute and power. Use it first on a slave, says the Egyptian, before you cut a free man. Use it first in the hospitals and clinics, where you find the modern slaves, as your chief hastens to more lucrative practice, is the modern formula. Cure it with a song or an herb—last of all, says the Zend Avesta, with a knife. We have learned

*As this went down in my pencil notes I cast about for a specific reference to illustrate the general sentiment, but I found none. Now as the essay goes into more permanent form the Proceedings of the New York Pathological Society, New Series, vol. xx, Nos. 6-8, October-December, 1920, comes to hand and I note that Dr. Rhodenburg (p. 144) says "the present outlook is pessimistic in the extreme," and in the discussion which followed, Dr. Wood, always distinguished for his candor, the director of the Cancer Research Laboratory, adds "much discretion should be used in talking about the cure of cancer."

something meanwhile, but atavism has always been a phenomenon of mental evolution as well as of that of animal and plant life. Even Celsus[6] declares: *"tertiam esse partem medicinæ, quæ manu curet, et volgo notum, et a me propositum est."* Third and last he turns to cure by the knife.

II.

This quotation from Celsus may serve to remind us of a question once much discussed in medical history but it has some implications which have not been given the prominence they deserve. Who was Celsus? We are occasionally reminded that the medical profession presents in its annals very few examples of medical men who wrote medicine well. It is less true of other branches of science. For reasons quite sufficient I pass over Greek writers, though even the novice can see in Hippocrates the excellence of the Ancient Medicine. When we begin with the Latin writers, few as they are, we find Celsus writes a prose which is unmistakably Ciceronian, prose that can be scanned.[7] His proemia, especially the one which opens his book, "De Medicina," so far as I know have not been approached either in medical history, or in any other medical essay, as examples of melodious prose. Of course there are a number of good writers in general literature who were doctors, there are men of science who have been great writers, Goethe pre-eminently in science, but Virchow was scarcely less distinguished in medicine by his science than by his mastery of the most barbarous tongue that has ever been used in its service.

Huxley, Tyndall and Darwin for science in English, but we halt when we try to mention men who have written medical science well. Doubtless there are others—Pasteur perhaps. But Celsus the first of the Latins who have come down to us belongs in the ranks of great prose writers. Coelius Aurelianus is tiresome. Pliny's prose is almost as bad as his science, but Celsus is different. Was he perhaps the poet Celsus, it has been asked, the friend of Horace[8] and perhaps Virgil?

It is in the Epistles (I. viii) of Horace, despite the fact that he addresses him as Albinovanus Celsus, that we find reason to suspect he is rebelling against the friendly advice of a physician as to what he should do for his health's sake and that his friend Celsus was a physician; it would lead me too far here and upon ground where I distrust my competency to discuss the matter fully, but I must admit that the reasons for supposing Aulus Cornelius Celsus lived later than Horace are hard to refute. However, it is not impossible that Albinovanus Celsus, a scribe and a knight in attendance on the Nero to whom Horace alludes, may have also been a physician, a knight in reduced circumstances, which will have its interest for us in this connection. The closing line of the epistle reads:

"Ut tu fortunam sic nos te, Celse, feremus."

"As thou hast borne the rebuffs of fortune, so we will bear with thee," it may be rendered. We infer from the other lines that it is Celsus who has ventured to offer medical advice, which Horace sportively rejects. But suffice it to say that by those more competent than I am, it has been entirely discredited that Cornelius Celsus was the Albinovanus Celsus here alluded to, a poet who plumed himself with the feathers of other birds of song, according to the other of Horace's epistles referred to. However, though our Celsus lived perhaps a little later than Horace and Virgil he has the grand manner of a great writer and a great patrician. Quintilian says[9] he wrote a book on Rhetoric, one on Military Science, and one on Agriculture.

The significant thing for us is that his work on medicine with which we are concerned is a part or rather a sequel to the one on agriculture. Of the latter we have nothing, but whatever may have been the quality of his other works which caused Quintilian to speak in a deprecating way of him, his work on medicine surely does not deserve such a tone, and apropos of his work on agriculture, was he a patrician who found enough medical opportunities on his plantations among his slaves to write such a book? Unlike his great forerunner, Hippocrates, and his eminent successor, Galen, he makes no reference at all to his private practice. But if it was limited to a few slaves on his own or the plantations of his friends and neighbors, his work is a miracle and he was a superman, it has been claimed. I doubt if we can go as far as that. Of course we can imagine such a thing possible, however improbable. Pliny says very few Romans took up medicine as a profession and they only who ran away to the Greeks *"quiritum paucissimi attigere, et ipsi statim ad Graecos transfugae."*[10] Yet here is a Roman patrician apparently, at least someone writing classical Latin on the model of Cicero, a man whose work, though of course largely Hippocratic, is stamped with a maturity of judgment and a stability of genius scarcely inferior to the Master and superior to anything found in Galen. At this point it is well to say that the importance of the question as to whether Celsus belonged to the higher classes or even to the patrician class of Ancient Rome is ancillary to our interest as to the social standing of medicine in the late republic and the early empire.

Under the later emperors, even those immediately succeeding Augustus, they had no social standing, but belonged to a class at whom any one, so minded, was privileged to cast a stone. In the earlier days of the republic nothing but hostility met invading Greek culture at Rome on the part of the nobility, and the elder Cato's enmity against physicians is well known. He damned all doctors and ordered his son to have nothing to do with them. Cabbage leaves and stalks were drugs good enough for him. To them and his slave wenches he clung with all the stubborn pride of an old aristocrat, always a little ridiculous in every age and sometimes amusing. Could a slave or a freedman, crouching among the clients of a noble Roman, have written the "De Medicina?" No one who has ever read it in the language that Cicero shaped could believe that for a minute. Could a man at Rome in the time of Augustus have practised medicine and preserved the free air that breathes through it? After the early years of Augustus great social changes become manifest. The middle class rapidly disappears, at least from the pages of history. In the disintegration, was

a man bred in the atmosphere that Virgil and Horace created by chance caught in the necessity of earning his daily bread? This is a conjecture not devoid of possibility. I doubt if Celsus was such a man. Quintilian has not expressed a high opinion of Celsus' abilities. We may utterly reject this so far as they are evidenced in the "De Medicina," but he wrote on agriculture. So did Cato and his discourse on cabbage is a part of it. So did Varro later in the time of Cicero who highly valued him as a litterateur as well as a friend. So did many another patrician of Rome. Noble ladies in England doctored, dosed perhaps it is better to say, their tenantry, quite in line with Cato and his thrifty but misguided endeavors to keep his slaves healthy and serviceable, but the book of Celsus is no receipt book of high born dames and country squires. Ilberg[11] thinks he wrote it for laymen chiefly, because he is shy of using "obscene" words. His works on Agriculture, Military Science, Rhetoric, may indeed not have sufficed to place him high in the esteem of Quintilian, but they were the occupations of gentlemen and the practice of medicine was not, whatever interest they may have had in its theory. There is more than theory and tradition in the work of Celsus.

III

The first writings in science of which we have any knowledge were metrical. Some of it, that of Empedocles pre-eminently, was said by those capable of judging, to have been fine poetry. The translation of its fragments is suggestive of excellence in the original. The last serious effort in that direction was the work of Goethe, but it was quite apparent even before Lucretius that the nature of the matter rendered expression in this form too difficult, the limitations were too many. The demand for emphasis and the bid for close attention, it was found, could best be enforced by rhythmical prose. So science and history abandoned the rhapsodies and followed in the wake of the orator, but on the whole in science it has been in a crude and imperfect way, when compared with his art. For instance, there are oases in the desert, there are stepping stones across the brooks, and in the midst of the orator's efforts to drive his argument home there are pauses to relieve the tension of his hearers and he diverts them by side excursions into jocosity and anecdote. So it is with the best prose writers, but the scientific paper is one long dusty level of tiresome and laborious march from one end to the other. If one arrives, one is exhausted; the majority of readers falter or fall by the roadside and never arrive at all. The arts of the orator are too various and numerous for mention and their subtlety often defies analysis, but it is remarkable that scientific literature is the only province in which they are all flouted. The compelling character of rhythmical cadence produces profound effects on the understanding as well as on the spirit of man. Why sneer at them when you want to drive your facts home? "You should have heard the beast* speak it," said Aeschines.

*I use the paraphrase of somebody else, I forget whom, not exactly warranted by the text to be found in Cicero, de Oratore iii, 56, "Quanto magis miraremini, si audissetis ipsum," but the story may be told differently elsewhere though it does not appear in Plutarch's Lives.

driven into exile by the eloquence of Demosthenes, when the Rhodians praised to the skies the written reports of his great rival's discourse at Athens. The power of the spoken word and the impelling force of personality cannot be enlisted in the service of science, except sparingly, for they do not lend themselves to sober analysis, but that is not so for all the arts of the orator. Not to use those available in the dissemination of scientific truth is stupidity doubly distilled.

The force of prose thrown into the rhythm by Cicero's art halted, in its oratorical form, the downfall of Rome; in its written form scarcely less than that of Plato it has arrested the attention of ages. The point with Cicero is, unlike the great Athenian, he dealt very largely in the commonplaces of the human mind. He draped wisdom already as old as civilization in the magic of his written words and he seems to make it his own. Plato's thought rests on something besides banality, but it would never have survived except for his art. Many of the replies to Cicero are published in his correspondence. Read his letters to his friends and then read their letters to him, read the stumbling phrases and the bad Latin of the clumsy brute, Antony, and one almost wonders whether such gaucheries are not responsible for some of the poor showing he makes in the ethics of history. Should science leave to politics and mysticism the power which is the chief motive force that sways the beliefs of men? It can be made no less powerful, one is almost tempted to exaggerate, in the diffusion of knowledge.

Led to Cicero and the power that made his fame immortal by the excellence of the writings of Cornelius Celsus, we find in the latter an indication that some cultured men in the budding glories of the Roman empire devoted themselves at least to the theory and probably to the practice of medicine. We have naturally, though incidentally, turned to the works of the man who shaped Latin prose into a mighty weapon and whose literary instincts enabled him to open up the avenues of the art of language to the brilliant men, coming after him, who graced the reign of Augustus. They are easily lost in the undergrowth again by the affectations of lesser men who mistake eccentricity for genius and the forest closes over them, but when found again one perceives that certain paths in good literature are indestructible, immortal, and above the shifting vogue of transient generations of men. However, in Cicero's mention of medical matters and medical men, we get, rarely it is true and but faintly, yet some light on the social standing of the latter among his contemporaries. "Salutation to Servius: I am in friendly relations with the physician Asclapo of Patrae. My association with him is as pleasant and as helpful as his art is to me, which I practise in my family; with his science as well as with his faithfulness and his humanity I have reason to be content. I recommend him to thee and ask thee that thou wilt take the trouble to let him know that I have taken pains to write concerning him and that my indorsement has been of service to him. I should be much obliged if thou didst this."[12] Practically the same thing is to be seen in his reference to Asclepiades,[13] so famous in ancient medical annals. Both were men whose

esteem he wished to secure. It is true Cicero was a "new man" and often had to lick the feet of the aristocracy; and of course the real nobles of Rome, no more than the plutocratic nobility of New York, had no cause and took no pains to be attentive to the non-medical influences of the medical profession.

Cicero, struggling like the "new man" in the great metropolis of the western hemisphere, left no stone unturned in his youth to enlist all sympathies for himself and he never lost the tendency though he somewhat neglected, perhaps to his own undoing, the practice of it in his old age, at the height of his fame. So we must not rate the significance of his complaisance too highly. Moreover in a way the form he uses is more or less a stereotyped one in the epistolary literature of ancient Rome, indeed of modern Rome and the modern Italian people, as Sedgwick points out in his "Marcus Aurelius," lately off the press. These faint landmarks we get in the last century before Christ and so far as they go they point to approximately the same social status, relatively, for physicians as exists to-day, but it soon deteriorated very much. Into that I can not here enter. Cicero speaks of the doctor as a friend but hardly as one of equal rank, in about the same tone we would expect from a kindly attorney at law to-day, risen to political prominence from the money bags of his clients, addressing Servius, one of his high placed and high polished friends. We note too Asclapo is a Greek of Patrae as Asclepiades was an Asian Greek from Bithynia, the province that gave birth to Galen. They were none of them, except Celsus, of ancient Roman stock, none of them, unless possibly Celsus, of blue blood. We know what Asclepiades was from Pliny and Galen, a brilliant, vulgar, noisy, loud blowing, wonderfully successful practitioner, courted by the mighty; and it is noteworthy in our present interest that Cicero sought his friendship and influence, but with Asclapo it may have been different. It was not on the cards for Cicero to proclaim him the most skilfull and the most eloquent of all doctors, as he did Asclepiades, and to want him to know he said so; but he esteemed Asclapo all the more genuinely perhaps, and our point is that he sought *his* influence also, even if only in stereotyped form. We shall leave him for a moment to return to Antony.

In the second Phillipic against Antony, he vituperates him with relentless eloquence and unrivaled billingsgate. To this Antony could make no reply but to cut off his head and nail it with the hands that threatened him, one on each side, to a plank in the forum, but this was later, though not much later either. In this and other orations the tongue, which his wife did not forget to pierce when he had stilled it forever, the tongue of Cicero taunted Antony with treachery, treason, cowardice, plunder, slaughter, dicing, whoring. He neglected nothing in the catalogue of all vices. Repeatedly in the senate and in the streets he reviled him with drunkenness; he had vomited in his toga, half drunk as he harangued the mob, after a carouse. *"Ab hora tertia, bibebatur, ludebatur, vomebatur."* Before a Roman audience he thunders against him for alienating the plough land of the Campania and other public holdings to pimps and mimes; in this connection—"to thy doctor three thousand jugera; what if he had cured thee?" Antony could scarcely have made any other reply than he did. Brutus, the philosopher, the orator, the tyrannicide, the haughty patrician, betrays a note to attract our attention: "Glycon, Pansa's physician, I commend to thee. (He takes no trouble to ask his good words may be repeated to Glycon.) We hear he has fallen in suspicion with Torquato for the death of Pansa and is in custody as a parricide"*—unjustly Brutus believes, but for us a hint of the evil repute of the doctors in the earlier civilization, an evil repute which was to grow under the emperors.

IV

There is another mention of Asclapo in the letters of Cicero, which is not entirely devoid of interest for us, all the more that it reveals to us the lovable side of the great orator's character, his tenderness of heart, his sympathy, his generosity, when his ambition was not at stake and his vanity not in play. He writes" to the ailing Tiro, his faithful freedman and factotum, that Asclapo had assured him of his recovery but he had better not go to Lyso's concert lest he should fall a victim of the "quartan crisis." He said that he had ordered an honorarium should be paid to the physician. With all the supple skill of the practical politician Cicero ingratiated himself with the powerful and often, to do it, turned aside from unselfish devotion to his country to ignoble ends. He often pretended affection when quite evidently he felt none, but behind all the insincerity and all the vacillation and fickleness of a vain and wonderfully alert and vigorous intellect there was a fund of warm affection in the man that wins our hearts and often obscures the cowardice and the self-seeking of the politician. His concern for the devoted Tiro, the modest unassuming editor of his letters after his death, secures our sympathy for himself and our esteem, as it doubtless did the affection of his humble follower, his private secretary, often his business agent. Cicero's weaknesses are forgotten as we read him writing to the invalid in his anxiety, putting behind him his desire for the invaluable services of the amanuensis of one of the busiest men the world has ever seen. "Don't trust thyself," he urges Tiro, "to the journey either by sea or land. I will see thee soon enough if only I see thee restored to health. . . . I beseech thee, Tiro, don't spare expense in anything needful to thy health. I have written to Curius; he shall give thee whatever thou say'st. Something should be given to the doctor too that he may be more attentive. Thy services to me are innumerable, domestic, forensic, in city and country, in public and private affairs, in all professional pursuits, in our literary activities. Thou wilt have accomplished all, if, as I hope, I can only see thee well. . . . For thy health think of a trip at sea, Tiro. I wish to hurry thee in no way; my only concern is that thou shalt be well. There is no one that loves me but loves thee too. Both for me and for thee it is all important that thou shouldst

*A parricide was not only one who had killed his father, but one who had killed his benefactor was also so called and so defined in English.—Brutus to Cicero, Ciceronis Epist. ad Brutus I, vi.

recover and it is also of concern to others." He repeatedly urges a sea voyage, one of the things which Celsus valued highly for the restoration of health. "We will be very solicitous for thy health, nor shall we wonder at not receiving letters from thee. . . . But for these winds we would not be sealed up here in Corcyra. Have a care of thyself, grow strong and sail as soon as thy health and navigation permit. Then, only, come to us."

One of his own illnesses he speaks of thus[15] in a letter to Gallo: "I am afraid of all diseases, not only of those which the stoics hold it as a reproach against thy Epicurus that he says dysentery and strangury trouble him, since one is due to gluttony and the other to a more disgraceful vice. I had been much afraid of dysentery and I thought perhaps a change of place or a mental rest, rather perhaps a relief from old age, that disease in itself, might help me." He runs away from sumptuary laws, which seem to have worked badly with him at Rome, but at his villa down in Tusculum they had welcomed him with festivities, given him a dinner, mushrooms, green vegetables and all sorts of herbs to season them, *"nihil possit esse suavius."* And during the augural banquet at the house of Lentulus, "such a diarrhea seized me that only to-day for the first time it seems to moderate. Thus I, who have cheerily abstained from oysters and clams, am betrayed by beets and marshmallows. After this I shall be more careful, but since you have heard from Anicius (he saw me sick at my stomach), you had good reason not only for sending to inquire for me but you ought to have come to see me. . . . I am thinking of staying here until I get better, for I have lost my body and my soul, but if I drive off the disease, I shall easily get those back."

He could joke about his own illnesses, but his nerves were racked at the thought of his wife's maladies and by his worries for his darling Tullia. The tender side of his soul is thus revealed perhaps, but also the temperament liable to nervous diarrheas. "All the cares and worries which I had for thee," he writes[16] Terentia, "were destroying me, and for Tullia, who to us is sweeter than life; all these I have laid aside, cast out. What the cause was of all the suffering I found out yesterday, after I left you. In the night I threw up bitter bile and I am so relieved that some god seems to have doctored me, to which god, as is your wont, you may show your piety and devotion—it is to Apollo or Æsculapius you owe it."

Biographical Data Concerning Laennec.—According to Letulle in *La Presse Médicale* for June 25, 1921, xxix, 51, the least details in the lives of men of genius should be of interest to the public. Many of these have already been published in articles appearing in the MEDICAL RECORD. The source of the data given by Letulle is evidently the recently issued biography by Rouxeau, which considers the life of the physician from 1806 to the date of his demise. Extracts from this biography as well as from the earlier volume by the same author dealing with the early life of the great man have already appeared in these columns. Laennec began the study of medicine at the age of 14 years. Wonderful as was his career, he was, as so often happens, unusually favored by fortune. His Uncle William was a prominent physician, Dean of the Medical School at Nantes. When Laennec reached Paris he had the good fortune to become the assistant of the great Corvisart, the leader of the profession in France, and physician to Napoleon. He was likewise fortunate in having Bayle for one of his masters. He passed from the guardianship of Bayle to that of Dupuytren. With three such tutors we can understand how he became the founder of modern medicine and a "teacher of teachers." At the age of 21 he published his phenomenal paper on peritonitis, thereby beginning a new chapter in medical evolution. At about the same time he began his treatise on pathological anatomy which was never published, but in which is to be found a wealth of discovery. He had to renounce this and other cherished schemes to get the money to live. A lifelong invalid, he was not like Buckle, Pope and others provided with compensating means.

Laennec's ill health was such that Letulle rates his biography among the martyrologies. He succeeded, fortunately, in publishing his work on mediate auscultation, which made him famous, during his own short life. In addition to his physical sufferings he had to bear calumniation, for he was a journalist addicted to polemics and made enemies, like all prominent men who take sides in politics. He had quarrels and feuds with some of his professional brethren and fought his former master, Dupuytren, and the famous Broussais. From his Breton blood he derived his Celtic fondness for music and poetry. His delicate ear for poetical and musical sounds has been brought in causal relationship with his discovery of lung murmurs. He suffered from asthma, neuralgias, and gout before becoming phthisical. The coldness and hauteur of which he was accused were clearly motivated by physical and mental suffering. He was not liked by his father, who was too egocentric to think much about him; there was no love lost between him and his brother and stepmother. But those who best knew him found him gentle and even timid by nature.

A CASE OF PROGRESSIVE MUSCULAR ATROPHY WITH COMPENSATORY MENTAL REACTIONS.

BY NOLAN D. C. LEWIS, M.D.,

WASHINGTON, D. C.

PATHOLOGIST TO THE GOVERNMENT HOSPITAL FOR THE INSANE.

THE following clinical considerations were gleaned from the hospital records:

The patient, L. M., 59 years, single, was admitted to the Government Hospital for the Insane, August 15, 1900, with a history of general muscular weakness and peculiar mental constructions.

The account of his condition he gave as follows: His parents died of "old age," and to his knowledge no one related to him had been affected by this disease. He did not remember childhood diseases, but gave a history of having had syphilis in 1865. His present illness began at 25 years of age with twitching pains, which were relieved by rubbing, and an atrophy in the finger and arm muscles, and with loss of strength and tone. This atrophy he thought to be due to injuries incurred from the frequent clubbings he claimed to have received on the Bowery, where he was often engaged in robbing people in the side streets, for which he served six months in the Tombs and also the same length of time on Blackwell's Island. Since the onset of his disease he had done everything to make a living, worked as a huckster, picked pockets, and also operated as a professional beggar, exhibiting his deformity as a means of support. He thought his actual ill-health began in 1861, at which time he claims a Jew shot him.

He was in Randall's Island Hospital for some time, where he was treated for his muscular disease. He thought he was followed from New York to Washington by some enemies and was picked up in this city in 1899 when he tried to see the President about some persecutions. He was sent to Washington Asylum Hospital for observation, and while here expressed hallucinations in both ears of voices which were "squealy" in character and extremely abusive.

Physical Examination: When admitted to the Government Hospital for the Insane the facial expression was quiet and contented, the attitude erect, and the gait uncertain and somewhat paretic. The skin was pale but well nourished and with normal moisture. The hair and beard were iron gray, and the nose red from superficial capillary dilatation. Scars from bullet wounds were present on the left shoulder and through the left thigh. The skeleton was well formed, 5 feet 7¾ inches tall, and weight was 155 pounds. The muscles of the left leg, both shoulders, both arms, and particularly all interosseous muscles of the hands were atrophied, lacking strength and tone. The abdominal walls were thin and flabby, and there was a marked general deficiency of subcutaneous fat.

The breathing was slow wtih the expiration prolonged, with a decrease in pulmonary sounds over the left side. The capillary circulation seemed feeble, and there was a large varicose vein on the inner surface of the left leg, and internal hemorrhoids were present. The maximum impulse of the heart was observed in the second interspace and the valvular sounds were slightly roughened. Pulse 80, regular, and of fair volume. The gastrointestinal system was normal, appetite fair, and teeth irregular and discolored. There were no positive findings in the genito-urinary system.

Examination of the nervous system showed a diminution of all reflexes, with an absence of the knee jerks and an uncertain gait, the left leg being raised higher than the right, with the foot hanging extended. There was a positive Rhomberg, but no ankle clonus or Babinsky. His general muscular coordination was impaired, and the movements were very jerky and irregular.

There was a partial paralysis of all muscles of the right arm and also of the right pectorales, subcapsular, and trapezius. All of the left arm muscles with the exception of the triceps and a portion of the deltoid

FIG. 1.—Showing the appearance of the hands after the disease was well under way.

were considerably weakened. No contractures were noted.

During examination he complained of sharp shooting pains through the entire body, and also of dizziness. His touch and pain sensations were impaired, and more so on the right than on the left side of the body, but there were no definite anesthesias. Temperature sensations normal, smell and taste normal, and hearing fair. The sight was impaired, the pupils being very small, and reacting sluggishly to light but well to accommodation.

Mental Examination: At the time of admission the perception, memory, reasoning, and judgment were fair, and he answered questions with intelligence. At times, however, he was suspicious that people were talking about him and forming a conspiracy to injure or kill him.

He had pronounced respect for the physicians, was rather reserved, appreciative, and tractable, with good habits, tidiness, and normal sleep. Personally, he

claimed to be mentally depressed, physically weak, and affected with great lassitude.

Notes on Physical and Mental Developments, 1906 (six years after admission): He was said by the charge physicians to suffer from progressive mucular atrophy. The muscles were extremely thin and weak,

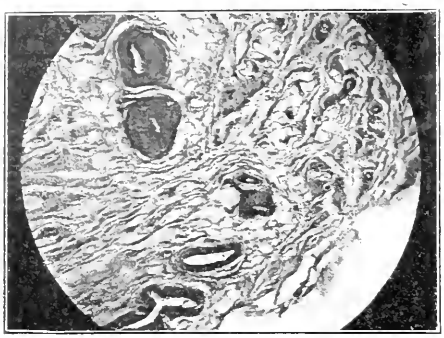

Fig. 2.—Photomicrograph of a section of the gastrocnemius muscle showing connective tissue, fat, and thickened vessels.

and he was unable to handle his arms except in a flail-like manner (Figure 1). His condition had advanced to such an extent that he was bed-ridden and unable to manage himself, otherwise his general health was apparently good. All of the upper arm muscles were in extreme atrophy, with barely remnants of former muscular structure.

Mentally he was very irritable and abusive, punctuating every sentence with an oath of some kind. His delusions of persecution were fleeting and ever changing, but he frequently thought that he had been kidnapped and brought to the institution for the purpose of being held and tormented. There was a complete lack of appreciation of his physical condition, a resentment toward being spoken to or disturbed in any way, and partial disorientation, but he could still give a fair account of his illness.

1907: During this year he progressed rapidly, becoming extremely helpless, and gradually developing delusions of grandeur. He imagined himself to be a very "smart" man, with plenty of money, and ability to deliver a speech to the House of Representatives. When spoken to on the ward he became very profane and went into tirades of abuse. He was still tidy in habits in spite of his extremely helpless state.

1908: The patient seemed fairly well oriented, knowing the names of the physicians and nurses, but was examined only with greatest difficulty and when asked a question answered—"Are you too — —— dumb to know yourself?" There was absolutely no use of the arms and hands, there being even insufficient muscular power to produce extension at the wrists. There was no grip to the hands, but the forearm could be partially pronated and supinated, the right forearm being apparently more helpless than the left. He could walk to the bathroom with the aid of an attendant, and ate his food in the following manner: Would lean forward taking hold of the cup with his lips to drink, while solid food he ate like one of the lower animals, lifting meat and bread from the table or cornering the piece, moving it toward him with lips and tongue. He always asked for what he wanted, and insisted upon eating it without the assistance of the nurses. He was now sure that the President knew about him, and in some way caused his condition, but was quite sure that it could be cured by a few applications of whale oil.

1913: He manifested good attention during the interviews, but became easily and highly excited, stating that he was Christ and that this was a "cruel" place in which to exist. He claimed that he was tracked here against his will by thieves and murderers and that he was Captain Kidd the King of the Highways. Although he was now absolutely helpless, and unable to leave the bed, he demanded his discharge and clothes so that he might go out to work for a living. The facial expression was hostile and he not only used a vile vocabulary as a means of protection but also expectorated freely on unwelcome visitors. His voice was very highly pitched and rasping, forbidding close examination and threatening to expectorate tobacco juice on the examiner.

1918: There was very little change in the general condition. His delusions now centered about the physicians who he thought stuck him with pins, tormented him with electricity, and tortured him in many other ways. Occasionally he became very noisy with protests against the nurses whom he imagined were putting various pastes on him. He was absolutely helpless so far as the trunk and extremities were concerned, rotation of the trunk being impossible. The head and tongue movements were apparently perfect; closing and opening the eyes, wrinkling of the forehead, and method of showing the teeth were all well executed. The diaphragm was apparently not affected, nor were the bladder or rectal sphincters.

Repeated Wassermann reactions on both blood and spinal fluid were negative. Spinal fluid cell .15. Colloidal gold reaction negative. Pandy: positive.

The patient in this year developed an extreme diarrhea, pulse gradually became more and more feeble, respiratory difficulties developed, and he died in coma July 1918 at the age of 78, eighteen years after admission to this hospital, with developing muscular atrophy and mental disturbance.

Post Mortem Examination.—The body was that of an aged man with a normally shaped skeleton a complete absence of subcutaneous adipose tissue, and a remarkable atrophy of the entire muscular system. The interosseous muscles of the hands and the triceps and solei were entirely gone, and were represented only by tendon sheaths and fibrous tissue. The atrophy of the forearms was remarkable where the skin was drawn loosely over the bones. The hands were flattened, "flail-like", and the muscles had apparently been useless for years. Sections of the affected muscles revealed a pale "fish flesh" appearance of the remaining bundles which could scarcely be distinguished from fat, and a large amount of fibrous tissue overgrowth between the muscle groups.

The following muscles were affected: Pectorales major and minor, Deltoids, Latissimus dorsi, Serratus magnus, Erectores spinae, Trapezius (both parts), Rhomboideus, Biceps brachii, Supinator longus, Brachialis anticus, Glutei, Adductores femoris (less than others), Quadriceps extensores, Peronei, Gastrocnemii, Teres major and minor, Tibialis anticus, Triceps, all Interossei, and abdominal muscles. The muscles of the

Fig. 3.—Photomicrograph of muscle showing wide separation of fibers and staining of sarcolemma cells.

neck, face, head, tongue, and diaphragm were not affected.

Microscopical examinations were made of all muscles and a few selected representatives reports are made below.

Gluteus Maximus.—The muscle bundles were few in

number and irregular in width, some being extremely narrow and others being wider in outline. These strips of muscle fibers were widely separated by bands of fibrous tissue and infiltrating round cells. All blood vessels in the supporting tissues were distorted, having irregular, thickened walls and reduplications of elastic

FIG. 4.—Photomicrograph of rectus femoris showing degenerations and localized swellings of fibers.

membranes. Some vessels presented multiple canaliculations while others were necrotic and contained calcium infiltrations with much destruction of the wall substance. A few mononuclear cells laden with débris were wandering in these areas. The nuclei of the sarcolemma sheaths were particularly numerous, many being arranged along the margins of the atrophied fibers in rosary formations. Throughout the sections, areas of degeneration and necrosis were seen in the muscle fibers. Cross sections of this muscle showed clearly the variations in the sizes of the individual fibers in the bundles, and also the irregular distribution of the degenerations. Occasionally the most extensive degeneration was seen in the central fibers of the bundle, but usually the peripheral zones were the areas affected, the appearance ranging from a blue finely granular alteration (hematoxylin stain) to complete necrosis.

Gastrocnemius and Soleus.—In sections taken from the lower portion of the muscles just above the tendo Achillis no trace of muscle tissue was noted. There was much fat and areolar connective tissue stroma, which was heavily stained and bearing various types of cells, such as large and small mononuclear phagocytes, irregular fibroblasts, and large pale cells bearing elongated nuclei. Many thickened arterioles and capillaries were a feature in all areas, and occasionally large vessels with endarteritis proliferans and surrounded by heavily stained connective tissue containing muscle remnants in the form of distorted sarcolemma cells (Figure 2).

In the "belly" of this muscle group, muscle fibers were present, but were extremely irregular in size, and in advanced stages of degeneration. Sarcolemma nuclei had everywhere assumed a rounded form, were arranged in chains (Figure 3), and in patches were heaped together in round or oval masses. In other areas the nuclei in contact end to end formed solid lines along the shrunken fibre. The sheath cells and small round cells had completely replaced the degenerated muscle fibres in many fields. The nuclei of the remaining muscle cells were far more numerous than is expected in an ordinary case of senility.

Diaphragm.—The muscles of the diaphragm showed very little change in the fibers, they being uniform in size, well formed, and in only a few areas affected by localized swelling of the fiber, traces of granular degeneration, and separation of the muscle bands by replacing connective tissue. The nuclear elements of the muscle cells and of the sheath were normal in number and distribution. The diaphragm was not involved in the general changes affecting the skeletal muscles.

Rectus Femoris.—These muscles exhibited localized swellings of the fibers (Figure 4), which reacted very weakly to the stains. Many fibers were interrupted for variable distances by complete fibrous tissue replacement, bearing many round cells and sarcolemma nuclei. Everywhere the muscle fibers were heavily nucleated, and in some areas knots of chromatin material were seen at the margins of the fibers, probably from coalescence of many cells. The longitudinal bundles exhibited an interruption characterized by a mere network of fibrous tissue containing very few nuclei, and these areas alternated with others heavily nucleated and containing short oval strips of swollen muscle cells, some of which were enormous in size.

Erector Spinae.—The prominent feature of these sections was the pale, swollen, scantily nucleated, homogeneous appearance of long strips of muscle cells in each bundle. In some other portions a heavy infiltration with round cells and overlapping nuclei was manifest. A few large bundles revealed complete interruption of the cells for some distance, with dropping out of tissue, or replacement with long thin strands of heavily nucleated tissue composed chiefly of modified sarcolemma cells. Nowhere through these extensively degenerated muscles were the cross striations absent, except in the completely degenerated patches.

Biceps.—These fibers taken as a whole revealed an advanced state of atrophy with a marked increase in heavily stained sarcolemma and muscle cell nuclei, and a frequent heaping up of the cellular elements. These atrophied muscle bands were widely separated by connective tissue growth bearing vessels conspicuously thickened by endarteritis and mesoarteritis. In many of the extremely atrophied fibers the cross striations were perfectly retained. In teased and stained fibers of the biceps, the sarcolemma cells evinced a remarkable proliferative propensity, to the extent that many muscle fibers were bound in on both sides by long skeins of these nuclei. The nuclei of the muscle cells were long, irregular, and finely granular. The interstitial tissues were a mass of various types of cells of connective tissue origin.

Triceps.—The muscle bundles were widely separated by a great abundance of supporting tissue, bearing thickened vessels, as were also the fibers in the bundles from degenerated elements. The muscle nuclei were numerous and heavily stained and the fibers showed irregularity, numerical reduction, variability in size, and occasonally a complete central necrosis, leaving only a thin line of tissue representing the periphery—some of these fibers exhibited fragmentation, local swelling, and ruptures.

Interosseous Muscles of Hand.—Sections from these areas showed a mass of grey, fatty substance, no feature of which might be recognized as muscle tissue (Figure 5). There were many irregular wide, short

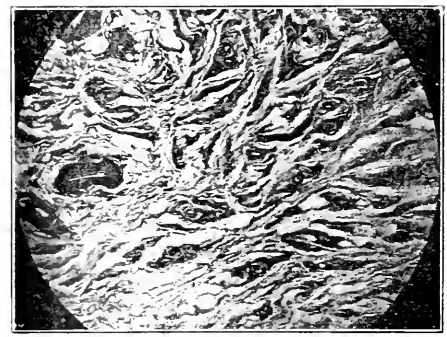

FIG. 5.—[illegible] of interosseous muscles, complete [illegible] of muscle elements by connective tissues.

bands of fibrous tissue bearing probably modified sarcolemma cells and many large fibroblasts and small round cells. Distributed through the sections were large and small obliterated, partially obliterated, and irregularly thickened blood vessels with an occasional wall undergoing hyaline degeneration.

The Nervous System. Brain: The dura was tightly adherent to the calvarium and was considerably thickened. The brain weighed 1300 grams, was well formed with notable convolutional complexity and with a very slight general senile atrophy. The right hemisphere was slightly smaller than the left, and a few

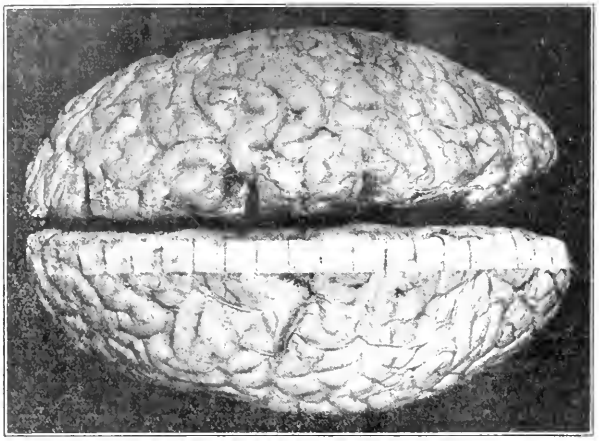

Fig. 6. Superior cerebral surface. Note the cloudy thickened appearance of the leptomeninges.

small patches of arteriosclerosis were located in the basilar artery. The entire pia-arachnoid was distinctly thickened, toughened, and milky throughout (Figure 6) with these changes pronounced along the surface veins and over the sulci. There were a few patches of morbid adhesion to the frontal cortex of both sides. The cerebrospinal fluid was normal in amount and appearance. No remarkable changes were seen on sectioning the organ, and no unusual gross changes were noted in the spinal cord.

Microscopical Examination.—Frontal Cortex: The meninges covering this region were thickened with fibrous tissue, presented prominent congested vessels, and had developed along the superior surface a few good sized patches of endothelial proliferation. The cortical architecture was somewhat broken up, the neuron cells were shrunken and heavily pigmented, and a mild neuroglial proliferation was in evidence. In the white substance there was an occasional area of fibre degeneration.

Precentral Cortex: The overlying meninges were irregularly thickened by connecting tissue meshes and endothelial elements, with localizd large sized patches of endothelial cell hyperplasia. Radiating from the meninges downward into the cortex were extending bands of fibrous tissue ramifying among the nerve cell layers. The meningeal vessels were thin walled and greatly dilated, but the vessels of the upper layers of the cortex were markedly thickened. The motor cells were narrowed and elongated, the majority presenting a finely granular degeneration of the cytoplasm with an increase in the yellow globular pigment. Some cells presented a margin well outlined by finely fragmented chromatin substance with the dendrites fairly intact, while in others there was a loss of cytoplasm, a dropping off of dendrites and pericellular accumulations of satellites. An abundance of neurophags were distributed through all layers of this region.

Post-Central Sensory Cortex: The parenchymatous cells of this area were shrunken, the outlines irregular, and the dendrites evinced, varicosities, localized swellings and granular degenerations. Many large sized neuroglia were present throughout the sections. The meninges of this region showed the same chronic changes described for the motor cortex. Sections through the hippocampus, first temporal and calcarine regions revealed very little additional information excepting there was a considerable number of small localized degenerations and dropping out of portions of fiber tracts, with atrophies and pigmentary alterations in the layers of cortical cells.

Basal Ganglia and Medulla: The choroid plexus showed a general atrophy of the epithelial cells, with considerable vacuolization. The ependyma covering the basal ganglia as well as that covering the floor of the fourth ventricle was broken in many places by granulations formed by proliferating neuroglia. Throughout the supependymal layers was a thick felting produced by overgrowth of neuroglia with deeply stained protoplasmic fibers. Many varieties of neuroglia bearing large granular nuclei were noted through the medulla and many neuroglia were packed about the nuclei of the cranial nerves—particularly was this true of the facial nerve nuclei, while the nuclei of the trigeminus were comparatively free from neuroglial infiltration. Throughout the motor tract much diffuse degeneration with a dropping out of fibers was noted. Sections through the regions of the fourth nerve nucleus showed considerable neuroglia increase and everywhere between the pyramidal fasiculi were seen Golgi cells of modified varieties. Considerable degeneration of the pigmentary type was noted in the nerve cells. Section through the Olives disclosed the upper median raphe to be choked by neuroglial overgrowth with much atrophy and degeneration with numerical reduction in the parenchymatous cells of this area.

Cerebellum: There was a moderate chronic fibrous thickening of the meninges and although the molecular layer of the organ was apparently narrowed and showed vascular dilitation with blood casts in the capillaries, no unusual sclerotic changes in the structures were present, nor were the neuroglial elements particularly increased. The purkinjian cells showed a numerical reduction with many peculiarities of distribution, shape, and structure. In general there was a unilateral granular degeneration of the protoplasm, although some cells showed complete granular degeneration with extremely pale staining properties, and a few exhibited sharp protoplasmic outlines with prominent nuclei, but in many cells the nuclei were barely

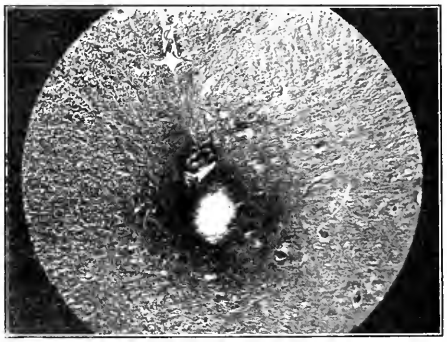

Fig. 7. Photomicrograph of the thoracic portion of the spinal cord, showing miliary glioma with central disintegration.

visible. The greatest reduction in the number of cells was apparently around the curves of the tips of the leaflets where there was considerable replacement and felting of the structure by supporting cells.

Cervical Cord: A great dropping out of fibers was seen in all tracts, particularly on the inner side close

to the posterior gray extensions. Some neuroglial increase was seen through these areas replacing the extensive loss of nerve fibers. The posterior tracts were in extreme degeneration with many small patches located near the posterior median fissure, but not to the extent of those seen in the thoracic region. Many deep stained amorphous globular accumulations of hyaline material were seen in the tracts of Gall and Burdach, and many neuroglia cells replacing sensory nerve fibers were seen through these tissues.

Thoracic Cord: Marked destruction was noted of the motor conducting fibers, which were thinly scattered and reacted weakly to the stain however, most marked degeneration was seen of all structures between the posterior horns. In these areas there were many large hyaline accumulations concentric in type and with numerous mononuclear phagocytic cells and only an occasional large fiber, remaining, there being almost a complete dropping out of the entire structure with a few remnants of fibers and a few remaining myelin sheaths. Occasionally on the border of the gray and white matter a densely sclerotic miliary patch composed of neuroglia cells and twisted, knotted nerve fibers replaced the architecture of the cord and sometimes there was a central dropping out of all these structures including the new formation tissues. (Figure 7). A few large swollen, deeply pigmented parenchymatous cells were seen around these miliary gliomata. The anterior horn cells presented the following characteristics: Some were entirely shrunken and degenerated, while others showed a deep yellow pigmentation and many presented a central area of complete degeneration surrounded by a peripheral zone of chromatin, finely granular, but heavily stained. The lumbar cord showed practically the same pathological changes as above described for the thoracic portion.

Spinal Nerves: The nuclei of the sheaths were elongated, very granular and were undergoing rapid proliferation, the nuclear structures in places being oval or oblong in shape, and of large size, while in other regions they were extremely eliptical, sausage shaped or spatulated in character, but were always granular. In some areas the spinal nerve with its ganglia was nearly obliterated by smooth fibrohyaline structures among which were accumulations of large sized, heavily stained mononuclear cells, bearing nuclei which could be described as vesicular in type exhibiting small areas with a pale interlacement of fine network. Congestion of all vessels of the epineurium was prominent throughout.

Median Nerve: The nerve fibers were compact, but the bundles were small and widely separated by areas of fatty arolar tissue. About one-half of the nerve fibers were seen to be in various stages of degeneration which for short distances were characterized by networks of granular debris, and in other places by collapse and closing of neurilemma sheaths with infiltration of connective tissue, cells, and large accumulations of nuclei. Fatty products from the dissolved myelin sheaths were seen through all portions of the nerve preparation, and iron hematoxylin preparations showed very plainly the extensive granular degeneration of the fibrils with occasional heavy stained bands of nerve structure which appeared to have undergone universal infiltration. Blood vessels are all packed with red blood elements.

Cross sections of these peripheral nerves showed the nerve bundles to be few in number, extremely small in size with the funiculi showing numerical reductions and an extensive degeneration of individual fibers. The perineurium was widened, very wavy, and composed of large numbers of fibres. The endoneurium was also enormously increased in amount. The replacing tissues between the nerve bundles contained many fibroblasts, the whole being imbedded in a mass of areolar fibrous tissue bearing large thin walled blood vessels.

Sciatic Nerve: The sciatic nerve in cross sections showed the nerve bundles to be very small with a widened perineurium. Connective tissues and fat separating the large bundles to a marked degree were supplied with blood vessels which were both sclerotic and congested. The nerve fibers showed an absence of about one-half of the usual number, and some of the remaining ones were swollen and vacuolated, while others were small and granular with the spaces occupied by the degenerated ones filled with debris. The perineurium was very cellular, showing many mononuclear phagocytes and neurophags laden with granular debris and fat. In a few nerve bundles could be seen the fibers knotting themselves into whirls growing wildly outside the endoneurium. In longitudinal sections the nerve fibers for long distances showed partial degeneration of the substance into a fatty, granular-appearing material, with the nuclei of the neurilemma extremely granular, some being vacuolated and more elongated in shape than usual. In portions of the sections the nerve fibers stained very heavily as if the substance had undergone some type of mineral infiltration, while in other places a fine network of granular fibers was seen extending along the path of former nerve bundles.

Thorax.—The lungs were tightly adherent posteriorly and in the apex of each lung a small, completely walled off, inactive tuberculous nodule was located. There was considerable emphysema throughout all lobes, the surfaces of which were pale in color, and somewhat mottled. Microscopically the alveoli exhibited an advanced vesicular emphysema with dilatation and rupture of the walls. Around the bronchi, and some of the large vessels, all of which were thickened, were rather dense deposits of exogenous pigment. In parts of the sections the alveolar walls were thickened and irregular nodules of fibrous tissue protruded into the spaces. Most of the large vessels were deeply congested.

The heart presented considerable epicardial fat. The muscle was relaxed, soft, and showed some surface fatty degeneration. The right ventricle was very thin and soft, and the left ventricle showed a moderate amount of interstitial replacement. All the heart valves were thickened and presented a number of sclerotic patches. The aorta had lost its elasticity, was much thickened, and the endothelium was studded by large elevated patches of fibrofatty production.

Microscopically the heart muscle fibers were thin and the muscle cells elongated and fairly heavily pigmented. The striations were easily seen and the nuclei of the muscle cells were well stained, regular in size and contour. A large amount of interstitial myocarditis was present in all sections but in some places it had largely replaced the normal muscular structure. The visceral pericardium was quite fatty in type, and evinced localized accumulations of fibrous tissue.

Abdomen.—The stomach, intestines, and pancreas showed no remarkable features. The liver showed very few gross changes, and the gall-bladder was normal. Microscopically the capsule showed some senile changes and congested vessels. The lobules in general were small in size with many individual cells presenting enlarged, heavily stained granular nuclei with karyorrhexis and karyolysis, while other cells presented small nuclei surrounded by pale protoplasm. Near the central lobular veins, many large sized hepatic cells were seen bearing large, darkly stained, lobulated nuclei in which individual chromatin structures were obscure. The cytoplasm in these cells was shrunken, contained fat and in places was bile stained. The portal canals had congested veins and a slight increase in the connective tissues.

The spleen was senile in appearance and somewhat softened with localized thickenings in the capsule and a large sago body of amyloid appearance attached. Microscopically the capsule was seen to be exceptionally fibrous, and blood pigment was in great excess through the substance of the organ. The malpighian corpuscles were filled with red blood corpuscles, and the arterioles were in advanced stages of hyaline degeneration. In general the stroma was slightly increased and the vessels were all thickened.

In both kidneys there was positive evidence of an ascending pyelitis, particularly in the right. There was a thin yellowish pus in both pelves which were dilated along with the upper part of the ureter which was filled with cloudy, purulent, foul smelling urine. The kidney substance was sclerotic, scarred and the surfaces pitted and granular with the capsule slightly adherent. The bladder was filled with the same type of urine which contained a large amount of amorphous material. Prostate was enlarged, soft, but not nodular. Penis and testicles were senile in type.

Microscopical examination of the kidney showed that the architecture of the cortex was entirely destroyed and in many instances could not be recognized

as kidney structure. A few partially fibrous glomeruli were still present and in places the cortex showed such a heavy lymphoid infiltration that its appearance resembled the structure of a lymphoid follicle. The capsules of Bowman were greatly thickened, and there was an enormous amount of hyaline material scattered through the tubules where in some instances the epithelium had undergone retrograde changes, the cells assuming columnar and high cuboidal types. In many places the tubules were collapsed with the cells degenerated and replaced by fibroblasts in great numbers. In the collecting tubule regions much fibrosis and degenerated epithelium were noted and in some places the lumina were completely filled with granular debris with here and there a cell undergoing necrotic changes. Abnormal and rapid mitoses appeared frequently. In many of the collecting tubules, masses of polymorphonuclear leucocytes were seen and all vessels were enormously thickened, many showing a remarkable endarteritis proliferans.

The kidney sections stained by orcein technique for elastic tissue exhibited an enormous amount of this tissue in the blood vessels of the cortex in which both large and small vessels contained knotted and wavy masses of elastic tissue. The large vessels showed many reduplications of internal elastic membranes.

Glands of Internal Secretion: The pituitary gland appeared to be atrophied, and was covered by a thick diaphragma sella. Microscopically the anterior lobe was seen to be surrounded by a thickened capsule composed of white fibrous tissue containing many newly formed vessels. The supporting tissues through the anterior lobe were enormously increased and the pars intermedia was partially replaced by connective tissues. In some portions of the gland the acini were large and filled with proliferating cells while in others atrophic changes were predominating with acidophilic cells in abundance. Only a small amount of colloid was present and the posterior lobe showed a general atrophy of its substance and some congestion.

The adrenals were small, pale, thin, and presented a terminal liquefaction of the medulla. The cortex exhibited a few pale yellow cortical hypertrophies. Microscopically the capsules were thickened and ramified into the upper two zones of the cortex, which showed a disorganized architecture with extreme fatty alterations of cells. The remains of the medullary portions contained masses of lymphocyte infiltrations and brown pigmentation.

The thyroid gland was small, firm and pale with sections showing large traversing bands of connective tissue, and a reduction of colloid substance. The isthmus was absent. Microscopical examinations revealed a dense fibrous tissue stroma in which there were many accumulations of thyroid epithelial cells. The colloid was reduced to about one-third the average amount and the acini were small and often occluded by densely stained cells, which had lost their normal vesicular appearing nuclei. All blood vessels were thickened and many were arteriosclerotic with calcium infiltrations.

Discussion.—In most instances of the progressive muscular dystrophies it is rather difficult to make a sharp differentiation into one of the more or less classical types, as there is usually some overlapping of symptoms and pathological features. In cases like the one under consideration where complete family and early personal histories are unavailable the task is still more ponderous.

As the patient was quite positive of the absence of other cases in his family line, and as the history of syphilis was rather vague and not borne out by subsequent laboratory findings, one is perhaps justified in assuming an etiology of personal endogenic factors.

While some of the following features are common in other types, the sum total of the facts listed below seems to indicate a position in the group of spinal forms described by Aran and Duchenne about the middle of the last century.

1. No other case in family history.
2. A member of the working class of society.
3. Atrophy began at 25 years, in peripheral muscles with gradual extension and with painful fibrillary contractions. No pseudohypertrophies were recorded.
4. Gradual impairment of sensations of touch and pain, tendon reflexes gradually lost, and positive Rhomberg.
5. Duration of condition over 40 years with muscles (excepting those of the neck), extremely atrophic; helpless and bedridden, but with internal organs functioning fairly well, involuntary muscles normal and spincters in good condition until death.
6. Progressive sclerotic atrophy of neuron cells of brain and spinal cord, advanced degeneration of sensory spinal tracts, miliary gliosis of spinal cord, degeneration of the peripheral nerve trunks and extreme atrophy and destruction of muscle fibers of the extremities and trunk.

The associated mental developments in this case are of particular interest as fairly early in his disease he developed vague ideas of persecution to account for his condition of unknown etiology, and in this connection he hallucinated abusive voices. Later he became very irritable and abusive with ever-changing, unsystematized delusions of persecution, with an occasional partial disorientation: simultaneously with this progress he gradually developed a lack of appreciation of his physical condition.

He resented being disturbed and as the muscular atrophy and resulting helplessness progressed he compensated completely by developing delusions of grandeur, and accepted only such aid as was absolutely necessary or was forced upon him. Gradually his beforementioned fleeting delusions became somewhat more definitely systematized and centered about the President on whom he placed the blame of being kept at the institution.

The frequent identification of himself with Christ, the greatest moralist, alternating with the idea that he was Captain Kidd, the king of robbers, is significant when one considers the patient's former profession and his prevailing belief that he was held for the purpose of torture (Crucifixion).

The utilization of the last remaining mechanism for bodily protection is also well illustrated as when the patient was completely incapable of any bodily motion (with the exception of the neck and head) he protected himself (often efficiently) from his supposed persecutors by a vile vocabulary and by expectoration.

Finally, compensation as a mental development in the face of extreme physical defect was seen when in an absolutely helpless condition this man demanded his clothing and his discharge from the hospital, that he might go out to make a living.

Action of Large Doses of Caffeine on the Abstainer.—Wedemeyer found in experimenting on subjects who had been weaned from coffee and tea during the war that the average drinker of these substances has more or less of acquired tolerance. With several exceptions these men showed marked excitement and signs of intoxication with progressive doses; and when 6 to 10 grams were taken daily over a period of 4 to 6 weeks the mental processes were notably weakened.—*Schweizerische medizinische Wochenschrift.*

THE USE OF POTASSIUM NITRATE IN OSTEOMYELITIS AND OTHER CHRONIC INFECTIONS.

PRELIMINARY REPORT.

By J. RAWSON PENNINGTON, M.D., F.A.C.S.,

CHICAGO, ILL.

My interest in this agent was revived about ten years ago, when a lady came to the office of my brother and myself, stating that she had a method for the local treatment of rheumatism with ox-gall and wanted us to try it out. She disclosed her formula; this — among other things — contained nitrate of potash. Finding there was some benefit in the remedy, we suggested making it known; she objected to publication; whereupon we dropped it.

In September, 1919, I accidentally met a Baltimorean, who claimed he had evolved a treatment for pyogenic infections which, he believed, was efficacious and wished to give it to the profession, but would first like to have his claims verified. He also claimed to use a "double synthetic salt—aluminum and potassium nitrate."

Three colleagues were induced to engage in a demonstration with me, which we continued for approximately nine months, treating over 200 patients. At the end of this time, not being satisfied the effect was due to the "double salt," I declined to join in the publication of a final report.

My informant stated he got the idea from an English engraver, and in October, 1920, being in

FIG. 1 (Left).—Taken December 15, 1920. Showing swollen condition of leg and foot and the ulcer exposing the tibia.
FIG. 2 (Right).—Eight days later, showing beginning of pustular formation from potassium nitrate.

Baltimore on other business, I found F. D. Pridham, the engraver in question. Soon after he sent me his affidavit, in which he testified he had used the method successfully on himself over twenty years before for osteomyelitis of the scapula, and on many patients since with like results.

During this demonstration period, my brother, Dr. W. D. Pennington, independently treated osteomyelitis and other infections, using in some in-

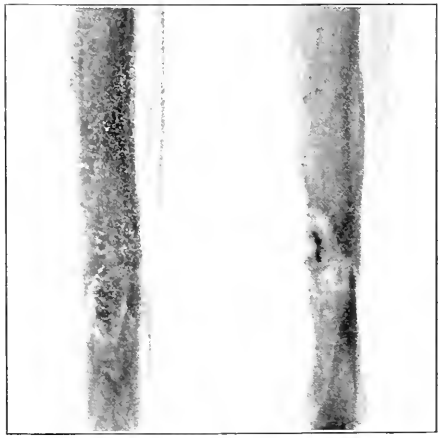

FIG. 3 (Left).—Anteroposterior radiogram (December 14, 1920) Showing worm-eaten condition of both bones, and large necrotic area at junction of lower and middle thirds.
FIG. 4 (Right).—Lateral radiogram, showing complete fracture of tibia.

stances the nitrate of potassium alone in about the same percentage as that of the "double salt"; in others, mixed with boric acid. The latter combination was made particularly because of the claims made for boric acid in osteomyelitis by Dr. A. J. Ochsner, and the reports by Professor Kahlenberg of the University of Wisconsin.

Upon my return from Baltimore I resigned from the combination and, with the aid of Dr. T. W. Blachley, began treating pyogenic infections with the nitrate alone, or combined with one or more of the following—boric acid, sulphate of magnesium, nitrate of aluminum, etc. The results obtained thus far are apparently the same or better than those by the use of the alleged "double salt"; moreover, the modifying agents may either be omitted or added to the nitrate in any proportions indicated. I am confirmed in my belief as to the preponderating effect of the nitrate by the analysis at the A. M. A. Chemical Laboratory, which showed 97.5 per cent. of potassium, and only 2.5 per cent. of the aluminum-nitrate.

The solution of potassium nitrate is applied through a dressing of rolled oats, which, in addition to being cheap and non-irritating, has considerable absorptive power. The salt is mixed with the oats and to this combination is added hot sufficient water to reduce it to a poultice-like mass. (The dose is governed by the reaction desired and ranges from 10 to 60 grains to the ounce of oats.) The poultice is spread on the affected area to the thickness of about 3/16 inch, then covered with oiled silk, paraffin paper, rubber dam, etc., and over this a bandage. Or the waterproof material can be cut to the desired size, placed between a double layer of gauze, and

the mass spread on this, then applied to the part. (The waterproof material is important, for the mixture must not be allowed to get dry.)

By aid of the *x*-ray plate and by palpation of the soft tissues the affected area is approximately

Fig. 5 (Left).—Taken July 20, 1921. Showing sequestra are separating, leaving a clean-cut edge of tibia.
Fig. 6 (Right).—Anteroposterior radiogram, showing bridging by a late callus (synostosis).

mapped out; the dressing of oats and nitrate is then applied well beyond the boundaries of the area involved. If there are any old sinuses which have for years been discharging a thin, serous fluid, in a few hours up to a day or so, this is replaced by creamy pus in incredible quantities. So far the skin is unchanged, but in two or three days or so small papules appear, and in about the same length of time develop into vesicles and then pustules, recalling the course of smallpox. The pustules at length rupture and continue to discharge pus, with the formation of new pustules from time to time, until the affection subsides. Each case is a law unto itself as regards change of dressing; a few may go two or three days, most need redressing every 24 hours, some occasionally several times a day. The lessening of the infection is shown by the change in the discharge—which, from thick pus, finally becomes thin and serous before ceasing.

This method upsets all our preconceived ideas and previous knowledge gained either by reading or observation. For instance, the nitrate is not antiseptic; when added to a culture the growth is greater than the control. Again, the number of bacteria in the discharge increases in a few days' time, instead of decreasing, as we would naturally suppose. In the next place it seems to influence favorably infection of many kinds. We have treated cases due to different staphylococci, streptococci, some bacilli (typhoid and tubercle), and even syphilis. A few cancers, as well, were relieved, but there, of course, as in syphilis, merely through the action on the accompanying infection, not the primary disease processes.

It is not clear as yet exactly what the action of the nitrate is; there is no effect at all when it is used for control on the opposite sound limb, nor does it have any when applied on gauze by itself without admixture with oats. In fact, if it is merely used on gauze over the affected side, the vesicles and pustules disappear completely. Various suggestions have been made as to the action—that the results are due to chemiotaxis, to liberation of oxygen in the nascent state, by the nitrate being decomposed into a nitrite, etc. But until further and precise information is to be had we may surmise there is osmosis with the skin as a dialyzer, and the reaction produced by contact with the diseased tissues sets up an enormous outpouring of lymph carrying with it the germs. There is an acute reaction on the part of the tissues, manifested by an enormous amount of leucocytosis and phagocytosis of a similar nature to that following an acute infection, and due probably to the toxins generated by the rapid increase of the germs. In addition there is evidently active dilatation and hyperemia of the blood vessels.

One of the many curious features is that treatment of the sinuses directly by injection of the nitrate has no influence whatever; it seems to need to be in contact with a larger territory. There is no reaction beyond the diseased area in the bones or soft tissues. Suppose we have a focus in the mid portion only of a long bone, and the dressing is applied for the whole length of the bone, no changes in the skin will occur and no pustules form beyond the area involved.

The improvement in a comparatively short time is startling. One of the first things noted is that pain disappears—on account of the relief of tension afforded by the profuse discharge of pus and serum. The skin and other soft parts regain

Fig. 7 (Left).—Taken October 20, 1921. Sequestra have been removed and synostosis is progressing.
Fig. 8 (Right).—Anteroposterior radiogram showing the progress of regeneration.

their flexibility for the same reason; muscles and tendons are freed, and if a joint capsule is thickened and infiltrated from infection near by, motion is restored and that reasonably soon.

It is nothing unusual for patients, especially

children, who have been bedridden—or, at least, crippled in their movements—to get about in a gratifyingly prompt time.

In the bones, of course, the effects are not so rapid, though in a few weeks the cloudy medulla shown by the *x*-rays clears up. In some the sequestrum has apparently disappeared, no trace being visible in the radiogram; in others it made its way out and was discharged.

So far as the nature of the affections is concerned, most of them naturally have been examples of osteomyelitis of long standing—from 1 or 2 up to 25 or more years' duration. A number had been operated on time and again, one, for example, by no less a man than J. B. Murphy and that 24 times! We have treated numerous examples of phlegmonous and other inflammations of the soft parts. One of the largest old-fashioned carbuncles I ever saw, located in the upper thigh, was successfully treated by my brother, Dr. W. D. Pennington, with the nitrate.

This being merely a preliminary report, I shall not occupy space with case reports, pausing only long enough to cite a typical one in brief:

Mr. R. W., aged 49, consulted me December 15, 1920, for a discharging sinus in right leg, pain, and gangrenous odor. While playing football 18 or 20 years ago he was kicked on shin about junction of lower and middle thirds; this was followed by pain and swelling which eventually subsided. Some 5 or 6 years later had pain in heel and ankle of same leg, was treated for "rheumatism." Finally openings appeared over the instep and inner side of ankle, but closed in due time. Three years ago pain followed by swelling and another opening appeared at site of original injury, and has discharged pus ever since. Leg has been growing weaker and weaker, until about a week previous, while he was walking along, it gave way; this was followed by quite a little pain. The odor, which is gangrenous in character, has been gradually growing worse for several weeks.

I found the limb swollen, hard, and dark purple. An ulcer about the size of a half-dollar is seen at the junction between the middle and lower thirds, exposing the tibia, which is black in color. Crepitus is easily obtained. The blackish bone seems to be the distal fragment of the tibia, as moving the foot moves this portion but not the bone above it. (The color may be due to the application of medicine which he has been using). There are a number of lymph nodes in the groin, one or two the size of a guinea hen's egg. The general appearance is septic.

December 15. Radiogram the same day showed a fractured tibia, and osteomyelitis of both bones. Placed on nitrate treatment at once.

For several weeks was dressed at the office every day in the afternoon, applying the dressing himself at home in the morning. As the condition improved it became possible for him to continue at his business, and occasionally be out of town for several days at a time, applying his own dressings.

July 10, 1921. Patient has been out on road for previous month. Moving foot moves distal fragment.

August 6. The black sequestrum seems to be loose, and was removed on the 11th.

The infection caused a pathological fracture. The applications of the nitrate of potash alone checked this destructive action, greatly increased the outflow of pus, and started up osteogenesis.

August 17, 1921. Patient now walking without aid of crutch.

In conclusion it may naturally be asked what advantage this plan possesses over the one by operation. To this I would reply, recurrences are common after mechanical removal of infected areas; so far I have never seen this with the nitrate, the cases remain healed. Next, such patients as decline any "cutting," as they term it, will submit to this plan. Again, other patients, who, for financial or other reasons, cannot undertake a stay in the hospital, may avail themselves of this ambulatory method. Finally, this nonoperative procedure is at the command of any member of the profession, whether he is accustomed to surgery or not; in fact, it is practicable in any village, hamlet, or even dwelling.

21 NORTH STATE STREET

OBSERVATIONS OF THE WHISPERED VOICE SOUND IN LUNG CONDITIONS OTHER THAN PNEUMONIA.*

BY HENRY H. LISSNER, M.D., F.A.C.P.

LOS ANGELES, CAL.

ON September 6, 1919, I published, in the MEDICAL RECORD, a paper entitled "The Whispered Voice Sound, an Aid to Early Diagnosis of Pneumonic Consolidation." At that time I called attention to the fact that in pneumonia, before the other evidences of consolidation were present, such as dullness on percussion, bronchial breathing, rales, etc., it was possible, by the aid of a stethoscope and the whispered voice, to pick out patches of consolidation, and by this means diagnose pneumonia much earlier than had previously been done.

Having followed the application of this particular sign for the past two years in conditions other than pneumonia, I am now prepared to discuss the value and accuracy of this method and to present the advantages it has over the other, and more frequently used diagnostic clinical methods. Its application is not only of value in conditions without consolidation, such as bronchitis, emphysema, and asthma, but it also has a definite place in the diagnosis of tuberculosis, with or without cavity formation, malignancy of the lung, pneumothorax, empyema, and other lung conditions.

Just a word with reference to the technique: The patient is stripped to the waist and is examined preferably in a sitting posture, as a comparison of the two sides is more accurate than when in a recumbent position. If too sick to sit up, the patient is turned on either side, as far as possible lying on the chest and abdomen, if the respiration is not interfered with too greatly. The instruction is then given to whisper "one, two, three," with a definite staccato, using only the one inspiration for the whisper of the three words, and taking a breath again at the end of each phonation. The whisper should also be accomplished during expiration and never during inspiration.

The character of the sound as heard in pneumonia is particularly close to the ear, sharply defined and clean-cut, and is best compared to the sound that is heard by placing the bell of the stethoscope over the occipital protuberance and having the individual whisper "one, two, three." The bony skull conducts the sound of the voice and gives a clear, audible repetition of the sound as heard in pneumonia.

In bronchitis the whispered voice sound is not

*Read before the Clinical and Pathological Society of Los Angeles, Cal.

increased, but is heard over the normal areas which have already been pointed out, *i.e.* at the hylus of the lung, bifurcation of the trachea, and over the upper part of the spine of the scapula, as a distant rush of air which might be likened to a soft blowing

Fig. 1.—Shows on the right side (the reader's left) pneumothorax, collapsed lung, pneumopericardium, complete obliteration of the heart shadow, and tuberculosis on the left side involving the upper two lobes and compensatory emphysema of the lower lobe.

sound, such as might be heard when an attempt to whistle is made without much air pressure behind the effort.

In bronchiectasis the character of the whispered voice depends entirely upon the degree of dilatation of the bronchi, and the amount of infiltration around them. The sound is therefore rather closer to the ear, louder and more distinct than in simple lung infiltration, and presents along the course of the bronchus or over an interspace, areas of definite clearness of voice sounds with areas of normal voice sounds interspersed. Of course, in a condition of this sort the personal equation must play an important part, as the response of the whispered voice as heard must depend entirely on the degree of dilatation of the bronchus, or its approach to definite cavity formation. Over a cavity the sound is loud, tubular in character, and is practically of the same type, nature, and intensity as would be heard if one were listening over the trachea.

In tuberculous infiltration the sound is not as clear or close to the ear as it is in pneumonia, but, on the other hand, it is very much more distinct by comparison than the sound which is heard over normal areas, depending entirely on the amount of infiltration and relative consolidation present. Where there is a cavity beside the infiltration, the sound again varies as to the size of the cavity and, as above mentioned, where the voice sounds are distinctly heard and there is an absence of sound in other areas along the same interspace one can almost with certainty make the diagnosis of dilated bronchi or early bronchiectasis. As the size of the cavity increases the transmission of the voice is increased until it is heard clearly and distinctly as if it was heard over the trachea itself. The pitch is higher, closer to the ear, and more rasping in character compared to the staccato heard in consolidation.

In pleurisy with effusion or empyema, either general or walled off, the sound is absent over the effusion but increased above the effusion over the compressed lung. This observation holds true whether the effusion is in the general pleural cavity or localized between the lobes. Here, again, the intensity of the sound and its character must be differentiated between that which is heard in simple lung infiltration and the natural gradation between this and true consolidation. The differential diagnosis is, therefore, very clearly brought out between the dullness due to consolidation and the dullness due to fluid, since in consolidation the whispered voice sound is increased over the dull area, while in the presence of fluid the whispered voice sound is absent over the dull area but is increased above it.

In spontaneous pneumothorax there is an absence of the sound over the area on the chest wall which is not in contact with lung tissue. The findings are practically the same as in pleuritic effusion. This fact is rather in striking contrast with the auscultatory sounds which can be heard over the entire chest wall anteriorly and posteriorly even though the lung is collapsed, but the voice sound is not transmitted. This is due to the fact that the collapsed lung expands and recollapses during every respiration, but on whispering, the lung not being in contact with the chest wall, the path of conductivity is not complete.

In emphysema and chronic asthma the sound is diminished, and if the increase of the whispered voice sound is heard in an asthmatic patient, particularly below the clavicle, this would be very suggestive of a fibroid change in the lung due to tuberculosis.

In carcinoma, depending upon the extent of involvement, the sound is increased but not to the extent as is heard in pneumonic consolidation. The

Fig. 2.—Shows complete pneumothorax and collapsed lung on the right side (the reader's left), tuberculosis of the left lung, and in place of the compensatory emphysema of the lower left side there is a compression of the lower left lobe. The heart shadow is also barely visible on the left side.

reason for this is obvious as the infiltration of the carcinomatous tissue is not as pronounced as the consolidation of pneumonia.

I will report one case of diagnostic significance and interest, also on account of its rarity.

Miss R. C. was referred to me for an acute pulmonary hemorrhage on December 7, 1920. No extensive examination was made at the time of the first visit but the patient was sent to the hospital.

December 9.—The patient had had two slight hemorrhages since first seen. On examination the left lung showed considerable moisture and bubbling, particularly at the end of inspiration. There was a pleuropericardial friction rub. There was also cardiorespiratory murmur, accompanied by a sound resembling the dropping of water at the end of deep inspiration, which was heard in the left axilla and over the precordia. The whispered voice sound was lost over the left side in the axilla and the base posteriorly, except that it was increased for a slight area at the hylus and extending out toward the axillary line, where it was again lost. The heart rate was 140. There was a presystolic murmur. The heart tones were distant and there was a suggestion of a churning sound over the precordia.

On the 10th of December there was hyperresonance over the left lung and the area of cardiac dullness was not obtained because of the hyperresonant note, which extended from the left to the right side. The right side showed dullness from the apex to the middle lobe anteriorly, and there was moisture over the right upper lobe. The whispered voice sounds were increased on the right side anteriorly over the upper lobe, and posteriorly over the upper and middle lobes uniformly. Over the lower lobe posteriorly the voice sound was not increased but was apparently more normal in type and character.

On the 24th of January there was hyperresonance bordering on tympany over the precordia. I was unable to percuss the border of the heart because of the lack of the line of demarcation between the cardiac dullness and resonance on deep inspiration. At the level of the fourth interspace there was a pericardial friction rub, a pleuropericardial friction and a metallic tinkling sound with an apparent rush of air into the pericardium at the end of deep inspiration. The heart rate was 140. The tinkling sound was about synchronous with the heart beat and not with the respiration as it was when the patient was first seen.

The clinical interpretation is as follows:

There was a partial spontaneous pneumothorax on the left side, pleuropericardial adhesions, pneumopericardium and pulmonary tuberculosis of the right upper and middle lobes, with compensatory emphysema of the lower right lobe.

Following a severe coughing spell the patient thought that she felt the heart move or change position. She explained that for a while she felt the heart pulsate in the left axilla and then shift toward the mid-line.

An examination of the chest showed the left side to be more bulging than it had been at the previous examination. The breast was tense over that side and there was less respiratory excursion. The percussion note was tympanitic or a high hyperresonance. The area of cardiac dullness was eliminated. The splash sound or the metallic tinkling, which was heard on other occasions, was absent at this time. There was a complete absence of whispered voice sounds over the left side, and there was an increase of whispered voice sounds posteriorly just at the root of the lung. On the right side the whispered voice sounds were markedly increased throughout the entire lung. It would seem that another collapse had taken place, which had pushed the heart over to the right side and had compressed the lower portion of the right lung which had been previously emphysematous.

The accompanying *x*-ray pictures verify the above clinical findings.

From the study of this case, in conjunction with others, I have gathered the impression that the clinical diagnosis carefully carried out, with attention to detailed physical examination, is of greater value than a laboratory diagnosis in which the clinical findings are not considered. In this day and age, where the laboratory is accessible to nearly every clinician, whether it is in his own office or in some outside special pathological laboratory, the great tendency is to look to it for the diagnosis before a definite clinical picture has been formed. The laboratory should not be used as a short-cut to diagnosis, nor should it be considered in the light of "the practice of medicine made easy," but should be called upon only for the verification of, or as an aid to the arriving at a proper diagnosis. In other words, the laboratory should be considered as a means to an end rather than the end itself. I am fully convinced that in the careful working out of a clinical examination the errors in diagnosis will be reduced to a minimum, and it is with the development of such diagnostic points as I have tried to show here, that greater aids to more accurate clinical work may be anticipated.

HYPERNEPHROMA OF THE STERNUM.

BY JAMES A. MacLEOD, M.D., M.R.C.S. Eng., F.A.C.S.

BUFFALO, N. Y.

ATTENDING SURGEON, BUFFALO CITY HOSPITAL; CONSULTING SURGEON, BUFFALO HOMEOPATHIC HOSPITAL.

AND

WILLIAM F. JACOBS, M.D.

BUFFALO, N. Y.

ATTENDING PATHOLOGIST, BUFFALO CITY HOSPITAL.

A HYPERNEPHROMA is a tumor which arises from an aberrant piece of suprarenal tissue. It runs a malignant course, and, as in other forms of malignancy, secondary growths occur in various

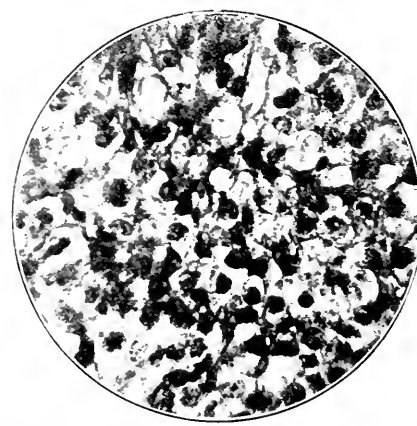

FIG. 1.—Microphotograph of section taken from sternal tumor of the first case; one-eighth objective, 800 magnifications.

parts of the body, most commonly in the long bones; the primary tumor, however, may remain quiescent for many years before it takes on its malignant characteristics. While it is regarded as a primary tumor of the kidney, we see no reason why it should not arise from an aberrant piece of suprarenal tissue situated elsewhere.

Hedblom in a recent contribution entitled "Tumors of Chest Wall," reported 213 cases of tumors of the chest wall collected from the Mayo Clinic and the literature; of these cases 46 were tumors of the sternum. We can find no special

mention in the literature of hypernephroma occurring in the sternum. We have had two such cases, one in the service of Dr. MacLeod at the Buffalo City Hospital, and the other in the private practice of Dr. Jacobs. In order that these cases may be added to the literature we give a brief summary of each. It may be of interest to note that at one time or other each of these cases was regarded as an aneurysm of the aorta; in the second case, up to the time of the postmortem examination.

Case I.—C. S., a male, 54 years of age, was admitted to the Buffalo City Hospital on May 31, 1921, with the diagnosis of aneurysm of the aorta. Through an interpreter the following history was obtained: Up to six months prior to his admission to the hospital the patient was a big husky man. At that time a swelling appeared upon the sternum; this was incised at another hospital and pus was said to have been obtained. During the following six months he steadily lost weight, dyspnea appeared, and he suffered pain and stiffness in the left side of his neck. Examination of the patient on admission showed that he was emaciated; his temperature was 98° F.; there was a tumor of the sternum, at the junction of the manubrium and gladiolus;

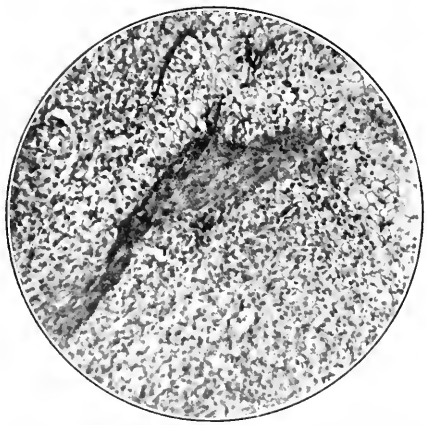

Fig. 2.—Microphotograph of section taken from sternal tumor of the first case; two-thirds objective, 250 magnifications

the tumor was hard, irregular and nodular on its surface; it was about the size and shape of half of an orange, overlapped the sides of the sternum, and was deeply fixed to it; the skin was adherent to its superficial surface at the site of an old scar; the tumor pulsated, but the pulsation was of the transmitted type rather than the expansile. Examination of the urine was negative and his renal function was 36 per cent. in two hours. Examination of the blood showed that the urea nitrogen was 17.8; the blood count showed 11,600 leucocytes with 76 per cent. polynuclear cells; the Wassermann tests were negative. Examination of the spinal fluid was negative. The lungs and abdomen were negative. Examination of the heart showed that the apex impulse was displaced upwards and to the left; there was a musical murmur just below the sternal tumor, and a rough systolic blow in the aortic area; the pulse was of the collapsing type, al though no aortic diastolic murmur was heard; the two radial pulses were equal in volume, time and tension. The *x*-ray examination by Dr. Clifford Orr showed that the sternal tumor arose from the sternum itself and extended anteriorly and posteriorly; that there were old sclerotic changes in the chest, but no evidence of any active disease.

A tentative diagnosis of sarcoma of the sternum was made and a small piece, somewhat friable and grayish in color, was removed for microscopical examination. Microscopically the tissue was found to be very cellular, with very little stroma; the cell type was large with a clear protoplasm, and a deeply strained nucleus centrally placed; the shape of the cells was at times somewhat rectangular, at times roughly columnar or cubiodal; there were, also, some small hemorrhages in areas that seemed to be breaking down. A diagnosis of hypernephroma was made and the study of the case continued to determine, if possible, a renal tumor as the primary source.

The patient was referred to the genitourinary department for an investigation of the kidneys. Dr. Frederick J. Parmenter reported that he found no evidence of hypernephroma by the cystoscope, but the sediment from the urine obtained from the right kidney, when sent to the pathological department, was found to be very cellular, with plaques of cells corresponding morphologically in size and shape to those found in the specimen removed from the sternum. An *x*-ray examination by Dr. Orr showed a cloudiness of the right kidney. These further studies suggested a renal involvement, either a metastasis or a primary growth.

The man's condition did not warrant any operative interference and consequently he was treated along palliative lines. His condition steadily retrogressed and he died on July 6, 1921. Unfortunately the patient's relatives refused a post mortem examination and so the latter laboratory work could not be substantiated.

Case II.—This case may be summarized as follows: J. B., a male, 69 years of age, was admitted to another hospital complaining of pain and swelling in the sternum, cough, backache and weakness of the legs. His family and personal histories were negative. Six months prior to his admission to the hospital he noticed for the first time a swelling of the sternum; it was then about the size of a hickory nut. Thereafter the swelling increased in size rapidly, and on admission to the hospital it occupied the entire sternum below the suprasternal notch, the dimensions being three and one-half by six inches. His general condition was good. The Wassermann tests were negative. The sternum was evidently eroded. The tumor had an expansile pulsation and he was discharged in about three weeks with a diagnosis of aortic aneurysm. About three weeks later he died and one of us was called upon to make a post mortem examination for an assumed case of aortic aneurysm. The body was then found to be emaciated. The sternal mass proved to be entirely sternal; it was cylindrical in shape, its long diameter being six and one-half inches, its anteroposterior diameter three and three-quarter inches. A tumor about the size of a chestnut was found in the left kidney. The gross appearance of the two tumors was characteristic; the texture was somewhat friable, the color was "cafe au lait," and there were hemorrhagic areas throughout. Microscopically the cells were large with clear protoplasm and deeply stained nuclei centrally placed; the cells were somewhat rectangular, columnar or cuboidal in shape, and were arranged in irregular collections, at times in aveoli; the stroma was very limited and irregularly disposed of.

288 Linwood Avenue.

CARCINOMA OF THE LUNG: REPORT OF A CASE.

By G. A. FRIEDMAN, M.D.

New York

Recent literature on the subject seems to point to the fact that pulmonary carcinoma is not as rare as some believe. A correct diagnosis of the condition can frequently be made provided one keeps in mind the possibility of such occurrence. Fishberg emphasized this in a recent paper. However, it is almost impossible to be sure that the carcinomatous growth in the lungs is primary, unless a complete autopsy has been made. The report of this case was prompted by the fact that the diagnosis of carcinoma was established beyond doubt

by the sections of a metastatic nodule in the skin.

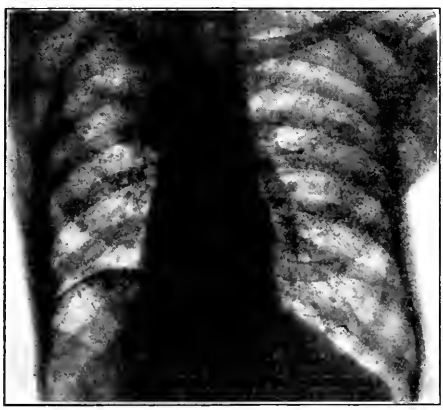
K. S., male, aged fifty-five, married, admitted to the Beth David Hospital, February 19, 1920; died, March 3, 1920. Chief complaint: Great weakness, pain over the precordium and epigastrium, dyspnea and hoarseness.

Past history: Negative, except that he had scarlet fever as a child.

Personal history: Heavy smoker. Venereal infection denied.

Present illness: Began seven weeks before admission, when he noticed that he was getting weak. Two weeks after onset he became hoarse, dyspneic, and cyanosed. Has lost about 10 pounds in weight.

Physical examination: Emaciated, rather cachectic looking, dyspnea, cyanotic, and hoarse. Eyes and ears, negative. Teeth in poor condition; tongue coated; odor from mouth. Neck, negative. Chest, thin; diminished expension on left side. Lungs, dullness on left side from apex to third rib, anteriorly, and to spine of scapula posteriorly; diminished voice and respiration over entire left lung; no rales. Heart, negative. Abdomen, negative. Extremities, negative. Rectal examination, negative. Skin, nodule in the second right interspace, about three inches from the sternum, freely movable, not tender, about the size of a pea. Nodule in the left buttock, freely movable, about the size of a hazelnut, not tender, fluctuating. Spine, negative.



Roentgenogram showing consolidation in the upper part of the lung and increased mediastinal density.

Joints, negative. Temperature, occasional rise; highest, 102°. Respiration between 20 and 28. Pulse between 72 and 110.

Laboratory findings: Wassermann, negative. Stools, negative for occult blood and parasites. Urine, negative. Blood, white cells, 15,200; polynuclears, 43 per cent.; lymphocytes, 53 per cent.; eosinophiles, 1 per cent.; transition, 1 per cent. Marked secondary anemia. Larynx, examination unsatisfactory because patient intolerant. Gastric analysis: nothing obtained on fasting stomach after preliminary test supper. Test breakfast: 120 c.c. obtained; free HCl, 7; total acidity, 39; no lactic acid; no Boas-Oppler bacilli.

X-ray examination of the stomach showed very slight irregularity of the stomach which might be due to adhesions; moderate retention after 5 hours. Chest, distinct consolidation occupying the upper left lung. This consolidation is suggestive of tuberculosis. There is a distinct area of increased density in the upper part of the mediastinum, apparently continuous with above mentioned area. This is suggestive of a neoplasm.

The nodule excised from skin showed alveolar carcinoma.

1006 Park Avenue.

X-RAY DERMATITIS.

By Mary L. H. Arnold Snow, M.D.,

New York.

(*Concluded from page* 931.)

Chronic dermatitis is found principally among *x*-ray operators. It is usually the result of a series of exposures and used to occur frequently when the hand was used often in connection with the fluoroscopic work. The skin is well described by Codman.[7] In the less pronounced forms it appears "chapped and roughened, and the normal markings are destroyed, at the knuckles the folds of skin are swollen and stiff, while between there is a peculiar dotting resembling small capillary hemorrhage." It is characterized by hyperkeratosis. The skin is apt to be drier than normal. Atrophic changes are seen. Hyperkeratosis is usually found about the knuckles as with keratoses. These keratoses may disappear and then reappear, degenerating or healing, according to the condition or treatment. They are apt to become epitheliomatous. Tousey[29] believes "the hyperkeratosis which is a characteristic effect upon the skin is an exaggeration of the normal degeneration through which epithelial cells pass." Telangiectasis may also be present.

In dermatitis with ulcerations, representative of a fourth degree dermatitis, the condition may last for years. When we consider the results observed after a series of rayings for uterine fibroid, as shown by an examination months after the last treatment, it may emphasize the tendency of the continued effect of the rays over a long period of time.

It is thought that the skin absorbs rays equivalent to those absorbed by 3/5 of a mm. of aluminum. The *action of the x-ray* may be stimulating or inhibitive, according to factors governing its potentiality. The rays at first have a contractile effect which later, owing to lowered metabolic activity, is followed by a vasodilatation, including a vasodilatation of the cutaneous arterioles and cutaneous capillaries. At times the blood serum effuses through the walls of the capillaries and edema is present, as noted in the reported case of tonsillar raying. It lowers oxygenation and blood pressure possibly by affecting the activating substance or hormone of some or one of the internal secretions. "Surgical[6] and traumatic 'shock' reduces the epinephrin content of the glands to only a fraction (8 per cent.) of their normal amounts." (Corbett) It is thought possible that "suprarenal deficiency may thus be a factor in the debility and prostration of acute infections," as such a deficiency is present.[24] "The locus of action[22] of epinephrin so far as the circulatory system is concerned is mainly on the small blood vessels, constricting them and thus raising the peripheral resistance." Epinephrin acts only on blood vessels that are supplied by the sympathetic nervous system. It is thought by Gradinescu[35] that "the suprarenal secretion controls metabolism by controlling the permeability of the blood capillaries, and hence the exchange between the blood and the tissues. He claims that adrenal deficiency causes the blood plasma to pass into the tissue spaces and the body cavities to such an extent that the concentration of blood corpuscles be-

comes twice as great as the normal. The viscosity of such blood is obviously great and the circulation correspondingly impeded." Cannon[34] associated "diminished clotting time of the blood" as one of the adaptations partly dependent "on the presence of excess of epinephrin in the blood." This is a factor for consideration in connection with the action of remedial agents in *x*-ray dermatitis.

Scholtz[37] found after extensive experiments that: "1. *X*-rays influence especially or exclusively the cellular elements of the skin. They degenerate; while the connective tissue, the elastic tissue, musculature and cartilage are changed only in a slight degree, as a result of the cellular degeneration and the inflammatory reaction consequent to it. 2. Degeneration affects the epithelial cells in the highest degree, and to a less extent the cells of the glands, the vessels, the muscular tissue, and the connective tissue. 3. The degenerative appearances are of various kinds, and affect both the protoplasm and nuclei. 4. As soon as the degeneration of the cells has reached a certain point, an inflammatory reaction appears, which manifests itself in a marked dilatation of the vessels, with gathering leucocytes and marked emigration of the blood-corpuscles. When greater cell regeneration occurs as a result of stronger exposure collections of leucocytes press into a mass of degenerated cells and accomplish their further destruction. The changes in the large and small vessels are apparently of great importance as affects the further development and slow healing of the ulcerations." There is stimulation, then degeneration, a necrotic process being present, followed later by regenerative processes or a continuance of the necrotic area if a dermatitis be severe.

There is a great question as to the cause of *x*-ray phenomena. Some believe these have an electrical origin, others that they are directly due to the *x*-rays as demonstrated by Elihu Thomson, cited by Pusey and Caldwell,[38] who believe the histologic findings favor a theory that the changes "are due to a form of energy of high actinic power to which the tissue cells are susceptible," and that they do not resemble ordinary inflammatory changes. From the time of exposure until a dermatitis occurs, preceding the ulcer, there is no "distinct increase in urinary nitrogen,"[37] although a lethal dose of hard *x*-rays from a Coolidge tube "increased" the elimination of urinary nitrogen on the day following the *x*-ray exposure and remained high until death, often an increase of 50 to 100 per cent. above the normal base line. "The blood nonprotein nitrogen commonly shows a marked increase (twice normal) on the day before death and triples on the day of death." Beumer[38] rayed the suprarenals in a case of diabetes with general improvement following, it being "most pronounced in the drop of the sugar content of the blood."

Ehrmann[39] explains the erythema and pigment formation from *x*-rays as follows. The ray acts on the capillaries and causes hyperemia, simultaneously there is an outflow of plasma containing hemoglobin in solution, which gives the reddish tinge to the skin. After awhile the coloring matter "in the interstitial spaces of the tissues breaks down into gloden yellow hemosiderin," resulting in the yellowish brown skin until absorbed. If many melanoblasts, there is an abundance of material, and through excitation by the *x*-ray, a large quantity of melanin is formed, which causes a "sepia brown skin." The iron of the blood[40] "under stimulation by hard rays gives out an abundant *very soft* radiance—true specific secondary rays—which are intensely active within a very limited range."

According to Block[41] "the normal as well as the pathological pigmentation of the skin is produced by the epithelium of the stratum germinativum in deep pigmentation, also by the superjacent cells of the stratum spinosum, also by the deep layer of the cells of the hair follicle and of the hair papilla. Under abnormal conditions the cells become active and there is more active pigment formation—the formation of the melanin pigment occurs in the protoplasm of the cell." He explains that "there exists in the cells of normally pigmented skin an oxidizing enzyme and upon the relative amount of this oxidizing enzyme depends the reaction to a stimulus such as light." Hence may be explained the variations in the degree of pigmentation produced by the action of rays of light on the skin of different individuals. Some believe "the epithelial cell of the stratum germinativum forms the pigment," others that "the pigment is formed in these chromatophore cells of mesoblastic origin." Those regarding chromatophores as pigment carriers obtaining the pigment from the epithelial cells or melanoblasts "to carry it away along the lymphatics" observe that chromatophores are not found "in non-pigmented scars," A. Ch. Hollande[42] states "that cells of mesoblastic origin in insects can form melanin in their protoplasm. Under the influence of light, owing to the presence of chromagenic melanogen and a tyrosinase enzyme, granules of melanin are formed in the vacuoles. Subsequently the melanin leaves the phagocyte, passes away in the blood, and is taken up by other cells." A. Richards[43] called attention to the effect of the *x*-ray on enzymes. It may stimulate or inhibit their activity according to the strength of applications. With, Kissmeyer, and Wassermann,[44] in a study of pigmentation during life, and With and Wassermann, in a study of pigmentation after death, concluded "It is derived from the epidermis and is produced by the oxidation of 'dopa,' or dioyphenylalanin in life, carried out by a ferment in the cells of the basal layer." May not the action of the ray stimulating pigment formation be due to its action on the ferment?

Sajous[45] believes melanin is formed "when oxidizing substance, *i.e.* the albuminous portion of hemoglobin, has become vicariously oxidized in any organ (hematoidin) or in the skin—the constituent of oxidizing substance which becomes oxidized when melanin is formed is the adrenal secretion."

The erythema petechiæ may be due to the lowered catabolic activity and the vasodilatation which is followed by an accumulated waste in the blood which might even result in skin disturbances as blisters or ulcerations.

In considering the cause of the itching accompanying an *x*-ray dermatitis, it is interesting to note some conclusions by Dr. Frederick G. Harris[46] in the correlation of various experimental and clinical observations in a study of eczema. "Since the vasomotor changes in eczema are so intimately asso-

ciated with itching and it has been shown that epinephrin prevents them both and is a normal constituent of the blood, it requires no great imagination to suppose that a deficiency of the active epinephrin in the blood could account for the increased sensitiveness of the skin on the one hand and the itching on the other. Might not the epinephrin act on the cutaneous reflex arc? The rather frequent association of eczema, low blood pressure and asthma, all conditions counteracted by epinephrin, is suggestive, to say the least." The same author experimented with anti-trypsin, having in mind the trypsin-antitrypsin balance causing skin reactions as he thought of the possibility "that chemical irritants penetrating to the rete mucosum could absorb antitrypsin, resulting in a solution of the epithelial cells and vesicle formation."[47] A study of the effects in the cause and cure of conditions in *x*-ray dermatitis along these lines would be of interest.

An erythema dose needs no attention except suspension of *x*-ray treatment until it has subsided. In regard to the second, third, or fourth degrees we have two powerful agents in radiant light and heat from a carbon filament lamp and in the use of the ultra-violet rays, and radium in some of the sequelæ of the fourth degree. In an article entitled "The employment of the Arc Light as a Prevention to X-Ray Dermatitis in the Treatment of Deep-Seated Conditions," Dr. William Benham Snow[48] in 1904 said, "One year's experience in the employment of a thirty-five ampere arc light, projecting parallel rays from a parabolic mirror as provided in a marine searchlight, has demonstrated its great value in preventing *x*-ray dermatitis." He advocated "an arc light of sufficient intensity to produce heat which can be just tolerated over a circle 15 to 20 inches in diameter when the patient is placed 10 feet from the apparatus, *i.e.* with parallel rays thrown against the surface." The same writer notes that in the treatment of *x*-ray dermatitis "No agent is as generally efficient as applications of radiant light and heat—the two conditions dermatitis from radiant light and heat and from the *x*-ray arising from opposite causes, one from excess of stimulation and the other from excess of inhibition." The blood stream absorbs most of the actinic rays.[49] Light acts particularly on inflammation by inducing relaxation and by increasing metabolic processes, assisting elimination, promoting assimulation, and increasing oxidation through heat induction. Freund has aptly said, "Light changes a passive congestion to an active one," which accounts for the changed appearance of an *x*-ray dermatitis after treatment with light. Since then we have treated many cases of *x*-ray dermatitis with radiant light and heat. The carbon filament lamp yields the best results. The applications are for from one-half to one hour and sometimes longer, according to the severity of the case. The lamp should be at such a distance that it may be easily tolerated. If there has been a rupture of the vesicles the wet surface will soon become glazed and the other parts will show a relaxing effect. It alleviates the itching and burning associated with an *x*-ray dermatitis.

The ultraviolet rays are another valuable agent. Their source in the past has been an iron electrode lamp, the electric spark, or an electric arc having an iron-cored electrode. Now we have the tungsten arc and the mercury vapor lamp. It is best to precede the use of the ultraviolet rays by a radiant light treatment to secure an erythematous effect, the more blood, the greater the absorption surface or the greater the quantity to absorb the rays. J. East[50] thinks by this method the iron and sulphur in the blood bring in oxygen and carry out carbonic acid. Margaret A. Cleaves, M.D.,[51] in her work on "Light Energy," long ago noted that ultraviolet frequencies had an affinity for oxygen, and believed the oxidizing action was shown "by the blistering of the skin and bactericidal effect" when ultraviolet light affects the free oxygen on the surfaces of the body. It is known that rarefied air at high altitudes will produce an erythema if tanning hasn't developed—even blistering sometimes occurs. The ultraviolet rays have a peculiar sterilizing effect on bacteria as well as varied chemical, biochemical, physical and physiological effects. They are decidedly bactericidal. Moore[52] demonstrated positively the destruction of streptococci and staphylococci and Plank claims of diphtheria bacteria.

The action of ultraviolet rays offers a wide field for study, one part of which is concerned with its actions on the blood. The blood contains ferments—that are closely connected with immunity questions—proteases, nuclein ferment, lipases, and amylase, as well as an antiferment known by some as "antitrypsin." Clotting occurs by the blood platelets and possibly leucocytes disintegrating and "as a result of which there is shed forth into the plasma a substance called prothrombin which afterwards becomes activated or converted into thrombin," which in turn "attacks a protein present in plasma called fibrinogen, producing from it in threadlike form the insoluble protein, fibrin." Soluble calcium salts and "thromboplastic substances derived from the tissues outside the blood vessels" are necessary requisites. Blood also contains an anticlotting substance, antithrombin. Harris and Hoyt[53] believe that ultraviolet "light is generally highly toxic, even for colorless organisms," and that this is due presumably to photochemical reactions. Their results are "in harmony with the view that the susceptibility of protoplasm to ultraviolet light is conditioned by the aromatic aminoacid radicals of the proteins." Kober's[54] investigations show that "the absorption of aliphatic amino-acids in acid or alkaline solution is only general in the extreme ultraviolet region" and, "with the exception of the aromatic derivatives, phenylalanine and tyrosine and amino-acids, where they are marked, do not show any special absorption, being general in the extreme ultraviolet." In the blood are found amino-acids as alanin, valine, and histidine, and the above conclusions give us cause to believe they are affected by the ultraviolet rays.

It has been shown that "ultraviolet rays change starchy solutions into maltose and dextrin" and also "inulin (dahlia starch) into glucose and levulose."[55] They also change saccharose into glucose and levulose,[56] all of which indicates the promotion of the activity of ferments by ultraviolet rays. They destroy the antitryptic properties of human blood serum,[57] which shows an inhibitory action against an antiferment. A. Chauchard[58] and B. Mazonie claim the rays destroy amylase and invertase (in malt

and yeast) from which it would seem that the rays have an inhibitory action on a ferment, but I consider that the test, since it includes other factors in malt and yeast, bactericidal, the result, cannot be taken as conclusive evidence. H. Agulhon[60] discovered that whether "properties of diastase in solution" were destroyed by the ultraviolet rays depends on their wave length, only waves having wave lengths less than 3,022 Angström units having such effects. Biochemically, according to Maurice Breton,[61] "they do not affect the properties of sera rich in antibodies, but antigens and antibodies no longer fix alexins." They coagulate protoplasm and blood plasma. Ultraviolet rays have the property of making blood coagulate sooner,[62] which undoubtedly makes them so efficacious in the treatment of ulcerated and raw surfaces. Traugott found red corpuscles unaffected. A 10 to 15 minute exposure increases the number of leucocytes and lymphocytes but with a shorter exposure there is a difference between the number of leucocytes in capillary and in venous blood. Blood platelets are also increased in number.

If epinephrin is an element to be considered in the clotting of blood as well as the itching present in *x*-ray dermatitis, it would be an interesting study to learn the effect of the ultraviolet rays on this hormone. Ultraviolet rays may burn as well as the *x*-rays, but as Dr. Plank[63] says, "the latter occludes all blood vessels, both surface and deep, causing destruction, whereas the former destroys only the surface vessels and then only the pathological ones wherein the endothelial cells are more readily proliferated."

In applying the ultraviolet rays due precaution as to protection of the operator and the exposed parts of the patient must be taken as to the reflected rays as well as the direct rays. Brown glasses are best for the eyes.

We used ultraviolet rays in combination with light rays from a 35-amperage arc as early as 1903 in the treatment of *x*-ray dermatitis. In 1904 Dr. Margaret Cleaves[64] noted, "a case giving symptoms of the left labia majora being badly swollen, red hot, sensitive, and complaining of great distress about the vulva and to the left side. A 10-minute exposure to the ultraviolet light energy from the condenser lamp resulted in immediate relief from pain and sensitiveness, with greatly diminished swelling and lessened heat. The following morning the parts were normal and the patient was comfortable." A red skin reacts more quickly than a deeply pigmented skin, as we have often observed in the treatment of cases who have had many *x*-ray exposures. Diesing[65] claims that the pigment of the skin resorbs the ultraviolet, and Weidenreich[66] believes that the pigment and sebum are regulators of heat for the body. Bach,[67] in 1916, reported that Steuermach (Krakau) cured an *x*-ray dermatitis on himself "by subjecting himself once a week to treatment with the Alpine lamp until slight erythema was produced."

We have had excellent results from an air-cooled Burdick lamp. One case of stubborn dermatitis of the epigastric region of the second degree was cured in one treatment. The patient was rayed for a presumably malignant growth. He did not return until fourteen days after the last exposure. Below each breast and over the umbilicus and in the vicinity were ruptured vesicles. The umbilicus was raw and ulcerated in one spot. After a few treatments given with radiant light and heat the ultraviolet rays were applied over the umbilicus for three minutes at a distance of 20 inches. On his return, the umbilicus and the skin around it was healed but the parts beneath each breast were not. One application for five minutes at 15 inches resulted in complete recovery. Not only is it beneficial in acute but chronic dermatitis as well; a single application of one minute, 20 inches distance, gave a physician suffering from chronic dermatitis of the hand such immediate relief that he remarked that he hadn't been able to close his hand like that for more than a year. Dr. Howard Plank[68] reports "such cases as *x*-ray burns and telangiectasis are being treated with these rays with apparent good results." It also has an atrophic effect on hypertrophied tissues. Dr. Chris. Sampson, in discussing "Actinic Rays,"[69] said, "there is nothing like ultraviolet rays for sterilizing an open, foul ulcer or other destructive processes. The *x*-ray dermatoses and ulcers on the hands that have persisted for seventeen years I have seen cleared up by the Kromayer lamp with, in some cases, the addition of diathermy to soften the areas and produce a deeper hyperemia than was possible with the rays alone. You must produce an erythema.

Tousey[70] quotes the cure of "irregular keratoses and fissures (of the palm) remaining after *x*-ray treatment, by three chlorin ionizations." No pigmentation was left. He advocates the daily use of lanolin or cold cream for *x*-ray keratoses to keep them "innocuous." 10 to 20 per cent. salicylic acid, adhesive plaster and avoiding *x*-rays, he claims removes *x*-ray warts, but they are apt to recur. The same author[71] reports that "Holzknecht has cured about 50 cases by the application of hard filtered *x*-rays and an equal number by the gamma rays from radium." The applicator has a coat of 4 mgm. of radium per square cm. of surface. The filters used are 2 mm. silver, 1 mm. aluminum, 1 mm. of copper and a thin layer of cotton. The time was "from 1½ to 8½ hours."

Knox[72] claims that "the curative effect of radium depends in many cases on the Becquerel rays stimulating the connective tissue and producing fibrosis." Roberts thinks "there is reason to suppose that the blood stream is hostile to intrusive epithelium." He suggests the study "of normal epithelium and connective tissue in nutrient media while they are subjected to *x*-rays or radium or both, or to the influence of endocrine secretions or of various toxins," and concludes, "The phenomena observed in the chorionic trophoblast, in chorion epithelioma, in *x*-ray dermatitis and cancer, as well as in the experimental growth of the two tissues liable to malignancy, support the view of this relationship between epithelium and connective tissue, and suggest that a morbid condition of the pituitary may be a fundamental cause of the disease. Radium element acts like emanation.[73] It "increases tissue oxidation and the activity of ferments; it has a strong bactericidal action, though it slightly diminishes phagocytosis." There are hemoglobin increase, leucocytic diminution and "dilatation of the peripheral blood vessels."

For the keratoses, radium has been found most satisfactory. Formerly, and even now, by some the cautery and the curette are used for keratoses, and excision and skin grafting for ulcers. Fulguration is also sometimes used, but the use of radium plaques in skillful hands will result in the eradication of these annoying *x*-ray sequelæ.

We have used the *x*-ray for twenty years and have never had a dermatitis of the third degree even in the early days of the use of the *x*-ray when unfiltered and indefinitely measured doses were given. The *x*-rays, with their varying range of activity from stimulation to inhibition, stimulant if in small doses at long intervals of time, distance being a factor, inhibitant if the strength, time and distance are sufficiently increased, inhibitant even to the death of a part—demand skill and knowledge on the part of the operator for the production of best results with least harm. Particularly is this so now that the newer *x*-ray therapy uses such heavy doses when the removal of one filter from a filtration of 10 mm. may cause an "incurable" dermatitis as one operator noted.

When the factors as heretofore enumerated as to the various stages of *x*-ray dermatitis are considered, the intolerable itching, burning, atrophy, tension, raw and bleeding surfaces, ulceration with accompanying bodily discomfiture, urgent demand is made for alleviation and cure. In the past, ointments and drug therapy have been practically failures. Our experience during the past two decades has demonstrated the value of reflected radiant light and heat. Too much stress cannot be laid on its great therapeutic value. It relieves the itching, possibly through the induction of vasomotor changes. It increases the circulatory activity in the passively congested tissue, inducing first relaxation then contraction. It promotes oxygenation and the metabolic activity of all processes, hastening the regeneration of tissue in need of repair. It relieves tension and has a sedative effect generally. It overcomes atrophy through its effect on the circulation, which also hastens the removal of waste products, and possibly increases locally the supply of epinephrin, a hormone. The patient improves physically as well as locally. The fact is the light from the carbon filament lamp is best because of its richness in infra-red and yellow rays representative of heat and maximum absorptive region by the blood. We never have found the tungsten filament lamp of so great appreciable value in the treatment of *x*-ray dermatitis. Our experience with ultraviolet rays in the treatment of *x*-ray dermatitis had been of comparatively recent date. We have had excellent results. The greater the influence of an agent for stimulation, the more marked its effect when employed as an inhibitant. It is thus with the ultraviolet rays, so great care must be taken in their application. Time and distance demand special consideration. Radium we also found of value.

Radiant light and heat, ultraviolet rays and the gamma rays of radium, we have proved them all agents to be considered in the treatment of *x*-ray dermatitis. Time and investigation will probably demonstrate that each has a certain selective field. Thus far in our experience radiant light and heat will conquer the reactions from the *x*-ray with the exception of the hyperkeratosis, the ultraviolet rays will do what radiant light accomplishes, but they have also a marked atrophic effect on hypertrophic tissue as does radium, but radium to this date is limited in the treatment of *x*-ray dermatitis to the keratoses. The *x*-ray in its induction and the above-mentioned agents in its cure call for further study as to definite action chemically and physiochemically. Clinically many questions have been answered, but further study and greater consideration of idiosyncrasy and susceptibility will tend to lessen the frequency of *x*-ray dermatitis and hasten recovery. From the foregoing facts we claim recognition in the treatment of *x*-ray dermatitis, of radiant light and heat, except for keratoses; ultraviolet rays in general; and radium and ultraviolet rays in the treatment of keratoses:

1. Because of the great demand for a remedial agent with which to combat the dire effects of an *x*-ray dermatitis.

2. Because these agents have been proven to counteract the effects of the *x*-ray as above enumerated.

3. Beause they not only inhibit the degenerative process, but institute regenerative processes, especially is this true of the radiant light and heat and of the ultraviolet rays.

4. Because radiant light and heat and ultraviolet rays have a systemic effect which raises the patient's resistive powers and assists in the re-establishment of his normal physical condition.

Considering the exigency of *x*-ray dermatitis, its annoyances, sequelæ, and difficulty of treatment, too great stress cannot be laid on a plea for a trial of these physical agents, with due regard to technique, especially radiant light and heat and the ultraviolet rays, when clinically and technically their action is a known asset. All who are called upon to treat *x*-ray dermatitis, whether acute or chronic, will find in them remedial agents satisfactory alike to physician and patient.

THE NEGLECT OF THE NARCOTIC DRUG PROBLEM.

By ERNEST S. BISHOP, M.D., F.A.C.P.,

NEW YORK.

In dealing with the narcotic drug situation or problem I shall not discuss the great mass of generally unappreciated and neglected scientific and other literature which has been accumulating for over a hundred years on this subject—lost sight of in the frenzied competition between various panaceas and "treatments" and "cures," medical, medico-commercial, medico-political, legislative, administrative, uplift, "reform," "control," and otherwise.

I shall not go into the psychological or the physiological or the pathological or the clinical or the therapeutic or the research considerations and controversies. I shall not attempt to condense into abbreviated finalities the generally unappreciated, unrecognized, and undigested mass of accumulated record and experience, scientific and lay, upon the many angles and problems of what has become, or, rather, been made into, a most bitterly controversial subject.

I shall simply try to portray what seem to be some of the generally unsuspected but really fundamental features and facts which constitute the present narcotic drug situation—which has arisen from the neglect of the narcotic drug problem—the chaos which has come to exist and in the persistence of which all discussion of special issues and problems merely adds fuel to the flames of discord and bickering and recrimination, and postpones real progress and final remedy and practical control.

For over two years the lay press has been pretty constantly portraying various spectacular, criminal, or morbid angles or manifestations of what is popularly called the "drug evil." For two years it and the medical press have reflected the conflicts over the medical and pseudomedical issues and false issues of the drug situation. For two years administration has been divided as to the meaning and interpretation of laws and the proper bases and policies of administration and application. For two years have gone on in various parts of the country, and especially in New York State, almost constant struggles before the legislatures in most bitter and factional and partisan contests for the passage of bills of various and absolutely conflicting presentations and opinions and interests. For two years the honest doctor and druggist and the innocent type of addicted sick have been in constant uncertainty, shuttlecocks batted from one policy or interpretation or opinion to another.

For two years the types of individuals included among the hundreds of thousands of honest and innocent citizens who have contracted opiate addiction through ignorance or through necessary or unavoidable therapeutics, some of them on the battlefields of France, have been worried and frightened and harassed to the great detriment of their personal, social, and economic status and efficiency, and have been more and more abandoned by the medical profession and medical institutions.

For two years, from all accounts, the criminal and illicit and "underworld" smuggling and peddling of what are popularly and loosely described as "habit-forming" drugs have been growing by leaps and bounds and becoming more and more organized. For two years, as a result of this stimulated criminal and illicit traffic and its commercial extension, the condition known as drug addiction has been spreading among the youth and ignorant and curious and adventurous of this country.

For two years has been going on between medical or pseudomedical factions, and somewhat within the medical profession, a most violent exacerbation of one of the most bitter controversies and conflicts between opposing theories and factions and interests as to the character of this condition of drug addiction, and the proper or desired lines of treatment of or attitude toward its clinical aspects and sufferers—a controversy which has at times threatened to split medical organizations and has displayed some of the most bitter personalities and personal attacks to be found in medical history.

The whole situation presents a picture of one of the most confusing muddles imaginable—a muddle of controversy and of personal and group opinion—a strife of influence of power and of propaganda and publicity—a veritable chaos of internal struggle in the midst of which all the evils of the situation are increasing, and real control and study and constructive remedy are aborted and postponed.

This situation had its origins prior to two years ago, breaking out into periodical flare-ups of greater or less intensity and extent. The last two years, however, have seen an aggravation of it which has extended into circles previously untouched. The controversy has extended even into departments of government, and rocked the machinery of legislation, has violently disturbed the lay press, and reached into many avenues and places outside of the medical profession. This is, of course, natural and unavoidable, since in many of its manifestations and connections it touches upon nearly every angle of human life or activity.

In spite of all this and of its open record and dissemination, the situation itself and the multitude of problems connected with it are to-day as much unsettled as, if not more unsettled than ever. There is scarcely a topic or issue in it which has not been made the subject of violent disagreement and upon which cannot be found opposing statements, statistics, and reports.

About the only undisputed fact in the present situation is the rapid extension of criminal and illicit "underworld" smuggling and peddling, and the increase of addiction through its commercial extension and the activities of its agents, and, as claimed by many, through the unfortunate and curiosity-stimulating publicity given to morbid and spectacular incidentals and fungous features which have fastened themselves upon and obscured the real narcotic drug problem.

This rapid extension of underworld smuggling and peddling and the increase of addiction among the youthful and curious and adventurous, and some of the defective, was foretold and warned against in open legislative hearing and elsewhere nearly two years ago, if the then apparently settled plans and policies which had been recently worked out and generally agreed upon after thorough study and investigation should be upset and discarded and the experience of the preceding six years ignored.

One of the most forceful warnings of this sort came in the form of a protest from the New York State Association of Magistrates against what was known as the Cotillo Bill, then before the legislature and having among its proponents those who seemed likely to dominate the opinion of recently appointed officials, medical and lay. This protest from the judges stated that this bill and the ideas behind it "would utterly destroy the constructive work of five years," would "threaten public calamity," that "the underworld and illicit traffic would find a new and appalling impetus and violations of the criminal law as to both narcotics and incidental crimes vastly increased." All of these had markedly decreased under the policies adopted as a result of experience and study during the previous two years.

Discussion to the same effect as that from the judges is to be found in the report from the Legislative Committee of the Medical Society of New York State at its last annual convention, and in many other places.

Ample justification for these warnings seems to be found in the present situation, in which smuggling and peddling of narcotic drugs and the criminality associated with and growing out of such smuggling and peddling have already completely overshadowed all other manifestations and increased to proportions formerly undreamed of, increasing the census of "underworld"-created addiction cases far beyond any previous proportion.

This recognized increase has been attributed to all sorts of extrinsic causes and influences by those promoting the ideas and theories behind the Cotillo-Smith or Fearon-Smith Bill type of legislation and interpretation. The older workers and students, however, men of longer experience and familiar with previous similar and similarly created situations, find its origin intrinsic and along the lines of explanation embodied in the protest of the judges against the Cotillo Bill and the criticisms of it contained in the report of the committee on legislation of the New York State Medical Society.

It is significant that the introducer of the Cotillo Bill did not push it further for passage after he heard the facts and arguments arrayed against it and its ideas.

It is also an interesting fact that, although the bill itself was defeated, it has since been shown in open record that the ideas behind the bill, and probably the influence of the proponents of the bill itself, prevailed in actual administration of existing law through the medium of administrative rules and regulations which, as has also been pointed out by high judicial authority, were contrary to the intents and purposes of that existing law and acted practically to repeal it. The report of the Legislative Committee at the last convention of the New York State Medical Society warns of the same attempt being made to influence the interpretation and administration of the Federal (Harrison) Narcotic Act.

So that we have had in New York State the interesting anomaly of existing statute interpreted and administered to give it the force and effect of its rejected opposite. This state of affairs has, however, provided a practical tryout for the ideas expressed in and behind that rejected opposite—something which would seem to have been unnecessary after the revelations of the two years' investigation of the New York State Legislative Investigation Committee under Senator Whitney, and the several years of study of the narcotic committee of the judges of the State under the chairmanship of Judge Collins, and the experience of the former Federal administrators, and the mass of available literature and record, medical, and otherwise.

To one at all familiar with this mass of data there should be no difficulty in tracing the real origin and machinery of the developments of the past two years. It is clear that they are directly traceable to newly arisen forces which, through the incident of political or medico-political appointment, about two and a half years ago obtained positions of unusual command of publicity and influence, and announcement in which they unfortunately ignored the experience of the past and its literature and record, and reintroduced ideas and administrative experiments which had hitherto repeatedly and calamitously failed or were obviously unsound.

The fundamental origin of the present situation and conditions connected with it lies in the neglect of the real issues and problems of the narcotic drug situation—the issues and problems and needs which were pointed out and made basis for constructive work and plan by practical consensus of administrative, scientific, judicial, and other experience and opinion two and a half years ago.

Perhaps the really basic problem of the whole situation lies in the failure as yet fully to understand and generally to appreciate the effects of the continued action of narcotic or opiate drugs upon the human body, one of the most generally neglected fields of medical and scientific study and investigation.

Senator Whitney, at the conclusion of a speech in which he outlined to a medical audience the purposes and plans originally laid down but never followed for the then newly created New York State Department of Drug Control, put into a nutshell the findings of his investigation and of those who had cooperated with it, medical and official and lay. In speaking of narcotic drug addiction and of the situation, he concluded with the words, "*The cause of which is ignorance, the results of which are misery, and the remedy for which is education.*"

It is the neglect to recognize the needs expressed behind this statement which is largely responsible for the possibility of continuance of the real evils of the situation, and of the bitter strife and persistence of recurring panaceas and formularized remedies, medical, pseudomedical, politicomedical, legislative, administrative, and otherwise, which have chased each other with confusing and kaleidoscopic rapidity through legislative halls, through administrative considerations, through medical and lay press to the utter distraction from the constructive work of the preceding years and the possible constructive work of the present. It is also this same neglect which has left us in present confusion and without generally recognized foundation for constructive work for the future.

The fact of the matter is that the fundamental and basic problems of the narcotic situation have received always very little attention during times of such strife and controversy as we have been going through. In distracting and mud-slinging controversy and at times personal attack over various incidentals, "we have left undone the things which we ought to have done"—and "we have done the things which," previous experience should have taught us, "we ought not to have done."

We have played with phrases and panaceas and "Morrison's Pills" and formularized statements and remedies, and in the heat of bitter and often personal conflict and controversy over them have

for the period of this warfare left untouched the basic problems of science and medicine, as well as public health education and study and research; but without these there can be no solution or efficient machinery for any constructive remedy, and without them chaos and misery and injustice have come to prevail.

In our quarrels over panaceas and phrases we have not only driven out the constructive foundations and plans for remedy, but we have driven in the now dominating factor in the situation, one of the most horrible productions and exploitations of human misery ever known. We have fostered the market for the wares of the underworld drug smuggler and peddler, and, through allowing the general ignorance of physical narcotic effect to continue, have permitted its extension through the same nefarious channels of traffic in the needs of human flesh and its ills.

Three years ago or more the preliminary report of the Whitney investigation of the New York State Legislature attributed the extension and growth of this smuggling and peddling traffic to conditions in administration reacting upon the medical profession in a situation for which it found itself entirely unprepared. Today it finds itself as much unprepared as it was then and far more discouraged and confused—the usual result when bickering and quarreling take the place of cooperative, honest endeavor, and when factional strife replaces effort at mutual understanding and tolerant interchange of information and experience and ideas, and when lurid or persistent reiteration of morbid or misleading incidentals replaces broad and dispassionate survey and discussion of all available facts.

It is unfortunate that the original purposes and plans of the now abolished New York State Department of Narcotic Drug Control could not have been completely carried out and given a thorough and fair trial.

Its original purposes were to have established one non-partisan office or center or clearing-house for the collection of all available information upon the subject of narcotics and narcotic drug addiction and for the further investigation into the various angles and problems of the subject—for the fostering and encouragement of all possible lines of honest work and study, for the open discussion and correlation of various activities, for the investigation and improvement, where necessary, of conditions in institutions treating these narcotic patients and the betterment of their methods of treatment and results, which had been shown by the investigation to be in many cases largely unsatisfactory; to have instituted as soon as possible a well-equipped and competently and scientifically conducted State institution in which the clinical and scientific problems of this condition could be studied and developed and from which could go out education for the betterment of methods of handling and treatment of these cases (for which betterment a plea is contained in the Report of the Special Committee of the Treasury, June, 1919); and for the institution of measures looking to the proper enforcement of the laws against the frankly recognized evils which had been uncovered.

All of this was aimed at (1) the rational prevention of extension of narcotic drug addiction; (2) the suppression and elimination of the "underworld" and "underground" narcotic traffic and smuggler and peddler; (3) the best possible immediate care of existing sufferers according to their individual personal needs and deserts; (4) the development as rapidly as possible of competent means and methods of treatment for the cure of as many as possible of those already in existence; (5) the protection of the public and the sick against the charlatans and all sorts of incompetents; (6) the spread of non-spectacular information and education concerning this whole subject into all possible places and along all possible lines.

The investigation by the Whitney committee was the outcome of a previous situation parallel and similar to the one existing today on a national scale. It grew out of a similar deadlock between conflicting conceptions and opinions and interests. It worked coincidentally with the special committee of the judges of the State conducting simultaneous study, and it had the cooperation of that committee and of the Federal officials then in office and of the representative bulk of the medical and pharmaceutical professions and of other people legitimately interested in and affected by this situation. Its thousands of pages of transcribed testimony and its reports afford a mass of very valuable material for the study of the present investigator.

Unfortunately, as I have said before, in the upheaval of the war and in the reawakening of violent controversies over partisan issues, and in the advent of administrators who were apparently unfamiliar with the work of the Committee of Investigation and the original plans for the conduct of the commission, its real purposes and plans were never carried out.

It was unfortunate, for in such plans and constructive lines of broad approach (whether carried on under a commission or otherwise, most of the older and more experienced workers and students and the older administrators saw the earliest solution of the narcotic drug problem and the earliest remedy and control of the narcotic drug situation, and the elimination of the two chief exploiters of its victims, the camp-followers and scavengers of its neglected needs and of its illicit opportunities and of its controversies and battlefields, the vendor or promoter of the fake "cure" and the "underworld" smuggler and peddler of narcotic drugs.

There is a great amount of real work that needs to be done, work in scientific study and therapeutics and administration and practical control. How can any of it be competently done until there is a general and widely recognized and agreed foundation of real knowledge? The earliest possible obtaining of this is the great need of the present situation, caused by the neglect of the narcotic drug problem. We should have had enough of formularized remedies and panaceas. The only slogan should be tolerant cooperation and hard work through every honest agency. All else has failed.

New York, December 3, 1921.

THE MOTOR DISTURBANCES OF SYRINGOMYELIA.

THE motor disturbances in syringomyelia comprise the symptoms of anterior polyomyelitis and usually are first made manifest by muscular weakness—of the upper limbs most frequently. The hands become clumsy and are quickly fatigued. These patients complain almost constantly of numbness, tingling, and sometimes peculiar sensations of glacial cold or burning. Then after a variable lapse of time one is struck by the emaciation of the hands which is accompanied at first by a decrease of the muscular strength which can be verified with the dynamometer, and progressively increases until functional impotence ensues. Atrophy of certain muscles or groups of muscles will be noted, this atrophy often commencing in the thenar eminence. Muscular atrophy is an almost constant symptom of syringomyelia and generally is localized from the onset and almost exclusively in the upper limbs, especially the small muscles of the hands. Then the ulnar group of the forearm becomes involved, the topography of the atrophy corresponding to the territory of the eighth cervical and first dorsal pairs. The consecutive deformities are the same as those observed in progressive muscular atrophy, and although usually the atrophied muscles are innervated by different nerves, the predominance of the atrophy or even its exclusive localization in muscles supplied by the same nerve has occasionally been met with. In these circumstances the atrophy and paralysis are systematized. But this systematization is not, strictly speaking, absolute, and Déjerine and Thomas maintain that the topography of the atrophy is always radicular and is never exclusively limited to the domain of a single peripheral nerve.

When the muscular atrophy involves both upper limbs the same muscles on both sides are usually, but not always, involved, so that the hands may assume different attitudes as time goes on. Finally, during the greatest part of the evolution, the atrophy may be limited to one upper limb—unilateral syringomyelia—in which case the disturbances of sensibility exist on the atrophied side. The atrophy follows an ascending evolution passing from the hand to the forearm and later to the arm and shoulder, but this ascending evolution is not always so regular and after the hand the pectoralis, deltoid, and other muscles of the shoulder may become involved, the muscles of the forearm and arm being more or less completely passed over. The atrophy then extends to the muscles of the back, the intercostals, and those of the abdominal parietes, and lastly to the lower limbs. Here also many irregularities of evolution may be noted, the atrophy sometimes passing from the upper to the lower limbs without involving the trunk. Extension of the atrophy to the lower limbs and trunk is far from being as frequent as restriction to the upper limbs. The distribution of the atrophy offers great variations. The muscles of the lower limbs most frequently atrophied are those of the calf, the adductors of the thigh, and extensors of the foot.

In its ascending progress the atrophy does not always respect the muscles of the neck and head and may involve the trapezius, scalenus, and sternomastoid. Death is sometimes caused by paralysis of the intercostals and diaphragm. Instead of beginning in the muscles of the hands the atrophy may first attack the shoulder muscles, thus simulating the scapulohumeral type of progressive atrophic myopathy. In these circumstances the atrophy is limited to the domain of the fifth and sixth anterior cervical roots. More exceptionally, the atrophy progresses symmetrically and rapidly, like amyotrophic lateral sclerosis. The majority of observers attribute a segmentary arrangement to syringomyelitic muscular atrophy; extending from the periphery toward the roots it involves larger and larger segments—first the hand, then the forearm, arm, and shoulder. On careful examination it is easy to see that this socalled segmentary distribution really does not exist and that in syringomyelia, as in hematomyelia, the topography of the atrophy is radicular—the scapulo-humeral type at its onset is quite striking in this respect. The paralysis is not always exactly proportionate with the atrophy and frequently it is more marked than might be supposed from the state of the muscles.

The atrophy does not involve an entire muscle at once, the fasciculi often being attacked separately in the same muscle; this fascicular atrophy is more frequently observed in the deltoid. Fibrillary jerks are frequent, not to say constant, and are an early sign, but may last for months or years. They are more numerous and easy to see in muscles undergoing atrophy after prolonged exertion or when the patient is exposed to cold. The atrophy and twitchings may be concealed by the fat when this is well developed, and when the fibrous tissue takes on considerable development in symmetrical atrophy of the deltoids the resemblance to myopathic atrophies may be very great. Idiomuscular contraction is exaggerated but is slow and paretic. The electric reactions are

weak or absent, according to the muscle; the reaction of degeneration—total or partial—exists when the atrophy is undergoing evolution.

Besides muscular atrophy, other motor disturbances exist, such as paralysis with or without contracture, tremor, and various phenomena of excitation. Besides sudden hemiplegic, monoplegic, or paraplegic paralyses, which are rare and rather complications than symptoms of syringomyelia—supposed by some to be due to hemorrhage or intramedullary edema—paresis of the lower limbs with contracture is rather frequent; but syringomyelia with contracture of the lower or all four limbs should be regarded as a special form of the affection. Tremor has been observed, especially in the fingers. It does not occur during rest and walking does not provoke it. A simple mechanical stimulus causes it to appear. Other spasmodic phenomena have been observed and as far back as 1892 Critzman (Thesis, Paris, 1892) described a clinical type of syringomyelia that he called the lateral amyotrophic sclerotic type. Cases of spasmodic tabetic syringomyelia have also been recorded. Briefly, observers have noted spasmodic phenomena in this affection, a symptomatology recalling that of spasmodic tabes dorsalis, multiple sclerosis, and lateral amyotrophic sclerosis, but the symptomatic picture of involuntary movements in syringomyelia has only comparatively recently been studied.

RADIUM IN NON-MALIGNANT DISEASE.

RADIUM, undoubtedly, in spite of a recent pronouncement, has its chief sphere of usefulness in the treatment of malignant disease, either by itself or in conjunction with or as an adjunct to operation. Although the therapeutic and perhaps even curative value of radium is mainly witnessed in maladies of a malignant nature, good results have followed its employment in non-malignant conditions. In a paper read by Dr. W. H. B. Aikins of Toronto at the meeting of the Ontario Medical Association, and published in the *Medical Press and Circular*, October 19, 1921, attention is directed to the use of radium in non-malignant disease. Aikins has done a good deal of work with this agent in cases of splenic leucemia, and a report of the results has been drawn up by Dr. F. A. Clarkson of Toronto. This report bears out the following contentions: From the many hundreds of cases recorded in the literature nothing can be more certain than that radium will bring about a remission in a patient with splenic leucemia who has not been treated previously. Within 48 hours many of the unpleasant symptoms of this incurable disease will be ameliorated. The appetite returns and sleep is restored. In a few days the dreadful weakness so characteristic of the malady is greatly improved and many patients are able to return to their work for a time. The change in the blood picture is most marked. Within a few weeks the leucocytes will fall from 500,000 or more to normal, while the spleen will shrink to its usual size. Unfortunately these changes so rapidly and so painlessly brought about are only temporary. When a patient is treated the second time the results are not so marked, and after a time radium seems to lose its effect. The results, however, are so satisfactory that one is safe in saying that life has been prolonged and the patient has been rendered much more comfortable. In lymphatic leucemia and in Hodgkin's disease the effects of radium, although not so striking as in splenic anemia, are, on the other hand, sometimes more lasting. Radium has been used with beneficial results in tuberculous adenitis, and Aikins cites several cases from a large number treated by him, in support of this statement. That radium affords specific treatment for certain forms of uterine fibroids is now well established, but Aikins points out that there are some very definite contraindications, such as large fibroids, malignancy, and inflammation of the pelvic organs. Also it must be noted that radium is not always advisable for women under 35 years of age, as there is grave danger of cessation of the menses. Therefore it may be stated that for women over 35, with fibroids not larger than a 3½ to 4 months' pregnancy, radium is the treatment of choice, except in cases when it is contraindicated because of malignancy or pelvic inflammation.

The author is especially enthusiastic with regard to the value of radium in the treatment of toxic goiter. In fact, he is of the opinion that toxic goiter is never a surgical disease, on account of the nervous and heart symptoms and the shock to the system caused by operation. Radium has none of these drawbacks, is simple of application, and Aikins' experience has been that in the majority of cases its effects are quite as satisfactory as those brought about by operation. Its disadvantage is that results are slow to come and therefore a great deal of patience is demanded. Keloids of all kinds are very successfully treated by radiation. It gives splendid results with naevi, and angiomatous naevi, and also with angiomata. Psoriasis and chronic eczema are responsive but require persistent treatment. Warts and simple papillomatous moles soon vanish under radium treatment, but it is safer perhaps not to treat pigmented moles in this way, for while they are removed easily by radium, in certain cases their disturbance may set up a melanesis in the blood which will result in metastases. Lupus erythematosus is generally treated with excellent results. The field of radium therapy in non-malignant disease appears therefore to be fairly wide, and Aikins claims that its use with an accurate knowledge of its powers and limitations is extremely valuable. But it is the potentialities and possibilities of radium which most puzzle those who have studied the subject and are conversant with its use. Treatment by radium is scarcely in its adolescence, but it seems to be advancing rapidly and bids fair to take a leading place among curative and healing agents. Aikins does not unduly praise its therapeutic properties and his paper is a fair

presentation of the position occupied by radium among the many methods for dealing with disease at the present time.

THE EUGENIC MARRIAGE.

PLANS of a far-reaching and drastic nature have been proposed, and indeed made law in some places, for the purpose of ensuring the propagation of a healthy stock, but it cannot be said that they have met with any large meed of success. Although many people both physically and mentally unfit breed children, natural selection is always at work preserving, to a large extent, the best types and eliminating the most defective. Moreover, it is by no means the most physically perfect who ought to survive for the good of the race. Not only are they frequently the least immune to the onslaughts of infection, but the defective physically or, at any rate, those of puny physique, are often endowed with great intellect bordering on genius.

Sir S. Squire Sprigge, editor of the *Lancet*, brought out recently a book* one chapter of which is devoted to a consideration of marriage in which the controversial points are discussed. He believes the time has not yet come when the legalized interference of the medical man in respect of marriage designs would serve practical purposes commensurate with its inconveniences. He holds that marriage may be regarded theoretically as an individual, social, or racial affair, according as the contract has for its essential object the promotion of the happiness of the pair concerned, consolidation in social politics, or the maintenance of the race in good and improving health. But it must be remembered that whatever object any two persons who are marrying may think is their essential one, they must play their part, being married, as factors in present society, and also as factors in the future of the race. If two persons could decide that they would belong to one class, and to one class only, that is that they would marry out of consideration simply to personal happiness, or social convenience, or respect for eugenics, it would be feasible sometimes to assist them with a medical opinion as to whether they were or were not fitted to belong to the particular class selected; but, even so, the difficulties of civilized life might outweigh the advantages of scientific correctness. It is pointed out that too many of the problems of heredity remain as yet unsolved, and too much waste land lies between the territories of physiology and psychology, to make it safe for medicine to prophesy as to the physical or mental health of the offspring of any particular pair. Putting on one side the social difficulties in the way of refusing a marriage certificate unless each of the parties desirous of entering into connubial bonds could produce a health certificate, the question may be fairly asked what taint or inherited predisposition to disease is to constitute a cause for the refusal of a health certificate. As Sir Squire Sprigge remarks, the medical man takes much on himself if he declares that a family history of cancer or tuberculosis is a sufficient cause. Again certain nervous diseases are hereditary, though many marry with a family history of such troubles and have children free from the taints. It goes without saying that the obvious degenerates, the drunkards, the imbeciles, and the syphilitic should not marry, but love laughs at locksmiths, and mates will mate, with sanction of the law or without, as needs must.

The author submits that, in the present state of medical knowledge, no case can be made out for compulsory health certification previous to marriage. In a complicated society like that of Great Britain the legal restrictions would be insuperably difficult to enforce, though younger countries may find the task simpler.

A good deal of stress is laid by the author upon the fact that it is not alone physical suitability that makes for happy marriages. Ignorance or incompatibility of temper may lead to differences of opinion about the management and future of the children which must have an unfortunate effect upon the next generation. He deprecates the institution of any form of medical priestcraft, and holds that the position of independent adviser is a stronger one than that of State certifier, though whether it is as strong today as it was formerly he doubts.

*"Physic and Fiction," by S. Squire Sprigg. Hodder & Stoughton, Ltd., London.

MIXTURE OF RACE AND FACIAL TYPE.

ILLUSIONAL and accidental resemblances constantly occur, even in comparative racial purity, which falsely suggest a mixture of race, perhaps harking back for generations. Men of undoubtedly pure Aryan ancestry occasionally present the oblique eyes of the Mongol, a negroid nose, etc. The individual known as "Chang the Chinese Giant" of circus fame is known to have been a Manxman. When to these purely illusional resemblances there is added actual race blending the problem becomes more complicated. Are certain features in a given subject derived from known alien ancestors or are they explicable by coincidence? Mendelism makes it possible for some individuals of mixed race to escape the features of one parent race altogether, as shown in rare cases where a couple have had a very large number of children. If a white man and black woman could produce a sufficiently large number of children, one or more should be pure white. In the *Upsala Läkareförenings Forhandlingar* for September 1, 1921, xxvi, 5-6, Lundborg writes briefly on individuals of mixed blood studied by him in Sweden—crosses of Swedes with Finns, Jews, Gipsies, Walloons, etc. In the reigning and noble houses of Europe, he says, mixing of different strains has gone on for centuries. As a result, the nominally Alpine types of Central and Eastern Europe occasionally present facial types belonging to the Nordic races. These resemblances, he believes, are not accidental. It is also certain that the *milieu* exerts an influence on the facial type, else many stocks originally Asiatic would not resemble so closely the European races among whom

they have lived for centuries. But there are certain laws in the blending of races whereby certain measurements become definitely modified. The broad face tends on the whole to lose its breadth when crossed with a long-faced race, even if it often crops out in exaggerated form in certain individuals.

An Occupational Form of Pneumonia.

A form of pneumonia which is occupational and dependent on inhalation, while at the same time of bacillary origin, is described in *Journal de médecine et de chirurgie pratiques* for September 10, 1921, cviii., 17. In reality two separate conditions exist, one a pneumoconiosis and the other a frank pneumonia, due to any one of the banal exciters of that disease. The dust in question comes from the slag of phosphoric acid works and is used as a land dressing; and the workmen most exposed to it are the factory hands and those who handle the refuse afterwards, as the teamsters and cultivators. The mortality of these subjects who contract the pneumonia is over one-half of those attacked. The disease develops rapidly and the sputum, while viscid, is not rusty or red, but comparable in appearance to honey. The inhalation of dust is but one predisposing factor. Another is alcoholism, for like all workers in dust these men are habitually thirsty. Exposure may be another, although not mentioned by the author, who is Dr. Monnier of Nantes. At autopsy the lung is found in grey hepatisation, while a diffuse nephritis is present. The author has studied this affection for many years, and as far back as 1899 one of his internes devoted to it his graduation thesis. He is confident that the deadliness of this pneumonia is determined not by the germ but by the inhaled dust. Still in the worst cases he has found the Friedlander pneumobacillus, which is regarded as more deadly than the pneumococcus. A similar occupational pneumonia is said to occur in sandblasters. In the industrial process of dephosphorating calcium phosphate by adding sulphuric acid, the slag, which retains enough phosphorus to be useful as a fertilizer, contains several irritating impurities, and has an acid reaction, sufficient even to make it irritating to the hands.

News of the Week.

Health Education and the Nutrition Class.—Under this title the Bureau of Educational Experiments has published a report giving the results of its three-year experiment with nutrition classes in a New York public school. The experiment was carried out at Public School 64 on East Ninth Street, from February, 1918, to June, 1921. The school offered a fairly homogeneous Jewish population, somewhat removed from the worst slums, though the neighborhood was crowded and unsightly. Dr. William R. Emerson of Boston organized the work and trained the workers. Four hundred and four children took part in the experiment. Of these 104 normal children were studied as "control groups." In addition to the special provision for diagnosis and care of individuals showing defects or morbid conditions, a nutrition class was conducted calling for a daily regime of good eating habits, abundant food, frequent rest, and constant fresh air. The main conclusions derived from the experiment are as follows: "Gain in fitness, as represented by increased weight for height was greatest from September to February. It seems that New York City children in the public schools show a season of maximal weight increase in the fall and early winter. Any attempt to improve a child's weight for height will appear relatively successful if begun at one season of the year, and relatively unsuccessful if begun at another season. Gain in fitness was greatest on the part of the children supposedly well. It was also observed that gain in fitness was greatest on the part of unusually "bright" children. A number of children having intelligence quotients of 125 or over were examined and a larger percentage of underweight was found among them than in any other groups studied, yet under improved conditions they responded better than the others. Except for this group having high intelligence quotients, mental tests failed to reveal any significant difference between the underweight children studied and the normal children of the control groups. The report has been published by E. P. Dutton & Company and makes a volume of 281 pages.

Would Have All Hospitals Admit Students.—In the interests of scientific medicine, Dr. John B. Deaver of Philadelphia has recently suggested that a threefold demand should be made respectively on the hospitals, the Legislature, and the public. Of the hospitals Dr. Deaver demands that without exception they shall open their wards to medical students and that any patient, whether private or not, shall be accessible as a subject for clinics. Of the Legislature, and incidentally of public opinion, Dr. Deaver asks for pathologists an unrestricted right of animal experimentation. By the public Dr. Deaver wants an abandonment of the "silly and selfish sentimentalism" that leads them to deny surgeons the authority to make post mortem examinations. It is vain, Dr. Deaver thinks, to ask for legislative help in this direction until the public has been brought to "a more intelligent attitude."

Hospital Notes.—William Fellowes Morgan, chairman of the Executive Committee of the United Hospital Fund of New York, has issued a statement asking the support of the entire city for the city's hospitals. The goal set for the annual hospital collection this year is $1,000,000.

A square block between Webster, Summit, and Orchard streets and Central Avenue, has been purchased as a site for an addition to the Providence Hospital, Alameda, Cal.

An informal campaign is being conducted to raise a fund of $50,000 for the Children's Hospital, Denver, Col., for the purpose of erecting an additional building on property adjoining the present hospital buildings.

A new seven-story nurses' home and training school is being erected by the Sacred Heart Hospital at Spokane, Wash.

The building committee of the Meriden (Conn.) Hospital announces that it is ready to let a contract for a new $375,000 hospital. The contract

is to be placed at once and work will be started as soon as possible. The hospital will provide more than one hundred beds.

Plans have been drawn for the new hospital of the Sisters of St. Francis in Santa Barbara, Cal., to cost when equipped about $200,000. The new structure is to be erected on the site of the old hospital.

Dr. Elmer E. Eddy of Redwood, N. Y., has been appointed village health officer at Alexandria Bay to fill the position left vacant by the resignation of Dr. C. M. Lukens.

Dr. S. C. Hollis has been appointed by the Town Board to the position of health officer and registrar of vital statistics of the town of Adams, N. Y., for a term of four years beginning January 1, 1922.

Dr. C. Floyd Haviland has resigned the position of superintendent of the Connecticut State Hospital. Dr. Roy L. Leak has been appointed assistant superintendent in his stead.

Gifts and Bequests.—Adolph Lewisohn has given the pathological laboratory of Mt. Sinai Hospital, New York, a gift of $150,000, to be known as the Adolph Lewisohn Foundation.

By the will of the late Emma Louise Lennig of Philadelphia the sum of $5,000 is bequeathed to the Children's Seashore Home at Atlantic City.

Physicians Ask Veto of Anti-Beer Bill.—The New York Medical Association has sent a petition to President Harding petitioning him to veto the bill supplementary to the Volstead act. A portion of the petition reads as follows: "This prayer is inspired by the usurpation of Congress, under Section 2 of this act of the therapeutic right of the physician to prescribe a legitimate medicinal agent in any form than that dictated by Congress. This is a sacrifice of principle to expediency as well as a form of inhibition never before attempted in the history of legislative government elsewhere throughout the civilized world. There is nothing in the history of the practice of medicine in this country to justify this control by Congress, neither is there anything inherent in the powers, the traditions or the knowledge of Congress to justify this assumption of the suzerainity over the profession of medicine as practiced in the United States." The letter was framed by Dr. John P. Davin, who also directs the attention of the President to a letter in the *Journal of the American Medical Association* signed by nine physicians in this State, condemning the measure, and quotes a part of this letter.

Institute in Public Health Nursing.—The New York State Department of Health will conduct a two weeks' Institute in Public Health Nursing in Albany from November 28 to December 10, for the benefit of nurses of the State who have not previously had an opportunity to receive such instruction. All phases of public health nursing from both the technical and administrative standpoints will be presented. The course will consist of lectures and field work. Upon the completion of the course an examination will be given. The only expense will be that for travel and maintenance as no fee is required. For further information address Charles C. Duryee, M.D., State Department of Health, Albany, N. Y.

The New York State Society of Industrial Medicine will hold its second annual meeting at the Onondaga Hotel in Syracuse on December 10. A symposium on "Industrial Medicine and Its Relation to the New York State Compensation Law" will be held. Among those who will participate in the symposium will be Dr. Henry D. Sayer, State Industrial Commissioner; Dr. A. C. Snell, Rochester; Dr. George E. Tucker, Hartford, Conn.; Dr. William Mehl, Buffalo; Dr. Glen Smith, Schenectady, and Dr. Riley M. Little of the State Department of Education.

The Radiological Society of North America will hold its annual meeting at the Hotel Sherman, Chicago, December 7, 8, and 9, 1921, under the presidency of Dr. Alden Williams of Grand Rapids, Mich.

Medical Society Elections. — THE JEFFERSON COUNTY (N. Y.) MEDICAL SOCIETY, at its annual meeting held in Watertown, Nov. 10, 1921, elected the following officers for the ensuing year: *President*, Dr. F. G. Metzger, Carthage; *Vice-President*, Dr. Murray M. Gardner, Watertown; *Secretary*, Dr. Walter Atkinson; *Treasurer*, Dr. A. H. Allen, Watertown.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK, at its annual meeting held Nov. 28, 1921, elected the following officers for the ensuing year: *President*, Dr. Orrin S. Wightman; *First Vice-President*, Dr. Arthur F. Chace; *Second Vice-President*, Dr. Eugene H. Pool; *Secretary*, Dr. Daniel S. Dougherty; *Assistant Secretary*, Dr. J. Milton Mabbott; *Treasurer*, Dr. James Pedersen; *Assistant Treasurer*, Dr. Ten Eyck Elmendorf; *Censors*' Dr. William P. Healy, Dr. George W. Kosmak, and Dr. Henry H. M. Lyle; *Chairman of Committee on Membership*, Dr. Frederick H. Dillingham; *Chairman of Committee on Legislation*, Dr. Alfred C. Prentice; *Chairman of Committee on Civic Policy*, Dr. Samuel J. Kopetzky.

Obituary Notes.—Dr. EDDY STEARNS HASWELL of Albany, N. Y., died in a local hospital on Nov. 19, at the age of thirty-five years. He was graduated from the Albany Medical College in 1909.

Dr. GEORGE W. H. MOORE of Northport, Wash., a graduate of the University Medical College of Kansas City in 1896, died in a local hospital on Oct. 31, at the age of sixty-four years.

Dr. LOUIS H. HENDRICKSON of New Holland, Pa., a graduate of Hahnemann Medical College and Hospital, Philadelphia, in 1899, died suddenly of heart disease on Nov. 11, at the age of forty-eight years.

Dr. LILLIAN A. BARTOLS, a graduate of the Woman's Medical College in Baltimore in 1901, died at her home in Dorchester, Mass., on Nov. 9, at the age of forty years.

Dr. JOSIAH E. COOPER of Springfield, Ohio, died suddenly of valvular heart disease on Nov. 3, at the age of forty-nine years. He was graduated from the Eclectic Medical College, Cincinnati, in 1896.

Dr. WILLIAM L. CARRISON of Toulon, Ill., died of injuries received when he accidentally fell from a window on Oct. 31. He was a graduate of the College of Physicians and Surgeons, Keokuk, Ia., in 1890, and was fifty-three years of age.

Dr. WILLIAM HITCH, a graduate of Jefferson Medical College, Philadelphia, in 1861, died at his home in Laurel, Del., on Nov. 11, at the age of eighty-four years.

Dr. JOEL DAVIS MADDEN of Ossining, N. Y., a graduate of the New York Homeopathic Medical College in 1876, formerly physician to Sing Sing prison, died on Nov. 18, at the age of seventy years.

Dr. ANDNES M. TALLMADGE of Arkport, N. Y., a graduate of the Chicago College of Medicine and Surgery in 1894, died after a lingering illness on Nov. 9, at the age of seventy-four years.

Dr. JOHN G. SMITH died at his home in Blair, Neb., from a fractured skull, the result of an accident on Nov. 10. He was graduated from the Washington University Medical College, St. Louis, in 1891, and was sixty-two years of age.

Dr. JAMES MILTON SPEAR of Cumberland, Md., died from heart disease on Nov. 17, at the age of seventy-eight years. He was a graduate of Miami Medical College in 1869, and a Civil War veteran.

Dr. JOHN J. FLYNN of Pittsfield, Mass., died in a local hospital following an operation for appendicitis on Nov. 13, at the age of sixty years. He was graduated from Jefferson Medical College in 1869. He was a member of the Western Massachusetts Medical Society and a member of the House of Mercy staff.

Dr. ELLWOOD PATRICK died at West Chester, Pa., on Oct. 29, at the age of sixty-five years. He was graduated from the Medical Department of the University of Pennsylvania in 1880. He was a member of the local school board for many years and its president for several years. He was a member of the Chester County Medical Society and of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Nov. 11, 1921.

Fever Situation in London.—It has been officially announced recently that in view of the grave situation which has arisen with regard to the prevailing London epidemics of scarlet fever and diphtheria, all the available accommodation being practically exhausted, special emergency proposals have been discussed and agreed to. The authorities of the Metropolitan Asylums Board have met Sir George Newman, chief medical officer of the Ministry of Health, and all the London medical officers of health, and it has been agreed: (1) That, forthwith, all applications for the admission of cases of scarlet fever to the Asylums Board's hospitals shall be made, in the first instance, to the medical officer of health, who will select the most necessitous cases and advise the board thereon; and (2) that preference in admitting cases is to be given to the poorest and more crowded districts, and especially to cases coming from homes where there is unemployment. It is thought that the necessity for these special measures will only last a few weeks. At the meeting of the Metropolitan Asylums Board November 5, Mr. Walter Eickhoff, in submitting the report of the Infections' Hospitals Committee, said that from September 4 to November 3, no fewer than 11,500 cases were admitted to the Board's fever hospitals. Of this number 6,500 cases were brought in during October, and the patients on November 5, in round numbers, were 9,500. Cases had come in so quickly, continued Mr. Eickhoff, that although they had made provision for 4,000 more beds than last year, sufficient accommodation could not be found to meet the requirements, and, after conference with the Ministry of Health, and the medical officers, it was decided to adopt a system of selection, preference being given to necessitous cases, and especially to those coming from homes where there was unemployment. There was a larger number of diphtheria cases this year than last year. They were happily now getting over the difficulty. They still had a certain number of beds in hand and they hoped before the Board met again they would be able to revert to the old system of taking in all fever cases, irrespective of circumstances. As a matter of fact, at the time of writing both scarlet fever and diphtheria have increased and the hospitals are not able to cope with the situation. However, cold weather seems to have set in and this change from the warm muggy weather which has prevailed for some time should have a tendency to check the further spread of infection.

The Red Cross League in the Fight Against Disease.—On November 10, last, a special meeting of the delegates to the International Labor Conference being held in Geneva attended a meeting to hear addresses by General Sir Claude Hill, Director General of the League of Red Cross Societies, and Dr. René Sand, Secretary General of that organization, on the work carried on by it in combating disease and spreading a knowledge of hygiene. Sir Claude Hill said in part, that it was not generally realized that the loss of efficient lives in peace time, through preventable causes, far exceeded the losses in war. He pointed out that Federal Public Health Department in Washington estimates at 8,000,000 the number of living Americans who must sooner or later die of tuberculosis, or over 8 per cent. of the total population of the United States. Again, the National Service Department in England found out, that, out of 2,500,000 men between the ages of 18 and 42 only 900,000 were physically fit for active military service, 36 per cent. Finally, the Health Insurance statistics for England showed that the 10,000,000 insured persons lose by disease each year more than 80,000,000 working days, the equivalent of over 250,000 working years.

Dr. René Sand said in part that, in order, first of all, to appreciate the effects of labor, of industrial life, and of excess he would give figures referring to children between the ages of 7 and 15 in England, where for the past twelve years, a really excellent system of school medical inspection had been in force of 7,000,000 children of school age, 1,000,000 were seriously handicapped in their growth and education by physical and mental defects; a second million was totally deprived of education as a result of disease or disablement; so one child out of every three was doomed to ignorance, suffering, and sometimes to early death. Next to show the appalling toll

levied on human life, he would take a small group of people during the first forty years of existence. Take ten young women about to become mothers: Of these only eight would produce a living child. Twenty years later, two of these children would be dead. In another twenty years only five of the group would be left, of whom two would be healthy, the remaining three, being more or less incapacitated. In other words, there was over 50 per cent. wastage of human life, and this not during the period of unrest following on the war, but in peace time, in time of full prosperity, in the best educated, best organized states of western Europe. Was this a process of natural selection, which, by pitilessly sacrificing the unfit, safeguarded the strength of the race? That was true only to a certain extent; artificial feeding, errors of diet, and infectious diseases attacked, maimed or destroyed the strong as well as the weak. Take as example infantile ophthalmia, responsible for so vast a number of cases of blindness; in England every year 6,500 children were attacked by this disease. The experience of fifty years had shown, however, that the infection was easily counteracted by a few drops of citrate of silver or even of lemon juice. Referring to the disablements brought about by ignorance of or neglect to employ preventive, curative, or remedial measures, the speaker emphasized the fact that these evils were for the most part avoidable. He would cite the case of the Norton company, Worcester, Mass., which, by organizing a really competent medical service, had reduced the number of days of sick leave by three-quarters, and the Goodrich company, Akron, Ohio, had achieved a reduction of four-fifths. It is estimated in America that the net loss through sickness to employers and workpeople amounts to several billion dollars each year. Dr. Sand concluded his address by an appeal to the labor organizations to come to the support of the Red Cross.

Delirium.—An interesting address on delirium was given by Sir James Purves Stewart at a meeting of the Devon and Exeter Medico-Chirurgical Society, held at the Royal Devon and Exeter Hospital on October 20, last. Sir James classified his subject in the three divisions of acute delirium, non-febrile, toxic delirium, and delirium in organic brain affections. After subdividing these forms of delirium, he discussed their diagnosis, prognosis, and treatment. Dr. Richard Eager, in discussing the address and speaking from his experience in mental hospitals, considered that acute delirious mania was a very rare condition, and that in the cases which had come under his notice there had been no high degree of pyrexia. Dr. Eager praised the good effects of Stoddart's treatment in this condition. He considered that "senile mania" was often influenced by traumatism, and that "exhaustion psychosis" was frequently wrongly classified as "delusional insanity." Dr. Eager advocated the early treatment of mental cases in special hospitals, regarding certification as an objectionable procedure. Dr. W. Gordon dealt with the "colored nightmares" mentioned by Sir James Purves Stewart and related his own visual impressions during the course of a severe infective illness. Dr. F. A. Roper advocated a more extended use of hyoscine in delirium. Sir James, in reply, acknowledged that hyoscine in repeated full doses had often proved of great value in the quieting of delirium.

Obituary.—Francis Arthur Bainbridge, M.A., M.D., University Professor of Physiology at St. Bartholomew's Hospital, London, died on Oct. 27, last, after a short illness. He was born in 1874 and entered Trinity College, Cambridge, in 1892. He obtained a first class in each part of the Science Tripos. In 1902 he was elected to a research scholarship of the British Medical Association. Bainbridge then turned his attention to general pathology and held for some years the Gordon lectureship at Guy's Hospital. Later he was on the bacteriological staff of the Lister Institute. However, his main interest was always in experimental physiology, and the opportunity to follow his bent came with his appointment to the chair of physiology at the University of Durham Medical School at Newcastle. Here he commenced a series of investigations on the mechanisms coordinating the activities of the heart and the respiratory center, which he continued at St. Bartholomew's Hospital and which he had in hand at the time of his death. In collaboration with his colleague at Newcastle, the late Prof. J. Menzies, he wrote perhaps the best student's text-book of physiology ever written. The premature death of Prof. Bainbridge is a great loss to British medical science and, indeed, to medical science everywhere. He was a man of short stature, frail physique, and weak constitution. Throughout his life he struggled with ill health, and, considering his handicap, his contributions to medical science were remarkable. He was a man of charming personality and will be missed by a large circle of friends.

A PLEA FOR THE SALE OF CHRISTMAS SEALS ON BEHALF OF THE ANTITUBERCULOSIS MOVEMENT IN THE UNITED STATES.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Because of the favorable reports of results obtained by the tuberculosis campaign in the reduction of the death rate from tuberculosis, many well-meaning people think that there is no longer any need to help in that direction. Yet if there was ever need of funds to carry on the antituberculosis work efficiently, it is now. Tuberculosis, as a rule, does not begin in adult life. It is most frequently contracted in childhood. While it may always remain a latent infection and never develop into a disease, where there is privation and want, underfeeding, insufficient clothing, and overcrowding, the infected child is bound to develop tuberculosis. Underfeeding, technically called malnutrition, among parents are in poor ar even moderate circumstances, owing to the hard times and approaching winter, is more to be feared this year than ever before. Many an adult predisposed to tuberculosis retains his good health in prosperous times because he can get good, nutritious food and have a comfortable home. It is different now with the vast army of unemployed, many of whom not only live less comfortably

and less hygienically, but must content themselves with insufficient food. Add to this their natural anxiety about the future, and I am sure that unless the situation changes soon we shall have a great many tuberculous adults. Let us come to the rescue of those thousands of children and the thousands of men and women who are in danger of becoming tuberculous.

But besides doing this glorious preventive work, we must also be reminded that there are yet many, many tuberculous cases without proper medical care, some who should be in a sanatorium, others in a hospital, others at least in more sanitary environments than they are at the present time, and others who should receive medical supervision.

I appeal to the hearts of men and women who have enough food, enough clothing, and a comfortable home, to think of the little children and the men and women who may be saved from contracting tuberculosis, and those who may be cured by proper and timely treatment and care. Let those who can not help by personal service do their share by giving freely and generously to this campaign. Let all show their interest in the fight for the prevention and cure by buying as many Christmas seals as they can. Every penny helps. Everyone will enjoy Christmastide with a lighter and more joyous heart if he or she can say: "I have helped a child or a poor man or woman not to contract tuberculosis, or I have helped one tuberculous sufferer to regain his health and happiness."

I have had the privilege of having been associated, as an humble antituberculosis worker, with many great, generous, and noble-hearted men and women who, after they had learned of the needs of the consumptive poor, found their greatest happiness in financially and actively joining this great humanitarian movement. It is true much has been done, but there is more to do. Not only must the work be kept up, in order to retain the good results already obtained, but it must still be expanded in order to get better and better results in the future.

The immortal Pasteur once said: "It is in the power of man to cause all parasitic (germ) diseases to disappear from the world." Let us begin with tuberculosis and show our power.

2. Some Criteria of X-Ray Diagnosis.—Frederick W. O'Brien asserts that the *x*-ray technician should be ruled out as one qualified to interpret *x*-ray shadows, and insists that the roentgenologist alone is the proper person to interpret *x*-ray findings. He should be a well trained physician specializing in diagnosis by means of the *x*-rays. The fluoroscope is of decided but limited value and should not be employed alone when desiring to detect early pathological processes. He would discourage the habit of asking for one plate of this or that part. The important thing to keep in mind is that the object of the roentgenological examination is to find out what is wrong with the patient, and it is better to ask the roentgenologist to make his charges consistent with the patient's means than to attempt to direct or limit the examination. Currently some members of the medical profession appear to have made overmuch of focal infection, and some of the dental profession to be surgically obsessed. In justice much of it may be laid at the door of the roentgenologist. The terms, pericementitis, apical abscess, pus pocket, pyorrhea and necrosis are used with a freedom that is startling. It should be written large on the minds of medical men and oral surgeons that a tooth that responds to vitality tests irrespective of the *x*-ray appearances of the same is, to the best of our present day knowledge, not a cause, primarily or remotely, of morbidity. Every area of increased radiability seen in the body structure does not signify necrosis. Just as one commonly witnesses, for instance, in a forearm that has been at rest, say for the immobilization of a fracture, an increase of radiability due to the atrophy of disuse, so in the alveolar processes one sees areas of increased radiability due to the atrophy of disuse, especially over bridges and about teeth that improperly impinge. Such areas are not infrequently called necrotic when they are nothing of the sort. The writer's experience leads him to believe that if an area of increased radiability seen at the apex of a tooth is well defined, black in tone and delimited by an area of increased density meaning calcification, the process is that such is an abscess cavity and not a pus sac or an active source of infection. Again in diseases of the lung, a definite roentgen diagnosis is made altogether too often on insufficient data. During the past year at the Boston Consumptives' Hospital he has personally examined over 800 thoraces, including suspects, early and advanced cases, and it often has been far easier to determine those not having tuberculosis rather than to say definitely that chests presenting patent evidence of pathology were tuberculous. If it be recollected that most of us are tuberculous, it is plain that the important thing to determine is who are the tuberculous sick, and this is a combined operation of internist and roentgenologist. It would be well if the term "negative" disappeared from the roentgen nomenclature, because of the false hopes raised by it; far better say "no pathology recognized."

3. Some Notes on Typhoid Fever.—Dwight O'Hara claims that the macroscopic method of testing the blood serum for typhoid agglutinins is superior in every way to the microscopic method. Among its advantages are the greater ease with which a uniform antigen can be kept on hand; the greater precision with which dilutions can be made, and the more sharply defined endpoint obtainable between positive and negative reactions. These factors bring back to the clinician a more scientific report, and should therefore be encouraged by him, even though he must needs submit 0.5 c.c. of blood or more in a small tube, instead of a few dried drops on the most convenient thing he can find about the house. The technique of the macroscopic method is described. On the basis of observations made during an epidemic of typhoid fever in Waltham, Mass., O'Hara concludes that negative agglutinations are more common in typhoid fever than is generally thought. High titres of agglutination occur mainly after the fourth week. The pro-agglutinoid zone is a possible source of error in reading agglutinations which are not set up in the higher dilutions. The typhoid patient's immunity, to be effectively protective, must develop in time to prevent the typhoid poisons from doing local damage capable of causing fatal accidents. Immunity in this sense cannot be estimated by titration of antibodies. A means of typhoid prevention is insufficient without ways to apply it. Preventive medicine must come to the community through the individual quite as much as to the individual through the community. This must be brought about through individual education.

2. The Diagnostic Value of Pupillary Symptoms in General Disease.—Matthias Lanckton Foster cites an instance of failure on the part of several physicians to recognize typical Argyll-Robertson pupils, which has led him to review the significance of pupillary reactions in general disease. He states that we must admit that the behavior of the pupils, taken by itself, is an unreliable guide to diagnosis. The pupils may be dilated, contracted, or normal in acute or chronic alcoholism, as well as in other kinds of poisoning, and their reactions may be increased, decreased, or unaffected; their condition depends upon the quantity of the poison taken, the nature of its action, the stage of its action when one happens to see the patient, and the latter's susceptibility. The same uncertainty of pupillary behavior exists in meningitis, most intracranial troubles, psychoneuroses, and many other diseases. In rare instances unequal pupils with normal light reactions are congenital and physiological, but one should not permit himself to make this diagnosis until after every possible affection of the central nervous system has been excluded. In spite of the uncertainty of pupillary behavior, observation of the pupils, when taken in conjunction with the other symptoms present, frequently proves a valuable aid in the diagnosis of general disease and should not be overlooked by the general practitioner.

9. Thoracic Tumor Mistaken for Aneurysm.—Hyman I. Goldstein reports an interesting case of a tumor of the anterior left chest, resembling in its appearance, shape, and location an aortic aneurysm. The patient had seen several physicians and, according to the statement of the patient, the diagnosis of aneurysm was made by several medical attendants. The chief complaint was sharp neuralgic pains in the left shoulder region, around the back and abdomen, and along the thoracic and upper lumbar vertebrae. There was no headache, no attacks of dizziness, no flushing or congestion of the face, no unilateral sweating, no cough; in fact, the patient presented no symptoms characteristic of a typical thoracic aneurysm. The symptoms were those of pressure neuritis. Furthermore, there was an appreciable irregular outline distinguished by palpation around this definite circular mass, which made one suspect a neoplasm. The blood Wassermann was negative. Dr. Henry K. Pancoast of Philadelphia, from his *x*-ray examination, reports sarcoma of the anterior chest wall, with metastases to the mediastinum and lungs in the region of the aortic arch and the base of the lung, and possibly a retroperitoneal growth.

14. Syphilis.—James H. Stevens asserts that syphilization of the people of the United States is progressing rapidly and that little can be expected of governmental supervision as long as our political system controls medical supervision. Until we can devise some simplification of technique which will place the treatment of primary syphilis in the hands of the general practitioner we shall not accomplish much by treatment. A simplification in the method of treatment is presented, the main feature of which is the use of arsenicals in concentrated solution. In the administration of neosalvarsan great quantities of water are not an advantage but a detriment. In 100 cases Stevens has used 2 c.c. of distilled water to the usual dose of neosalvarsan, and by this method has seen the nausea, vomiting, diarrhea, and headache which so often follow the administration of arsenicals in the more dilute solutions disappear. Syphilis reacts just as rapidly to the concentrated arsenicals as to the more dilute solutions. Reactions occurring with concentrated solutions are usually milder and if they occur come on at once and may be treated immediately. One-half c.c. of 1-1,000 adrenalin, in every case that shows reaction, fifteen to twenty minutes before administration will prevent repetition. The nitratoid is the only type of reaction to be expected with the concentrated solution. Reaction once established in a patient will invariably occur thereafter without regard to dose unless adrenalin is used. This applies to a series of administrations only. After a rest of several months reaction may not follow in cases which previously reacted. The mercurials are of value when used to the point of tolerance and kept there, but to expect results from most of the doses recommended is an absurdity.

6. The Phenoltetrachlorphthalein Test for Liver Function.—A. H. Aaron, E. C. Beck, and H. C. Schneider enumerate the disadvantages of the focal tetrachlor test for liver function and describe a method by which they have prepared a stable solution of phenoltetrachlorphthalein which has undergone no deterioration in eight months. They point out that for some reason the duodenal time tetrachlor test has been neglected. The test is performed by passing the duodenal tube and giving the patient 500 c.c. of cool water by mouth. This insures a continuous drip of 60 to 80 drops a minute of bile-stained fluid for a period of from a half to three-quarters of an hour, which gives ample time to carry out the test. One c.c., representing 50 mg. of the dye, is injected intravenously into the lumen of a prominent vein of the forearm. The establishment of a drip by the administration of water by mouth in no way interferes with the test. The end reaction is clear and distinct, and makes it a simple matter to decide at which point the dye is at maximum. In the nonpathologic cases the dye appeared in an average time of 17.2 minutes. The pathologic cases, not including a common duct obstruction case, definitely gave delayed figures, the average being 32 minutes. The estimation of the excretion of dye in a given time is of no value because of the leakage of contents into the intestine below. If the time of the first appearance of the dye is more than twenty minutes, one should be suspicious of hepatic involvement. In surgical cases the test may be of value in determining how much damage has been done to the parenchyma of the liver, which is an important factor in estimating shock liability. The appearance of the dye in fifteen minutes in the contents shows that, despite which procedure for fractional duodenal analysis is followed, bile from the liver is present from that time on. If the dye fails to appear in thirty minutes it is necessary to give additional water by mouth to maintain the drip. This dye test also demonstrates the presence of the tube in the duodenum.

9. The Use of Carbon Tetrachloride for the Removal of Hookworms.—Maurice A. Hall has tested this agent in dogs for the removal of parasitic worms, with special reference to its effect on hookworms. The results

have been very gratifying. In the case of animals given 0.3 c.c. of this drug for every kilogram of live weight, all the hookworms originally present were expelled, a result he has never been able to obtain in a series of tests of anthelmintics on hundreds of dogs during the past six years. The expulsion of all the hookworms present was also obtained by the use of a mixture of carbon tetrachloride and thymol in the proportion of 1 c.c. of carbon tetrachloride and 10 grains of thymol, and by a mixture of carbon tetrachloride and oil of chenopodium in the proportion of 3 c.c. of carbon tetrachloride to 1 c.c. of chenopodium. These mixtures, as well as carbon tetrachloride alone, were given in hard gelatin capsules, without purgation, to dogs after fasting eighteen hours. The carbon tetrachloride is also very effective in removing ascarides. Before adopting this drug for administration in human beings the question of its safety must be considered, inasmuch as, like chloroform, it may develop phosgen (carbonyl chloride) under certain conditions, and the suggestion is thrown out that the drug might act on the liver in a manner similar to the action of chloroform in delayed chloroform poisoning. So far as the dogs were concerned, no macroscopic changes were noted in the liver after the oral administration of the drug up to 1.5 c.c. per kilograms of live weight, though acute yellow necrosis due to chloroform is unmistakable in dogs after doses of 0.3 c.c. per kilogram. It would seem that discomfort and subjective effects, such as those produced by thymol and chenopodium, are not produced by carbon tetrachloride. This drug is also much cheaper than thymol or chenopodium and may be obtained anywhere.

12. **The So-Called Presystolic Murmur.**—William D. Reid brings out a number of points to show that the crescendo murmur ending in a sharp first sound or merging into a systolic murmur is wrongly designated as presystolic, since in reality it is systolic in time. This so-called presystolic murmur is due to a regurgitant stream of blood, impelled through the mitral valve by ventricular systole. The writings of a number of previous observers support this interpretation. Against the conception that it is due to the contraction of the auricle, there are in addition data presented in an earlier paper (*Journal of the American Medical Association*, lxxvi, 432, 1921) its quality, time, absence of a pause between it and the succeeding sound or murmur, its persistence in some cases of auricular fibrillation, and the occurrence at times of another murmur in true presystole. While the murmur is frequently observed in hearts whose mitral valve is stenosed, it may be present in conditions in which the mitral orifice is not narrowed.

13. **A Method for Determining Death by Drowning.**—Alexander O. Gettler reviews the surface and interior signs suggested by various observers as aids in determining whether death was the result of drowning and shows that most of these conditions are misleading and useless. The method described consists in collecting 5 to 10 c.c. of blood from the right and left ventricles separately and determining the sodium chloride content. An appended table makes it evident that the chloride content in the blood of the right and left chambers of the heart is the same in the various pathological conditions so far examined, the greatest difference being 5 mg. in 100 c.c. of blood. In some cases the left is higher and in others the right; but the difference is never greater than 5 mg. In eighteen cases in which there was no doubt that death was due to drowning, the difference in the chloride content in the right and left chambers was always much more than 5 mg., ranging from 19 to 294 mg. In all those cases in which drowning occurred in salt water, the left heart chamber always showed the high chloride content; in those cases in which the drowning occurred in fresh water, the left heart chamber always showed the lower chloride content. A difference in the chloride content of the two heart chambers exceeding 25 mg. indicates that the individual was drowned. Persons who are submerged while alive and die of shock during the first stage of drowning may not show this difference in chloride content. Such cases, however, are rare. The writer believes this is certainly the most specific of all the methods so far devised for proving that death was due to drowning.

1. Chronic Inflammatory Diseases of the Spleen.—Alexander George Gibson in this lecture limits himself to a discussion of those affections that are caused by invasion of the spleen by an organism, whether such invasion is indicated by the discovery of the actual organism, by the clinical aspect, or by the fact that the lesion in the spleen, being inflammatory, admits of this view as the most likely etiology. The spleen becomes infected in three ways: First, as a result of a general blood infection which subsequently may become restricted to the spleen, as in syphilis and tuberculosis; secondly, because the spleen in destroying blood cells comes into fuller contact with the organism, as in malaria and kala-azar; and thirdly, being the largest lymphatic gland in the abdomen, it may be the point of attack in any gastrointestinal infection. After describing the local and bodily effects of chronic inflammatory lesions of the spleen, Gibson states that there is no evidence at present available that the spleen of itself produces any internal secretion which is deleterious under any circumstances. He is frankly skeptical about any etiology which implies some undemonstrated nonbacterial toxin secreted by an abnormal metabolism of some splenic tissue. His working rule is to suspect all splenic enlargements of an inflammatory type as being caused by extraneous organisms until proved otherwise. In order to accept that a given organism is the cause of the splenic condition it is necessary, if possible, to fulfill Koch's postulates. The raising of this point is to draw attention to the very loose way in which many reports of cases are presented. For purposes of science only those cases in which the bacterial cause has been demonstrated should be included. A review of twenty-five reported cases whose syphilitic causation is probable indicates that the characteristics of syphilitic splenomgaly are an anemia tending to be of the chlorotic type. The white cell count varies. It was 4,560 in Stevenson's case, and as high as 21,000 in French's.

Attacks of jaundice are reported in several cases and hematemasis occurred in several instances. The reaction to antisyphilitic remedies is startling in its unevenness. A search must be made for the factor which explains why one case can be cured and another not. Tuberculosis of the spleen is extremely common as a secondary feature. An enlarged spleen is frequently met with in general glandular tuberculosis, but for the most part it causes no symptoms of splenic disease. Primary tuberculosis of the spleen is rare, but from the reported cases not quite so rare as the syphilitic. Seventeen cases of undoubted primary tuberculosis of the spleen collected from the literature are analyzed. These show that the tubercle bacillus may cause in the spleen both acute and chronic inflammations. The symptoms of tuberculous splenomegaly may be general and local. In about 25 per cent. of the cases there is fever. Sweating and collapse are mentioned, and very constantly loss of weight, weakness, and great lassitude. As regards local symptoms there is pain and a sensation of tumor and weight in the left side. The majority of cases are very chronic, but short illnesses terminated by death have been reported. There are fifteen clear cases of tuberculous splenomegaly in the literature that have been operated upon, with nine cures. Other clinical features have been enlargement of other glands, enlargement of the liver with cirrhosis, ascites, caries of the spine, meningitis, and intestinal ulceration. The degree of anemia is slight and has not been a marked feature in any case, and no case in this series showed an abnormally high blood count. Acholuric jaundice and splenic anemia are discussed, and the opinion advanced that there is no difficulty in presupposing an infective element in these, though among the cases of splenic anemia, after all those varieties depending upon a specific cause have been eliminated, there still re-

mains a group of cases not belonging to any known specific group. In closing, Gibson emphasizes the point that splenic disease as such may cause many symptoms and that the ultimate etiological subdivisions will not necessarily harmonize with the present merely temporary subdivisions which have been based on clinical observation alone.

3. Arrest of Auricular Fibrillation by the Use of Quinidine.—Arthur W. M. Ellis and A. E. Clark-Kennedy present a preliminary report of their results in the treatment of seven cases of auricular fibrillation, in five of which the administration of quinidine by the mouth has been associated with return to the normal cardiac rhythm. In all these five cases the change has been demonstrated by polygraph tracings, and in two of them by the appearance of a crescendo presystolic murmur at the apex. In one of these five relapse occurred soon after the drug was stopped, and again a second time when the dosage was reduced. In two the dosage was only decreased and there was no relapse into auricular fibrillation. In two of the five cases, shortly after the onset of normal cardiac rhythm, embolic infarction of internal organs occurred. The formation of clots in the appendix of a fibrillating auricle is not uncommon, and the loosening of these by restored auricular contraction and their projection into the general circulation is easily understood. The pharmacological action of quinidine is still undetermined. Electrocardiographic study shows that, under quinidine, alteration in both shape and size of the auricular and ventricular waves occur and are accompanied by a prolongation of the P. R. interval. It seems reasonable to suppose that quinidine abolished fibrillation either by increasing the conductivity or by prolonging the refractory period of heart muscle, with the result that the gap is bridged and circus movement ceases. The use of quinidine is not without danger, the risk of embolism being a real one. In the writers' cases the improvement in the general condition was not striking and much less marked than might have been anticipated, and perhaps little more than might be attributed to prolonged rest in bed. That quinidine will take a place in the treatment of cardiac disease seems altogether probable, but the authors show a commendable caution and are ready to admit that the nature of its action and the limitations of its therapeutic value remain to be determined.

4. Acidosis and Toxic Symptoms of Severe Diarrhea of Infancy.—R. A. Guy states that in England little attention has been paid to the study of this group of cases which have been shown by Howland and Marriott and by Schloss and Stetson to be accompanied by a state of acidosis. Accordingly, at the suggestion of Dr. Leonard Findlay, the present investigation into the alkali reserve of the plasma in cases of diarrhea in infancy was undertaken. The estimations were made according to the "micro-method" of Van Slyke. Three types of cases were studied, namely, normal infants, cases of dyspepsia, and cases with intoxication. From these the following conclusions are drawn: In certain of the diarrheas of infancy, symptoms of intoxication, the chief of which is increased pulmonary ventilation, are accompanied by a reduction in the reserve of bicarbonate in the blood plasma. The hyperpnea and the alkali reserve vary inversely. The reserve can be increased to normal by the administration of sodium bicarbonate. Hyperpnea is thus controlled and the general toxic symptoms are alleviated, but the ultimate outcome, in the diarrheal cases at any rate, is little influenced. Necropsy throws no light on the questions of the site or extent of the damage done. The usual lesions of gastroenteritis are the only ones found. Depletion of the alkali reserve is not a cause of the diseased condition, but is caused by it and is essentially, like an elevation of temperature or an acceleration of the heart rate, a variation in a physiological constant, an indication of deranged function. And just as fever and tachycardia demand certain therapeutic measures for their own sake, so acidosis indicates the administration of alkali and fluid and the stimulation of excretion. When the acid produced and the cause of its production are known more specific therapy may be available. These observations have confirmed the work of previous investigators.

1. An Address on the Clinical Types of Convulsive Seizures in Very Young Babies. John Thomson.
2. Bilateral Rigidity in Middle Meningeal Hemorrhage. Geoffrey Jefferson.
3. Metatarsus Varus. A. S. Blundell Bankart.
4. Two Cases of Pernicious Anemia with Infective Foci in the Alimentary Tract. E. F. Maynard and S. D. Sturton.

1. Clinical Types of Convulsive Seizures in Very Young Babies.—John Thomson, on the basis of a study of the notes on 200 cases of convulsions in infants under three months, divides them into three groups, namely: (*A*) Those due to local injury or disease of the brain or its membranes. (*B*) Those dependent upon cerebral disturbance due to acute disease of organs other than the brain. (*C*) Those due to cerebral disturbance connected with various forms of general infection and of debility. Under the latter group he classifies convulsions due to tuberculosis, congenital syphilis, debility, whooping cough, and the idiopathic convulsions of early infancy. It is to the latter he directs special attention. These occur during the early weeks of life and are not very common, for in the last twenty-five years he has seen only thirty-five cases in very young babies and two in rather older infants. In a typical case the child, when two or three weeks old, begins to have slight twitchings of the face and limbs, which recur at regular intervals, and soon develop into regular convulsive seizures of short duration. The fits may become very numerous and continue for weeks if they are not successfully treated. The administration of bromide has little or no effect in stopping the attacks; but if chloral is given cautiously and continuously in a sufficiently large amount, the fits not only cease rapidly, but do not return when the drug is discontinued; and the child grows up perfectly healthy in mind and body. There are two dangers connected with the treatment by chloral. One of these is the danger of inhalation pneumonia being set up if the child is carelessly fed while deeply under the influence of the drug. The other arises when the chloral is given in too small quantities. When this is done the drug may only depress the child's vitality without preventing injury to the brain cells by the toxin of the disease and the damage done may permanently injure the child's mental condition. A search for some analogous phenomena which may possibly help to explain the action of the drug in these cases has led to the discovery of a fact which seems to have a bearing on the question. It has been observed by C. Richet, Besredka, and others, that when a guinea-pig is put deeply under ether, alcohol, chloral, or certain other narcotics, before a second dose of a serum which is usually rapidly fatal, the expected anaphylactic shock is generally suppressed altogether, and after a period of unconsciousness the animal "awakes vaccinated." These experiments suggest the possibility that this particular type of convulsions may be due to a peculiarly modified form of anaphylaxis, or some similar process set up by the ingested cow's milk. The writer thinks there is enough information available to justify one in saying that this is at least the most hopeful direction in which to look for an explanation of the facts. Two somewhat different types of severe acute poisoning from cow's milk, which apparently depend on anaphylaxis, may be met with in the young, both of which fortunately are extremely rare. If it should be shown that the above hypothetical explanation of these cases is correct, the question naturally arises as to whether, when symptoms of poisoning from cow's milk, white of egg, oatmeal, or other common foods occur in young children, they might not be stopped permanently if the patient were subjected to a thorough chloralization for some days, while continuing the offending diet, and even whether a tendency to asthma and eczema beginning in infancy might not be permanently arrested in a similar way.

4. Two Cases of Pernicious Anemia with Infective Foci in the Alimentary Tract.—E. F. Maynard and S. D. Sturton report these cases of pernicious anemia in the first of which there was a history of colitis and in the second of diarrhea. In the first case a definite ring of ulcers was found in the intestine, and in the second an infective focus in the teeth. The second patient is

apparently in good health and having novoarsenobillon and vaccine weekly. Novoarsenobillon seems to be a valuable drug in this disease; the value of autogenous vaccines cannot be estimated as they were given concurrently with other treatment. Evidence of alimentary derangement was also present in a fatal case of pernicious anemia following dysentery which the writers treated in 1920. There was a history of alimentary derangement in a case of aplastic anemia and a case of pernicious anemia which Dr. Rivas Hunt has allowed the writers to quote. The latter appears to be enjoying normal health under treatment with novoarsenobillon. These cases afford additional evidence that invasion of some part of the alimentary tract by pathogenic organisms is an etiological factor in a large percentage of cases of pernicious anemia.

Endocrinology.

September, 1921, v. 5.

2. Endocrine Problems in Pelvic Surgery with Special Reference to Vicarious Menstruation.—Curtice Rosser reports three cases which serve to emphasize that, while in pelvic disorders there will always be a place for the surgical correction of mechanical, inflammatory, or neoplastic defects, by discriminating appeal to hormone therapy, needless surgery can be avoided and necessary surgery supplemented. The three cases reported have been selected because each is a fairly typical example of the syndrome produced by predominant disorder of one gland of internal secretion, because each gave a positive "therapeutic test," and because in each case a routine gynecological procedure would perhaps have been followed a few years back, without the possibility of correcting fundamental causes. The first case is an example of thyroid deficiency; the second a case of deficiency of the anterior lobe of the pituitary body, and the third, a definite case of vicarious menstruation, was treated on the basis of modification of excess of the ovarian secretion. In discussing the latter case the writer points out that while unquestionably organic, constitutional, or genital defects, environment, psychic shock, and any number of other factors, may increase or decrease the syndrome in a case of vicarious menstruation, one is fairly safe in looking for the fundamental cause in an unbalanced endocrine system dependent upon a perversion or excess of ovarian secretion. Dysovarianism may act both directly and through stimulation of the posterior pituitary, the thyroid, and possibly adrenals, so that the resultant complex becomes a general pluriglandular disturbance. There are two factors present, the primary amount of modification in the ovarian secretion and the degree of instability of the individual's sympathetic system and remaining endocrine organs. It is not difficult to carry a step further the signposts of the menstrual crisis—the various hyperemias and congestions, the increased vascular tensions—to produce the symptomatology present in vicarious menstruation.

3. The New Views as to the Morphology of the Thymus Glands and Their Bearing on the Problems of the Function of the Thymus.—J. Aug. Hammar states that it has been shown that the thymus gland is fundamentally an epithelial organ infiltrated with lymphocytes. The epithelial components in various mammals are of diverse origin—entodermal in some, and combined ecto-entodermal in others. In man the lymphocytic infiltration begins in the second month of intrauterine life. Contrary to the usual teaching, the thymus is not a transitory organ, but persists and functions even until old age. At puberty its parenchyma begins to be reduced, but the old theory of an "age involution" of the thymus was certainly incorrect. It has undergone revision to the effect that the involution does not appear until puberty and that it certainly causes a gradual reduction of the parenchyma, but in such a way that a functioning parenchyma remains as a rule, even in old age. Five types of thymus, depending upon age, can be differentiated: (1) Type of childhood; (2) puberal types; (3) type of youth; (4) adult type; (5) senescent type. These types are described. Descriptions of the thymus gland, based upon material from diseased subjects, are misleading. Such glands are never normal. Usually the parenchyma is reduced; occasionally it is hyperplastic. The normal ratio between corpuscles and lymphoid elements is disturbed. Even in healthy subjects the thymus is a very labile gland. The condition of the thymus gland, even in the present imperfect state of our knowledge, is suited to give valuable indications as to the state of the organism, and it is to be expected that, with extended experience as to the correlative conditions of the organ, these possibilities will be very essentially increased.

6. The Heart in Experimental Hyperthyroidism with Special Reference to Its Histology.—Hirotoshi Hashimoto presents detailed experimental data which he summarizes as follows: The buccal administration of toxic doses of thyroid caused, in addition to enlargement of the heart, the appearance of myocarditic lesions in a large percentage of albino rats; in 90 per cent. of the animals killed in the first and second week and almost all of those dying in the second and third week of a daily administration of 0.5 grams of dessicated thyroid. The myocarditic lesions consisted chiefly in dense accumulations of large "histiocytare" cells (Kiyono), derived from the the clasmocytes present in the interstitial connective tissue, in small circumscribed areas between the muscle fibers or not infrequently in the neighborhood of the blood vessels. These cells may be accompanied by a small or occasionally very large number of cells of lymphoid type, at earlier periods in the sequence of the myocarditic changes; in the later stages they may be associated with fibroblasts, increasing gradually in number, and eventually prevailing over the other types of cells. The muscle fibers may be destroyed in confined areas adjoining larger areas of myocarditic changes. The muscle fibers may show, moreover, slight but diffuse degenerative changes, apparently occurring independent of the interstitial changes described above. The interstitial inflammatory proliferation and the diffuse parenchymatous degeneration described above may both be attributed directly to thyroid intoxication. The hearts showing such myocarditic lesions are functionally inferior to normal hearts. In their histological appearance the myocarditic lesions resulting from thyroid administration are closely related to those observed by Aschoff, Tawara, and many others in the hearts of individuals suffering from rheumatism. The myocarditic lesions occurring in experimental hyperthyroidism induced by thyroid administration correspond to those in goiter hearts, first noted by Fahr. It is evident, therefore, that thyroid administration can cause not only tachycardia or hypertrophy, but also myocarditic lesions, all of which simulate the functional and anatomical changes found in human goiter hearts. This evidence lends support to the theory that the cardiac disturbances associated with goiter are due to thyroid intoxication, and further, to excess of thyroid secretion.

2. The Striatal and Thalamic Types of Encephalitis: A Consideration of the Symptoms and Syndromes Referable to the Basal Ganglia in Epidemic Encephalitis.—J. Ramsey Hunt has made investigations which show that the large basal ganglia, and especially the corpora striata, are frequently affected in epidemic encephalitis. Involvement of the corpus striatum produces three types of syndromes: (1) *A paleostriatal or pallidal syndrome—the paralysis agitans type.* (2) *A neostriatal syndrome—the choreiform type.* (3) *A mixed striatal syndrome—the combined paralysis agitans-choreiform types.* These types are believed to be dependent upon the existence of two distinct cellular systems within the corpus striatum. One, the *pallidal system*, which originates in the motor cells of the corpus striatum and links this structure with important nuclei of the hypothalamic region, and controls the various motor activities of the extrapyramidal tracts. When this system is involved the symptoms of paralysis agitans develop, that is paralysis of automatic associated movements with hypertonicity of the muscles and rhythmical tremor. The other, striopallidal or *neostriatal system*, which exercises a coordinating and inhibitory influence on the purely motor functions of the corpus striatum. When this system is involved, chorea or spontaneous movements of the automatic associated type develop. The mixed striatal types result from involvement of both systems with the production of symptoms characteristic of each. The recognition of these two systems and fundamental syndromes of the striatum serve to explain and reconcile many peculiarities of striatal symptomatology. The *pallidal* and *paralysis agitans* type of encephalitis lethargica may be general, hemilateral, or segmental in distribution. Abortive, relapsing, and progressive types are also recognized. The *neostriatal* or *choreiform type* may also be general, hemilateral, or local in distribution. There is an acute choreiform type; a choreo-athetosis and athetoid and rhythmical types. These types may occur in pure form or in combination. In the writer's series of twenty-five cases, eighteen were of the paralysis agitans type, four of the choreiform, and three of the mixed striatal type. Thalamic symptoms also occur in encephalitis lethargica. When present they consist of severe and persistent pain, with disturbances of superficial sensibility, more especially of the pain and temperature sense. Evidences of the complete thalamic syndrome are rarely if ever encountered.

7. Malignant Tricuspid Endocarditis: With a Report of Five Cases.—A. V. St. George states that primary acute endocarditis confined to one or other of the valves of the right heart is infrequent. Osler, in his Gulstonian Lectures, analyzed 209 cases of endocarditis and found the right heart alone involved nine times only. He mentions it as a rare finding and still more rarely diagnosed. The sign in tricuspid insufficiency, either relative or organic, is a jugular systolic (positive) pulse. Long continued physical signs in the lung which are evanescent or rapidly changing, together with the heart signs and associated with jugular and hepatic pulse, should make one fairly certain of tricuspid endocarditis. Bacteriologically the lesions in this series were associated with different varieties of pathogenic microorganisms. Lung emboli or abscesses were practically invariably present. The prognosis is extremely unfavorable, the average duration of life from onset of symptoms being two to three months.

10. The Heart Irregularity Called "Sino-Auricular Block."—S. Calvin Smith asserts that "sino-auricular block" is not as rare as the paucity of literature on the subject would lead one to believe. It was clinically suspected with some degree of certainty in scores of healthy young men in military examinations; it has been cardiographically proved to be present fourteen times in the last ten months of the writer's experience. "Sino-auricular block" can be clinically suspected in a person whose pulse is irregular as it returns to normal after exercise and who is free from symptoms and signs of circulatory fault. The condition is said to be differentiated from sinus arrhythmia and from premature contractions; in sinus arrhythmia the rate increases on inspiration and decreases on expiration, the irregularity disappearing when the breath is held. Respiration has no effect on the irregularity called "sino-auricular block." Premature contractions may be associated with other evidence of cardiocirculatory fault; they disappear on exercise and do not usually recur for several minutes following increased physical effort; they are especially noticeable when the patient is at physical rest or falling asleep. A person whose heart exhibits premature contractions (particularly if they be of ventricular origin) is usually conscious of the irregularity; the intermittency of "sino-auricular block" produces no such subjective symptoms. "Sino-auricular block" is not associated with nor is it the sequel of any one definite type of infective process. It is not necessarily dependent upon nor secondary to an infective process, as it occurs in individuals who are well. In a rapid heart it was recorded within twenty minutes following the hypodermic administration of strychnine and atropine. It has been observed in persons who had no other clinical evidence or physical signs of cardiovascular disturbance. "Sino-auricular block," in certain persons, can be made to appear following physical exertion, mental excitement, or emotional strain; it may also follow the administration of drugs; it is therefore due to a change in the nerve control of the heart. These premises lead to the deduction that "sino-auricular block" is not a pathological condition, but is, in all likelihood, a physiological manifestation in certain hearts. As such it does not require drug interference nor does it furnish an indication for modifying the individual's accustomed manner of living.

11. Bacteria on Subsidiary Coins and Currency.—Charlotte B. Ward and Fred W. Tanner carried out this investigation to determine the numbers and types of microorganisms on coins and currency being used in general circulation. They state that there seems to be little basis for the belief that coins bear any close relation to the spread of disease. Thirty-seven strains of microorganisms isolated from the coins were spore-formers, and probably spores are necessary before the organism can perpetuate itself for any considerable length of time on coins. This may explain why none of the commonly accepted indicators of pollution were found. It is shown in this paper that *Bacillus anthracis* was able to live for eighty days on pennies and seventy-one days on nickels when the experiment ended. The greatest factor tending to control the types and numbers of microorganisms on coins seems to be the metal of which the coins are made. Numerous instances are mentioned in the literature where it is shown that the metallic ions have a distinctly bactericidal effect. The same statement applies to certain salts of these metals. It is undoubtedly true that coins that are passing from person to person in general circulation come in contact with acids and alkalies with the formation of soluble salts on their surfaces. These tend to keep down the bacterial flora and to probably exert a selective action, destroying the nonspore-forming organisms. Mold spores were isolated in a few cases.

12. A Case of Meningitis in an Infant Due to Thread-like Diphtheroid Organism.—Milo K. Miller and M. W. Lyon, Jr., have isolated a diphtheroid microorganism named *Corynebacterium trichodiphtheroide* as the causative agent in a case of purulent meningitis developing in an infant suffering with bronchopneumonia. It appeared as a small bacillus in the spinal fluid, grew into irregular thread-like forms on first culturing, later becoming bacillary with Gram-positive polar bodies and segments of diphtheroid type. It was not pathogenic for rabbits or cavies.

The Hot Air Douche in Wound Healing.—Laqueur has extended the use of this recourse in threatened gangrene to badly healing wounds accompanied by a sanious discharge, obstinate ulcer-like defects, fistulæ, and deep suppurations of bone. This local management gives better results than the ultraviolet rays and noon sun. The author seems to employ the vapor douche rather dry than hot air in these cases.—*Schweizerische medizinische Wochenschrift.*

Book Reviews.

Gonococcal Infection in the Male. By Norman Lumb, M.R.C.L., L.R.C.P., Etc. Price $6. New York: William Wood & Co., 1921.

The author had already published monographs on Urethroscopy and on the Treatment of Gonorrhea, and the present volume is doubtless to be regarded as a successor to the preceding, with addenda. The two small monographs total 174 pages, while the corresponding chapters in the present volume (uroscopic diagnosis and treatment) add up to 225. There are also chapters on Anatomy of the Urethra, Bacteriology and Pathology, Uroscopy, the Complement-Fixation Test, Stricture and Impotence (as sequelæ of gonorrhea). The number of illustrations is 165. In reviewing the author's work on the urethroscope we remarked that hardly a word was wasted, there being nothing at all which could be called padding. We can testify to the same effect in connection with the present volume.

Chirurgische Operationslehre fur Studierende und Aerzte. Von Prof. Dr. Friedrich Pels-Leusden. Dritte, wesentliche verbesserte Auflage. Price 200 marks. Berlin and Vienna: Urban and Schwarzenberg, 1921.

The second edition of this work appeared in 1915 with 788 pages, and the present volume contains but 12 additional pages. This limitation, the author asserts, is to keep down the price. The addenda are chiefly under the head of war and post-bellum surgery, and the delay in the appearance of the present edition has been due to the necessary delay in coming by these data.

The Genuine Works of Hippocrates. Translated from the Greek, with a Preliminary Discourse and Annotations. By Francis Adams, LL.D., Surgeon. Two Volumes in One. Price $5. New York: William Wood & Co.

Just now there seems to be a revival of interest in the history of medicine. The appearance of this reissue of Adams' translation of the genuine works of Hippocrates should, therefore, be particularly welcome. Probably all physicians are acquainted with the name of Hippocrates; with some, this knowledge is extended so far that they know that he is the "father of medicine"; others, again, include in their knowledge the fact that he is the author or reputed author of the Hippocratic oath which they have heard read or perhaps have even read for themselves; still others know that the aphorism, "Life is short, and the Art long," is to be found in the works of Hippocrates. There is no reason why even this knowledge should not be further extended to include a perusal of the present volume, at any rate in part. There is a special reason why students of medical history should read some of the works of Hippocrates. Littré, in his edition of Hippocrates, says that when we inquire into the history of medicine and the beginnings of science, the first body of teaching that we meet with is the collection of writings known as the works of Hippocrates. Science mounts up to that origin, and there stops. Not that it had not been cultivated before this, and had not given rise to numerous writings; but everything that had been made before the physician of Cos has perished. We have only scattered and disconnected fragments remaining of them; the works of Hippocrates alone have escaped destruction; and, by a curious coincidence, there exists a great gap after them as well as before them.

The present volume begins with a preliminary discourse which contains an outline of the origin of Grecian medicine and a sketch of the life of Hippocrates. This is followed by a disquisition on the authenticity of the different treatises which have been attributed to Hippocrates. This disquisition is a fine piece of work, and Doctor Adams gives a critical résumé of the Hippocratic works (so-called, and also genuine), with some account of the various translations and editions which have appeared. Then follows the translation of the genuine works of Hippocrates, which was published by the Sydenham Society of London in 1849. This was the first attempt at a complete translation into English, and it remains the only such translation. This latter fact need cause no distress, for it would be difficult to improve on the work of Doctor Adams. Along with the translation the translator has furnished valuable notes, pointing out how, in several instances, the teachings of Hippocrates were still in force and in daily practice so late as 1849. The views of Hippocrates on the treatment of fractures and the use of bandages, splints, and rest; on the setting of a fractured limb in a faulty position; on the treatment of fevers by cold baths and fluid diet; on clubfoot, and the application of bandages in this condition; on dietetics, and on questions of obstetrics and gynecology, to mention only a few of the numerous subjects discussed in his writings, certainly evince a knowledge which too many "moderns" complacently assume to be the particular and peculiar possession of their own age. Case histories were known to Hippocrates; he reports several cases, and even says that some of the patients died; but he does not refer to the social prominence of the patients, or to the numerous physicians whom they had previously consulted in vain; nor does he indulge in remarks about his brother practitioners. In these latter respects he seems to have been hopelessly out of touch with more modern methods. If any of our readers are unacquainted with this volume they are strongly advised to dip into it and learn something about a real genius whose works have had a profound influence upon the science and art of medicine.

A Text-Book of Pathology. Seventh Edition, reset, with 509 text illustrations, many in colors, and 15 colored plates. By Alfred Stengel, M.D., Sc.D., Professor of Medicine, University of Pennsylvania; Physician to the Pennsylvania and University Hospitals, and Herbert Fox, M.D., Director of the Pepper Laboratory of Clinical Medicine, University of Pennsylvania; Pathologist to the Philadelphia Zoological Garden. Price, $8.50. Philadelphia and London: W. B. Saunders Company.

The first edition of this work was published in 1898, and each successive edition has been enlarged and improved until in the present one the writers have produced a most complete and comprehensive volume of 1111 pages. It follows the style of previous issues in presenting the text in convenient paragraph reference form. In order to include the many advances in pathologic knowledge during recent years, much new matter has been added, always, however, with the avoidance of speculation and controversy, the attempt being to give the practitioner and student a conservative and defensible opinion on the subject. In addition to new sections, those on nephritis, influenza, and lymphomata have been entirely rewritten. The text is enhanced by replacements and additions of illustrations to about one hundred. It would be difficult to construct a clearer, more concise and all-inclusive text-book on pathology than these authors have succeeded in developing. It meets in an admirable way the needs of the student and provides a most valuable reference book for the practitioner.

Handbuch Der Ärztlichen Erfahrungen Im Weltkriege 1914-1918 herausgegeben von Prof. Dr. Otto von Schjerning, Generalstabsarzt der Armee a. D. in Berlin, während des Krieges Chef des Feld—Sanitätswesens. Band VIII. Pathologische Anatomie herausgegeben von Ludwig Aschoff in Freiburg i. Br. Mit 134 Abbildungen im Text und 6 farbigen Tafeln. Price 150 Marks. Leipzig: Johann Ambrosius Barth, 1921.

This is the eighth volume of an encyclopedic handbook. The entire handbook is edited by Otto von Schjerning. The eighth volume deals with pathological anatomy and is edited by Ludwig Aschoff with the collaboration of others mentioned in the announcement. The first part is divided into two sections; the one dealing with organic diseases, including the heart, lungs, the kidneys, and glands of internal secretion; and the other section dealing with infections, more particularly tuberculosis. Part II presents a discussion of typhoid, paratyphoid, meningitis, influenza, cholera, and malaria. The third part discusses shock, fat embolism, and miscellaneous topics presented without apparent anatomic classification. The fourth part deals with wound infections and the complications incident thereto. The entire text is based on military experience in Germany. The work is sparsely illustrated.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held November 3, 1921.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

Anniversary Discourse.—A Layman's View of Medical Progress.—HENRY S. PRITCHETT of the Carnegie Foundation delivered this address, in which he said that it required considerable hardihood on the part of a layman to venture to speak to a technical group of men on matters pertaining to their particular field. As a matter of fact, however, the profession of medicine, the practice of medicine, and the teaching of medicine since historic time had been affected almost as much by laymen as by the profession itself. Among laymen there had been some confusion as to the amount of education a medical man should have. One reason for this was because there was confusion of thought because of failure to distinguish between the science of medicine as an experimental science on the one hand and medicine as the art of healing on the other hand. As a matter of fact, those engaged in scientific medicine and those who undertook to practise the art of healing constituted quite distinctive groups. Medicine as an experimental science was almost as old as history itself. In the Alexandrian School of Medicine, some 2,000 years ago, it was thought that a knowledge of the human body must be taught by dissection of the living human being and there was evidence to support the opinion that medicine at that time was an experimental science. To provide material for vivisection there was at that time a beneficent arrangement in that there was always a plentiful supply of criminals. Criminals, however, protested against this form of punishment and begged that they might be crucified or beheaded rather than given over to vivisection. But this was mentioned merely to show that there was a conception of scientific medicine even in those remote times. On the other side was the great group of people who had nothing to do with scientific medicine but engaged in the art of healing. Among the latter were the neuropaths, chiropractors, osteopaths, etc., who employed a part of scientific medicine, and at the other end were those who practiced medicine without the use of drugs, instruments or scientific appliances, like the Christian Scientists. The practice of medicine as an applied science had always been clearly defined to those who had engaged in the scientific study of medicine, and their idea was entirely different from the notion that any people who desired to do so might practise the art of healing. For this reason and because he had had something to do with teaching which had brought him into contact with scientific medicine as it had to do with medical education, he felt that as a layman he might speak of his conception of scientific medicine. The medical student had while in school a highly scientific training. He believed his methods were those of a scientific profession dependent upon experimental observation, analysis, and proof, all achieved by experimental research. All these were necessary if one was to be a part of that group of medical men taught in the schools. Whatever had to do with medicine and the profession of medicine was conceived as an experimental science for the prevention, diagnosis, and treatment of disease. Upon this conception was based the conduct of the medical schools and the method by which modern medical men were trained and brought into their profession. The ideas as to the teaching of scientific medicine had undergone radical changes in the last fifteen or twenty years, and as a result a process of elimination of medical schools that did not come up to the modern standards had been going on. As a consequence the number of medical schools in this country had been reduced from 160 to 85. This process had been mostly to the glory of God and the good of the State, and represented an enormous progress in the ideals and practice of medicine. All this had been due to the leaders in the profession who shaped the ideals of the practice of medicine and the ideals of medical education. This cleaning up had been thoroughly done. Indeed, in some instances it might have been wiser to strengthen a weak medical college rather than to kill it. There were communities where by the absence of any medical organization the ideas of the profession had become so confused that some individuals did not stop to consider whether the practice of medicine was a field subject to legal restrictions or whether it was a calling one might enter on the basis of his own inner consciousness. However, we stood at the end of a period of great medical progress in which achievements of the most notable sort had been attained. The real business of the next decade was the building up and founding of such schools as might be necessary to furnish the required number of reputable medical men. It seemed to him, as one who stood outside the medical profession and yet who was interested from the educational standpoint, that there were things we should have to remember. The progress and education of the profession would depend not upon a single means of education and not on the efforts of one group to prepare men to practice medicine but upon the co-operation and working together of four or five agencies in concord and unanimity. Taking a bird's-eye view of the subject in this light he would try to say briefly some of the things that appeared to him needed to be done in undergraduate medical education, in post-graduate medical education, in medical research, and in reference to the relationship of hospitals and organized medicine to them. In undergraduate medical schools, as a man outside the medical school yet in close touch with teaching, he had been struck by the fact that medical instruction seemed to be weaker than instruction in other professional schools. Very few men teaching in medical schools had given attention to the art of teaching. There should be increased emphasis on the art of teaching, and closely connected with that there should be reform of the undergraduate medical school. In his judgment that was one of the most important things to be undertaken. Today the medical schools were in much the same situation as the engineering schools were fifty years ago. When they began founding engineering schools they were founded on the fundamental sciences of chemistry and physics. Today in the engineering school one no longer had time to learn either chemistry or physics though they were fundamental to the entire work of the engineering schools. Today in the medical schools anatomy, physiology, chemistry, and pathology were taught alone. A man should learn these branches along with the practice of medicine just as in the engineering schools they had come to learn chemistry and physics along with engineering. Under the present curriculum the medical student was crowded with a burden he could ill carry, but he was not taught how closely pathology was associated with the actual practice of medicine. One of the greatest reforms to be effected was a restudy of the medical curriculum with the effort to arrange anatomy and pathology in such a way that a student began the practice of medicine and surgery along with these fundamental sciences. He was inclined to think this could be done best by the men who knew most about the methods of teaching, and, after all, medical education was not much different from other education. Education was one. First one must have a grip on the facts and then one must think about the facts. This applied to all professional education, whether it was medicine, law, or perhaps theology. The fundamental sciences of medicine were so closely associated with actual practice that the student must learn to think of them in terms of applied science. There was a general feeling among teachers who knew medical schools that the greatest improvement that could be brought about in them would be a reform in the curriculum, so that the fundamentals would not be separate things but part of one course.

Turning to the post-graduate school, to those who had to do with the educational side of medicine and to one who had visited these schools and studied them, the thought that stood out most notably was that only a start had been made when a man was put through the undergraduate school and turned loose on the community to learn to practice medicine. There should be the opportunity for the graduate in medicine to return to a post-graduate school and refresh his knowledge of medicine and surgery. As he had watched different groups of men, he had seen none so anxious

to learn as those who had practiced and returned to refresh and increase their knowledge of medicine. So it seemed that there must come a development of post-graduate medical education so that the medical practitioner could return and take up some of his fundamental studies or some branch of medicine or surgery in a more thorough way than was possible in the undergraduate school and might work in an atmosphere where other men already in the profession were working heartily and with spirit. When it came to the next agency of education, he felt that before this audience he ought not to spend any great length of time. He would, therefore, only emphasize the fact that medical education was impossible without the hospital as a part of the regime and the teachers of the medical school directing the hospital. However one might think of the undergraduate or post-graduate medical school, it would still remain a fact that neither was an educational unit until related to a hospital in the right way. That was so thoroughly admitted today that the proposition did not need to be discussed. It was also important that the education of the nurse keep pace with medical education in furthering the development and improvement of the hospitals. The trend today was to send the great bulk of medical students to cities where they received their training in laboratories, and this made them dissatisfied with the practice of medicine if separated from laboratory facilities; they felt that medicine could not be practiced away from the laboratory, consequently few men went into the country districts where no such aids to the practice of medicine existed. The old country doctor who was the salt of the earth had disappeared, and Mr. Pritchett said he believed he had gone not to return. He had heard the opinion advanced that there should be an inferior grade of medical men trained to meet this condition. To his mind this was not the solution of the problem, but rather in some way to reorganize the medical profession in small towns and country districts so that there might be opportunities which well-trained men would be willing to take. Some experiments along this line were being made. For a town say with 3000 inhabitants and a countryside which would bring the population up to 6000 or 8000, he would recommend a small hospital and a small group.

The next great agency related to medical education was medical research. The co-ordination of medical research with undergraduate and post-gradute medical schools and hospitals was a problem with which those interested in medical education were dealing today. Certainly the small-sized hospital could not do much in the way of research. With the spirit of endeavor to find the truth research must constitute a part of every medical school, and it had its relation to the hospital because in every community the hospital had come to be the agency which not only took care of the sick, but which also took care of the public health, and that function of the small hospital would be continued and enlarged. The man in the city who was engaged in scientific research was intimately connected with medical education and with the hospital. In speaking of medical research it must be stated that there was probably no subject and no field in which there was more fraud than in research. Every college and university, however small, coveted the reputation for research; institutions would rather have a fictitious reputation for research than the best reputation for teaching. We could never afford to lose sight of the fact that the primary duty of the university and the college was to teach, and the fundamental duty of the medical colleges was to train men for the practice of medicine. Huxley had pointed out that the medical school that conceived of its function in any other terms would become a fruitless and infertile agency. In this day of many societies perhaps there should be one for the prevention of medical research. On the other hand, to medicine, dealing as it did with the mental and the physical, dealing at once with body and soul, scientific research was an absolute necessity. It inspired the work of both undergraduate and post-graduate medical schools and of hospitals; it represented the fruit of their labors. In medical schools and hospitals the field for research was open and should by no means be neglected, but these institutions should remember that their first function was to teach clearly and well, and then the type of man turned out took easily to research. There were four types of research workers: First, the extraordinary man who was able to advance the boundaries of knowledge and to make discoveries. Those men were rare, and often it was the chemist or the bacteriologist who made the discovery which was applied to medicine. The great leaders of men were rare, and not many were caught in college and in the medical schools; they were usually men who were masters of their field. Back of them was another group, men who were industrious and willing to take up the technique and to apply it to a piece of work of great value which was not a discovery and that would never startle the world. Back of them was a group who took to research because it was easier than to teach, and lastly there was a group who seemed to be in research simply to spend money, and a great deal could be spent in that way. Mr. Pritchett compared research workers to prospectors who went out from their winter quarters to spend the summer in prospecting. When they returned in the fall one or two had found real metal; perhaps eight or ten had found something of value in advancing the resources of the country which would require a great deal of work to develop, but the great body of these men had just bored holes in the ground and amused themselves. While he did not wish to be discouraging, he must say that every man was not fitted for research. Again, when research was undertaken it should be something of real value. It might be a small thing, but it should be worthy of a man's real work. He was inclined to think that medical schools and colleges did best if they regarded teaching as their first duty and research as the breath of life, but to be the breath of life it must be real research patiently thought out and prosecuted with patient, thorough, humble work. Research was, then, of enormous importance, and those who had the real spirit ought to have the utmost encouragement. The enlistment of the devotion of men to this line of work was more a matter of the spirit of the place than of the actual subsidizing of men. In some small schools the personality of one or two strong men or of the governor of a hospital might bring men to take up an ambitious piece of work. There was much in the atmosphere of the medical school or hospital, and it was only where there was the real spirit of research that the work should be subsidized.

In the further development of medicine there remained one other feature to be discussed, and that was the organization of medicine itself. Medicine was organized today to a greater extent than any other group in the body politic. There were the county and State societies and the National Society, centering in a council like the Pope's conclave. The people at the top could put their hand on every individual in the profession. The profession of law could not be organized in this way, perhaps because lawyers were educated to disagree. The time had come when the profession itself should see that what it had been taught to render to mankind could be obtained by the general public, not only by the very poor who could obtain it in hospitals and clinics, or the rich who were able to pay for it—though it must be admitted that even though they were able to pay for it they sometimes received very poor advice—but by the common run of men, those with incomes of $100 to $150 a month, who now found good medical advice beyond their means. This could be brought about only by the medical profession through a co-ordination of the agencies of which he had spoken. The time had gone by when one man could practice medicine alone and do justice to the patient. Within the next ten years medicine would have to reorganize in such a way as to make the facilities of modern medicine available to people of average means and yet not to destroy personal initiative or the opportunity for a splendid medical practice. Practitioners of medicine should form an organization closely related to research and to the medical schools and hospitals, under conditions that would bring medical service to the public for what it could afford to pay. That could not be brought about except by the profession itself, and it was already being done in group practice; it brought to the men practising in the group the advantages of special knowledge that one man alone could not possess. There was another side of this matter constantly

brought to his mind. Education was expensive and perhaps medical education was the most expensive. The cost of medical education and the cost of medical service were so great that he did not see how medical schools, research work, and hospitals were going to be carried except by co-ordinating undergraduate and graduate medical schools and hospitals in such a way that diagnosis and treatment might be made available to the everyday man at a price within his ability to pay. This could only be brought about by a process of education, by teaching the public to appreciate the sacrifices the practitioner of medicine made. In his judgment the well-trained physician or surgeon had a character and idealism that made him perhaps the finest fruits of our modern civilization. On the whole there was no other human being who better represented the best of modern civilization than the well-trained physician who was abreast of his profession. He belonged to a profession in which science and human service were united, in which the finest type of scientific investigation and the highest ideals of service came together; he was thus a realization of the finest fruitage of our civilization. There was a flood of quacks and charlatans without any scientific knowledge who were today reaping a rich harvest from the public for which the public received no benefit, while the great advances in scientific medicine of the past fifty years were not available to a great body of the public. The present condition could not last. Men of a group could undertake to do for a community what no one of these men alone could do. It was carrying but one step further the co-ordination of medical schools and hospitals to have some arrangement by which the man of moderate means should contribute to them, and at the same time have the advantage of the best medical service this age could give him. The medical profession would never be raised by those outside its ranks; it could be raised only by the profession itself. Only the profession itself could make this ideal of service and usefulness a reality to the community. The bringing about of this improvement lay not with the men having to do with the schools or those having to do with foundations, but through those leaders of the profession who united in their own personalities the strictest views of scientific medicine, of the practice of medicine, and of human service. It was that kind of individuals who had brought medicine to what it was today and would bring it to be still more available to humankind the world over.

Dr. CHARLES L. DANA moved a rising vote of thanks for this extremely important, informing, critical, and instructing address.

FIRST DISTRICT BRANCH OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Fifteenth Annual Meeting, Held in South Nyack, N. Y., October 19, 1921.

THE PRESIDENT, DR. GEORGE A. LEITNER OF PIERMONT, IN THE CHAIR.

(*Concluded from page 963.*)

Fainting — Some Observations; Its Cause and Its Treatment.—Dr. JOHN WYCKOFF of New York presented this paper, in which he gave a "synopsis of the rôle of the nervous system in disease of the circulatory system," quoting from Langdon Brown, Chapter 5. He said that since fainting, according to their definition, was dependent upon a transitory cerebral anemia, and since the blood supply of the brain was directly dependent upon the systemic blood pressure, and since we knew the factors upon which this systemic blood pressure depended, we must look upon any case of fainting as being due to a disturbance of one or more of these factors. Before we could hope to understand the gravity of a given case of fainting, before we could have any idea of the prognosis, and before we could expect to treat it with any intelligence, we must determine which one or more of these factors was at fault. While hard arteries, that was, arteries with diminished elasticity, probably never were the sole cause of fainting, they undoubtedly made fainting more probable if there was a disturbance in any of the other three factors responsible for the maintaining of peripheral blood pressure. Fainting might be classified from its causes as being due to: (1) Some interference with the output of the heart; (2) some interference (lowering) of peripheral resistance; (3) diminution of volume of blood. Fainting due to the latter cause was nearly always due to hemorrhage; since its diagnosis was easy and it was a truly surgical condition it was not considered in the paper. Fainting due to fall in blood pressure caused by diminished peripheral resistance was a most common type. This was usually seen in cases in which there was a tremendous dilatation of the splanchnic vessels. These patients usually fainted when forced to stand upright for a considerable length of time, there being a loss of tone in the splanchnic vessels or sometimes lack of support of the splanchnic vessels from relaxed abdominal walls. This type of fainting was frequently seen in the army when men had to stand at attention for long periods of time as at inspections. In this type of fainting the pulse became rapid and the pressure fell, but this change in rate though rapid was not abrupt. As the patient recovered the heart slowed down rather gradually and not suddenly as in the paroxysmal tachycardias. These patients, in the writer's experience, had not shown marked sinus arrhythmia. The onset was usually not accompanied by palpitation. While such patients were usually given rapidly diffusable stimulants of the ammonia group the most efficacious treatment was to have the patient lie down with the head lower than the rest of the body. When these attacks occurred frequently the wearing of a snug abdominal binder which did not interfere with the movements of the body would often stop them. Exercises which strengthened relaxed abdominal muscles should be advised. School children who had such attacks should be excused from exercises where they had to stand upright for any length of time. There was a type of fainting seen when patients who had aortic insufficiency suddenly changed from a lying to a sitting or standing position. These were more frequently giddy attacks than real loss of consciousness. The quick rise in blood pressure due to the sudden change in posture forced blood back through the incompetent aortic valve and dilated the left ventricle, with a resulting cerebral anemia. The causes of a sudden diminution of cardiac output which resulted in fainting had been classified by Lewis as follows: (1) Retardation or cessation of ventricular action (a) caused by slowing or standstill of the whole heart, or (b) by slowing or standstill of the ventricle alone. (2) Acceleration of the ventricular action. Complete cardiac standstill was a comparatively rare condition. Lewis mentioned but two cases, and one of these was a case reported by Laslett. In the latter case atropine entirely abolished the attacks. Fainting due to sudden and profound slowing of both auricles and ventricles was extremely common. Such fainting was due to vagal stimulation which caused a depression and slowing of the sinoauricular node, the pacemaker of the heart. The stimulation which might cause such vagal action might be mental, as viewing some awful catastrophe or hearing distressing news, or it might be due to severe pain. This type of fainting was usually seen in adolescents or young adults. These patients were nauseated and frequently vomited, and after the attack often passed a loose stool. They broke into a cold sweat and their pulse became very slow. As they recovered the pulse became more rapid, but did not suddenly regain its normal rate. During recovery there was more or less sinus irregularity. Standstill of the ventricle alone was always due to auriculo-ventricular heart block. It occurred most frequently when patients who had a partial heart block developed a complete one. If the standstill lasted over a few seconds, the patients developed epileptiform seizures. Syncope due to auriculo-ventricular heart block was usually extremely easy to recognize. During the attack there was a complete ventricular standstill followed by a slow ventricular rhythm. The treatment of these cases was unsatisfactory. Atropine would increase the auricular rate, but had no influence on the ventricular. Patients subject to the attacks should not be allowed to go about alone. The prognosis was always grave. Many cases passed through the transition period dur-

ing which they changed from partial to complete block and finally became cases of permanent complete block. Such patients rarely fainted if they did not exert themselves and frequently lived some years with a great deal of handicap. The reasons for acceleration of the ventricle which frequently caused fainting were paroxysmal tachycardia, paroxysmal auricular fibrillation and auricular flutter. Each of these conditions was discussed, and it was pointed out that from the standpoint of prognosis and treatment it was necessary to determine whether the tachycardia was auricular, nodal or ventricular in type. The auricular type was frequently stopped by vagal stimulation. This might be done in three ways, by deep breathing, by ocular pressure, and by direct vagal pressure on the carotid sheath. A polygraph or better, an electrocardiograph, would always differentiate which type one was dealing with. Digitalis seemed to have no effect in paroxysmal tachycardia of auricular origin, but had considerable effect frequently in cases of nodal origin. Ventricular tachycardia was probably a dangerous condition in which to use digitalis, as the ventricle at such a time was apt to go into fibrillation, which of course meant instant death. Auricular flutter should always be suspected when there was a constant ventricular rate of 140 to 160. It should also be suspected in any case of tachycardia which slowed or in which the ventricle paused upon vagal or orbital pressure, but in which the rate returned to its former rapidity as soon as vagal stimulation was discontinued. The treatment of the condition was digitalis. In proper dosage this drug usually caused the auricles to go into fibrillation and the fibrillation could be controlled by its constant use. In some cases, if the digitalis was discontinued, the auricles returned to normal rhythm.

Dr. HAROLD E. B. PARDEE said he was interested in having the causes of fainting pointed out and in being shown to what particular group of cardiac cases they belonged. He cited one case in which there was a stoppage of the ventricular contraction and a typical Stokes-Adams syncope. He succeeded in taking electrocardiographic records during a convulsion. It was interesting to see how long the body could get along without the circulation. The time varied from 12 to 17 seconds from the stopping of the heart to the beginning of a convulsion, and when the heart started up again the convulsion passed off. This patient had this condition for about two weeks and then the heart again gave normal records. The patient had a mitral stenosis and it was probable that the Stokes-Adams attacks were due to some acute process superimposed on the chronic valvular disease. Dr. Wyckoff's records showing first the normal rhythm and later auricular fibrillation were very interesting. Auricular fibrillation was always associated with disease of the heart muscle while with extrasystoles the chances were that there was disease of the muscle but one could not be so sure of it.

Malignancies of the Colon; Their Consideration—Dr. JOHN F. ERDMANN of New York City read this paper in which he considered 129 patients that had passed under his operative care during the past six years. Of this number 15 were inoperable from the standpoint of metastases to other organs, and 9 were inoperable from the viewpoint of extensive regional metastases. The remaining 105 were operated upon according to some one of the various types of palliative or radical methods, which were considered in the paper. Malignancies of the colon had been observed over 50 per cent. more frequently during those six years than malignancies of the stomach. During this period carcinoma of the stomach (in the Post-Graduate Hospital) was seen in seventy patients, while carcinoma of the colon was found in ninety-six patients in the same service. These figures bore no positive relationship to the frequency or excess of the colonic patients but presented a fair indication of colonic malignancies. The sites of frequent occurrence in the order of frequency found in this series of patients was as follows: In that portion of the gut from the anus to the sigmoid, including the so-termed sigmoido-rectal junction, fifty out of the total of 129 cases; in the sigmoid zone proper thirty-seven; in the ileo-colic zone, or the cecum and the terminal ileum eighteen; in the hepatic flexure and the proximal half of the transverse colon fifteen; the mid-colic region, including the distal half of the transverse colon and the descending colon nine of the 129 patients. The regional frequencies presented food for thought as to the etiological factors so frequently given as stasis irritation. A series of eighty-six patients at the Post-Graduate Hospital were rather equally divided between the sexes, forty-six being males and forty females. But a marked difference in sex preponderance occurred in the female in cancers of the lowest segment. In the sigmoid, there were ten more males than females, while in the recto-sigmoid and recto-anal there were ten more females than males. The average age of the patients operated upon was 49 1/5 years, the youngest being a female of twenty-two years and the eldest a female of eighty-nine years. The rapidity of growth in cancer of the colon as in cancer in other parts of the body was influenced by the age of the patient and the type of the cell. The more youthful the patient the more rapid the growth. Multiple growths in the colon were not encountered in this series. From the standpoint of regional classification the symptoms should vary somewhat, but in the main they were prone to slight variation. It was a well-observed fact that in growths involving the cecum and the ileocecal region obstruction was a rarity, due to the liquid state of the contents of the small intestine. No acute ileus was observed in any of these patients suffering with a growth in this zone. It was also observable that tumors of the cecum were palpable as a rule late in the process of the disease and that the *x*-ray was not conclusive as early as in growths in the distal half of the colon. Pain, soreness and distress in the region of the appendix had led to some of these patients being operated on for appendicitis. In three cases in this series the true state of affairs had been overlooked by the original operators. Colic in this area was evidenced only when the growth involved the ileocecal valve area to such a degree as to become obstructive. Toxemias were seen more in the obstructions of the distal half, due to proximal deflection of the fecal current, the growth of intestinal bacteria and their absorption due to obstructive stases. Borborygmus was frequently present, especially when obstruction became evident. Dr. Erdmann stated that he had been laying special stress on the succussion sound in the cecal zone in various types of obstruction of the colon. This sound was made by the liquid contents distending the caput and the gas that of a necessity was forced into this portion of the intestinal tract. This succussion sound indicated an early operation. After further discussion of the symptoms, Dr. Erdmann said the treatment of these growths to-day resolved itself into the radical surgical procedure in the proximal $\frac{3}{4}$ of the colon; and the question of radical operation versus radium with or without excision. The preliminary to operation was thorough cleansing of the intestinal tract and the establishment of an artificial anus proximal to the growth. This site was a matter of choice to the operator, for years his selection had been the cecum because this location was remote from the field of final operation and did not interfere by newly formed adhesions nor by soiling; finally it was easy to close after its function had terminated. Cleansing of the distal bowel through a cecostomy was readily performed by irrigations after the cecostomy was old enough. A permanent artificial anus was to be made only in those patients in whom the growth was so firmly fixed to surrounding structures that removal would end disastrously or in patients in whom the contiguous and remote metastases were so extensive as to predicate an early demise with or without operative procedure. In this latter type with remote metastases, as in the liver, he had been doing the radical resection with anastomosis because in patients living from a few months to two or three years the disagreeable associations of an artificial anus could be abolished by an additional risk of a small percentage. He had been pleased with his results in this type of operation during the past five or six years. In the permanent artificial anus patients two methods of procedure as to the growth were to be followed. In the first instance the growth was left, while in the second it was removed with all the surrounding tissue. The growth was left in those patients in whom there was infiltration extending beyond the possibility of removal.

One might leave a double-barrelled anus so that radium could be applied from above and below through the upper and lower stomas of the bowel. In the event of a non-removable growth in portions of the colon proximal to the sigmoido-rectal zone, short-circuiting by means of a colonic or ileal byway was in order. This prevented an early total obstruction or a series of periods of partial obstruction. As to the methods of anastomosis he preferred the end to end, doing a plastic on the smaller caliber end to meet with the larger end, except in those cases in which the gut was friable from edema. In these a side to side anastomosis was as a rule successful. The operation of Mickulicz was quite amenable to the growths from the cecum to the recto-sigmoid junction. He had performed it, however, only ten times in the whole series, while end to end anastomosis was performed forty-five times and side to side anastomosis twelve times. He objected to the Mickulicz operation as being one of three or four times the duration of the suture method. The Mickulicz average time in the hospital was ten weeks, while that of suture anastomosis was four weeks. In regard to the implantation of the bowel in the perineum or high coccygeal or sacral zone, he found less and less objection to this procedure from his personal standpoint. He had been struck with the degree of control, often better than before operation, and also by the ease with which these victims preserved cleanliness. It was customary to have an artificial anus established from seven to fifteen days before the radical operation. After a consideration of operative details, Dr. Erdmann said that the advantages of the procedures outlined were (1) Extension of life with no foul discomforts, in those patients with existing metastasis in the liver at the time of operation, from eight to twenty-four months. (2) In those in whom no appreciable metastasis in remote zones was found, extension of life from months to years. In this series there were several patients of each variety living from one to four years. The mortality during the past three years had been in marked contrast to that of the first three years, about 5 per cent. in the former as compared to 15 to 18 per cent. in the latter. A great deal of this lowering of the mortality he felt was due to the preliminary drainage by means of an artificial opening, and the care observed in placing this opening remote from the field of expected removal. In closing, Dr. Erdmann emphasized the importance of proctoscopic and *x*-ray examination in every patient who had pain in the lower back, of perineal or sciatic distribution; who complained of distressing flatulence, abdominal colic, tenesmus, or blood and mucus in the stool, and a slow loss of weight.

Dr. RAYMOND P. SULLIVAN of New York City expressed the opinion that Professor Erdmann's series of 129 personal cases over a period of six years was an unusual experience of great value, and one which made possible practical deductions. The statistical percentages quoted seemed to coincide with those generally accepted. However, they justified repetition and showed what a tremendous problem colonic carcinoma presented. The successful treatment of carcinoma in any portion of the body was dependent upon the early recognition of the disease, and its early and complete removal. It was still a regrettable truism that these factors did not always obtain. The reason for this seemed attributable either to the patient or the physician or both. On the one hand there was a lack of education, or a tendency to neglect early signs of the malady. On the other hand, the physician was apt to fail in a thorough examination or proper translation of the symptomatology. Preventive measures *would* reduce the incidence of carcinoma, and herein lay the duty of the profession to intensify activity both from the standpoint of education and of therapeutics. Carcinoma was in the main a disease of middle life. It was related (W. J. Mayo) that since the Civil War fifteen years had been added to the average length of human life. With our present knowledge of precancerous conditions, and our present state of progress in handling them, it was our hope that proper radical treatment of these conditions would add another fifteen years or more to the life of man in this country within the next twenty years. The etiology of cancer was a much discussed topic. Many theories were advanced. The general impression seemed to be that several conditions were essential to the development of carcinoma. No particular theory seemed to account for the change in the cell that caused *it* to adopt a lawless existence and to lose its harmony with normal cell life. There was little change in the cancer cell from normal, yet cancer could be identified positively by the microscope. The diagnosis of colonic carcinoma had been well brought out by Dr. Erdmann, and too much stress could not be laid on the advice for the use of the proctoscope and *x*-ray as very valuable aids. Before the advance made by these factors, the diagnosis was principally dependent upon the cachexia, loss of weight, obstruction and palpable tumor. Dr. Erdmann had shown that these conditions indicated a time when operability was not so practical and hence should not be the guiding symptoms for treatment. Dr. Sullivan emphasized the advantage of a thorough, systematic and careful exploration of all the abdominal viscera whenever the abdomen was opened and the conditions permitted. To illustrate he reported the case of a young man, thirty-one years of age, operated upon by him at St. Vincent's Hospital on April 8, 1920. The case proved to be one of carcinoma of the splenic flexure. This was resected and a side to side anastomosis made. He was alive today, apparently enjoying complete relief of all his complaints. Prior to this operation he had had his appendix removed by a competent surgeon in 1914, and a second operation, in 1919, by still another surgeon for adhesions. Both surgeons had previously had complete *x*-ray examinations made and both opened the abdomen through a right rectus incision, but he continued to complain of intermittent colicky pains referred to the left upper quadrant of the abdomen associated with stomach distress, loss of flesh and strength without marked obstipation. The *x*-ray findings did not offer the help desired, but the presence of a small palpable tumor and the recurrent colicky attacks with signs of moderate distention of the ascending and transverse colon justified the diagnosis of chronic incomplete obstruction, and an exploration. To the speaker's mind, manual exploration at the time of the second operation would have revealed the presence of the tumor, and thus afforded an earlier removal of the carcinoma. In the treatment of colonic carcinoma there was a distinct field for aggressive surgery. Dr. Ewing stated that it was a rule to which there were notable exceptions that carcinoma of the colon and rectum was only moderately malignant. The course was comparatively slow, extensions beyond the intestinal wall occurred late and metastases were less frequent than with similar growths in other regions. The particular method of removal would depend upon the judgment and choice of the operator, as Dr. Erdmann had pointed out. The use of radium in colonic cancer—especially when the tumor was situated in the lower rectum or anal canal—might be successful, but should be combined with surgical removal. In the upper colon the early and radical removal should be the principal method of procedure. In the pelvic colon and rectum, the site of more than 60 per cent. of colonic carcinoma, the operative procedure was far from standard. To accomplish a reconstruction of the bowel after resection without permanent artificial anus *was ideal*. However, it was his belief that more ultimate cures would be effected with a permanent low mid-abdominal artificial anus and a total extirpation of the distal gut and tumor with the adjacent tissues than to attempt a reconstruction of the bowel integrity. The operability of carcinoma in any part of the colon was not easy of determination prior to exploration, especially when there was no definitely palpable metastasis, and a movable tumor. However, some interesting observations were reported at the last meeting of the Alumni of the Mayo Clinic by Dr. Walter Vaughan of Detroit. He stated that the human resistance to carcinoma might be determined by a differential blood count after the injection into the blood stream of a known amount of placental emulsion. The indication would be the reaction noted in the rise or fall of the lymphocytes, the rise indicating the maintenance of bodily resistance to carcinoma with no metastasis and hence operability. On the other hand a reduction in the percentage of lymphocytes would indicate a fall in the body resistance and metastasis and hence lowered operability. His observations were made in a large series of cases, with a

high percentage of positive findings at operation. The end results in the treatment of large bowel carcinoma were only slowly increasing along favorable lines. He felt that we should impress upon our minds the sentiment that success was the child of courage and reason, and that failure was usually sired by pessimism and damned by everybody. Dr. Erdmann had made very frank statements concerning the end results, and from these it was to be hoped that his next series of cases would show a still greater percentage of satisfactory results, and that he would be able to state that his cases were coming to operation at a much more favorable time.

Radium Treatment of Carcinoma of the Bladder. Illustrated by Lantern Slides.—Dr. BENJAMIN S. BARRINGER of New York City presented this communication, in which he stated that the treatment of carcinoma of the bladder at the Memorial Hospital had been divided into two periods, namely, that prior to June, 1919, when they were testing what could be done with radium applied through the urethra and without opening the bladder and that period since June, 1919, when they had added to the intraurethral treatment the application of radium through the bladder, opened suprapubically. The object of the latter phase was to destroy extensive bladder carcinomata which they had not been able to cope with through the urethra. During a period of 5½ years ending January, 1921, 142 cases of advanced carcinoma, four of small carcinoma, nine of extensive papilloma, and two borderline cases were treated. Their observations led them to believe that many bladder tumors ran true to their original histological structure. However, one must not forget that malignant degeneration might take place in a papilloma and therefore papillomata were potentially malignant. As was usual the fifth and sixth decades showed the greatest incidence of carcinoma. Tables were presented which emphasized the fact that most patients with carcinoma of the bladder had symptoms for a year or more before their condition was seriously considered. If they could be seen earlier very many more could be cured. Of the 153 cases, 119 were male and thirty-four female. This preponderance of males might signify that inflammation might be a causative factor in carcinoma of the bladder, since prostatitis and trigonitis have no analogue in the female. Loss of weight and strength, commonly supposed to be accompaniments of malignant disease, generally appeared late in carcinoma of the bladder. Hematuria was the most important symptom, being the first symptom in seventy cases in this series and the second symptom in sixty cases, appearing in 130 out of 138 cases. Other symptoms were frequent urination, dysuria, polyuria, retention, and incontinence. Usually cystoscopic diagnosis was not difficult. A raised thickened base meant carcinoma. All sloughy tumors were carcinomatous. The following method was used at the Memorial Hospital to show the tumor graphically and the infiltration of the bladder wall. The patient was placed flat on his back, the bladder catheterized, then with a large syringe blown up with air until the patient felt discomfort. The radiograph was immediately taken without withdrawing the catheter from the bladder. In most cases the results shown by the cystogram corresponded accurately with the findings on opening the bladder. Small urethral tumors accompanying or following malignant bladder tumors were often overlooked; it was safe to consider them malignant as the bladder tumor. If the tumor was confined to the bladder it might be suitable for removal by radium. Radium fairly consistently controlled hemorrhage, and might be used for this purpose even though the tumor had gone beyond the bladder. The question was often asked "even if there is no hope of cure, will not radium retard the tumor growth so the patient may live longer and more comfortably?" Undoubtedly this was true now and again. The cases in which radium did this were few, however, the failures so many that it was unwise to give radium therapy in those cases in which there was no hope of removing the tumor from the bladder. Papillomata and papillary carcinomata reacted variously to radium, although as a rule papillary carcinoma seemed to be more sensitive to radium than papillomata. Indurated carcinomata were best destroyed by implanting throughout the indurated area small bare tubes of radium. These bare tubes were very caustic, and very local in their action, extending over an area of about 1 cm. In using them even with great accuracy it was possible to miss some carcinomatous area. Therefore they used a combination of the bare tubes (in the depth) and the screened radium (on the surface) in every case of indurated carcinoma. Radium treatment was applicable to *intravesical growths* confined to and around the bladder neck, papillomata, pedunculated papillary growths, carcinoma of pedicle that could be reached, infiltrating sessile growths of no more than 2 cm. in diameter; to *suprapubic growths* other than the above and without metastasis and extensive infiltration of bladder wall. Large and multiple tumors offered an indication for section, to which all doubtful cases were submitted. By means of a flexible spring holder used through the sheath of the Brown-Buerger operative cystoscope a hundred or more millicuries of unscreened radium might be held up against the tumor for the period of half an hour while the tumor was being observed through the cystoscope. This might be repeated every two weeks or less often if the tumor was disappearing satisfactorily. If the tumor looked solid or hard or had a base which appeared indurated a radium needle screened simply by the steel of the needle might be thrust into its base. Needles of from 50 to 200 mg. might be used for a period of time up to forty minutes. After describing other methods of applying the radium to meet the different types of intravesical growths mentioned above, Dr. Barringer discussed the suprapubic application of radium in extensive carcinoma. Because they were unable to cope with extensive carcinoma of the bladder by the intraurethral method, in June, 1919, they began to open the bladders of selected cases and implant radium directly into the carcinoma. The technique of opening the bladder was described in detail. When the tumor was exposed it was sponged as little as possible to prevent bleeding and spreading of tumor cells. Any protruding portions of the tumor were snared off, using a simple wire snare. Indurated parts of the tumor were implanted with radium by means of needles thrust into them with bare tubes (0.5 mc.) of radium, using two of these to the square centimeter. These bare tubes were not put in the normal mucous membrane, but within about a quarter of a centimeter of the edge of the tumor. Finally surface radiation by means of tubes of radium screened by a half millimeter of silver and two millimeters of rubber and attached to a string were packed over the surface of the tumor and held in place either by gauze packing or little hooks on the silver tubes or both. A string was attached to these tubes, and they were pulled out after an appropriate time. Before introducing the tubes a can of ether was emptied into the bladder to kill any stray tumor cells. The bladder was closed with plain catgut, the strings of the radium tubes and the packing coming out through the small opening left in the bladder. Two cases operated on in this manner were reported.

Radium Treatment in Carcinoma of the Uterus.—Dr. HAROLD BAILEY made this presentation, which consisted of a lantern slide demonstration of the technique employed at the Memorial Hospital in the application of radium in uterine cancer together with a comparison of the results of radium treatment of carcinoma of the uterus by the methods employed in 1915 and 1916, when only small amounts of radium were used, and those in use at the present time, when massive doses of radium were employed. When they began to use the radium treatment in 1915 they thought their results were fair, but there were not living to-day 10 per cent. of those treated at that time. Massive doses were very much more efficient as shown by the statistics for 1920 and 1921. Unquestionably with the introduction of further refinements in technique there would be a still greater improvement in results.

Significance of "White Bile."—So-called white bile has been variously interpreted. It has been seen in obliteration of the common duct with dropsy of the gall bladder. Products are present which are unrelated to any of the normal biliary constituents. It is thought that a fluid produced by degeneration of the epithelium dialyzes with the blood, thus adding new substances to the contents of the bladder.—*La Medicina Ibera.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS OF NEW JERSEY.

June, 1921.

(*Concluded from page* 921.)

OBSTETRICS

1. What bones form the anterior, lateral, and posterior walls of the true pelvis?
2. At what period of pregnancy do abortions usually occur? What are the paternal causes?
3. What is eclampsia? Describe the treatment.
4. What are the causes of prolonged labor?
5. What are the causes of rupture of the uterus? What are the indications in the treatment of rupture?

GYNECOLOGY

6. Describe both the round and the broad ligaments.
7. Give the gross anatomy of the ovaries.
8. Differentiate pelvic hematocele from fibroid tumor of the uterus.
9. Give the etiology of amenorrhea and its symptoms.
10. Give the pathology of carcinoma uteri and the etiology.

SURGERY

1. Give signs and symptoms of popliteal aneurysm.
2. Give differential diagnosis of dislocation of hip (femur) from fracture of surgical neck of femur.
3. Give signs and symptoms of intestinal intussusception.
4. Give etiology and symptoms of cerebral abscess.
5. Give symptoms of acute osteomyelitis.
6. What conditions demand amputation of an extremity?
7. What are the sources of wound infection?
8. Define entrocele; epiplocele.
9. What are the causese of hemorrhoids?
10. What are the causes of nonunion in simple fractures?

HYGIENE

1. How would you prevent the spread of smallpox in a hotel?
2. What directions should a practicing physician give to prevent the spread of whooping-cough?
3. What conditions of ill health make residence in high altitudes dangerous? Why?
4. State physical condition that makes the practice of taking a hot bath inadvisable.
5. What diseases are communicable to man through cow's milk?

MEDICAL JURISPRUDENCE

6. State causes for which a license to practice medicine can be revoked.
7. Describe the Harrison Act as it applies to the practice of medicine.
8. What do you understand by "Vital Statistics"? Their scope and purpose.
9. State what you understand by the term quarantine.
10. State method for post-mortem for death following abortion. How would you determine if criminal abortion?

ANSWERS.

OBSTETRICS.

1. The *true pelvis is bounded* in front and below by the symphysis pubis and the superior rami of the pubes; above and behind, by the sacrum and coccyx; laterally by the ischium and ilium.

2. Abortions occur most frequently at about the second and third months. *Paternal causes of abortion:* Syphilis, old age, precocity, debility, tuberculosis, alcoholism.

3. "*Puerperal eclampsia* is an acute morbid condition, occurring during pregnancy, labor, or the puerperal state, and is characterized by tonic and clonic convulsions, which affect first the voluntary and then the involuntary muscles; there is total loss of consciousness, which tends either to coma or to sleep, and the condition may terminate in recovery or death.

Preventive treatment: Every pregnant woman should be under the observation of a physician; her general health, hygiene, diet, and exercise must be supervised; the urine must be regularly examined every week or even every day, if necessary; the quantity of urine voided, the amount of solids, and the presence of albumin and casts are to be noted; the woman should report at once any headache, disturbances of vision or digestion, or edema; her blood-pressure should also be observed.

Treatment of pre-eclamptic toxemia: Hot baths, diuretics, calomel or salines, plenty of water to drink, irrigation of the colon, elimination from the diet of meat (the patient should be fed on milk, fish, green vegetables, chicken, etc.), the blood-pressure may be reduced by the use of veratrum, chloral, or nitroglycerin.

Treatment after convulsions have developed: Administration of an anesthetic, and emptying the uterus as promptly and safely as possible.

4. *Causes of prolonged labor:* Defect in the uterine muscle or its innervation, exhaustion of the uterus, twin pregnancy, hydramnios, hemorrhage, premature rupture of the membranes, uterine inertia, obstruction.

5. RUPTURE OF THE UTERUS. *Etiology:* Pathological conditions of the uterus, cicatricial tissue in the uterus, obstructed labor, contracted pelvis, malposition of the fetus, and violent operative procedures.

Treatment of rupture of the uterus: "After rupture has occurred, especially if it be 'complete' and extensive, and the child should have escaped, wholly or in great part, through the rent into the abdominal cavity, laparotomy should be done at once, child, placenta, blood clots, etc., being removed through the abdominal incision; then, peritoneal cavity cleansed with hot saline solution; the rent in the uterus repaired by suture; or in case of an infected uterus, or one that will not contract, or in which the rupture cannot be well secured, the entire uterus should be removed."—(King's *Obstetrics.*)

GYNECOLOGY.

1. The *broad ligaments of the uterus* are formed of a double layer of peritoneum passing from the surfaces of the uterus to the sides of the pelvis. Between the two layers of this ligament on each side are the Fallopian tube, the round ligament, the parovarium, the ovary and its ligament, uterine and ovarian vessels, nerves and lymphatics.

The *round ligaments of the uterus* are two cord-like bands, one on each side of the uterus, attached to the body of the uterus just below and in front of the entrance of the Fallopian tubes. Each ligament runs forward and outward, between the layers of the broad ligament to the side of the pelvis. It turns round the inferior epigastric artery and passes through the internal inguinal ring, into the inguinal canal, and out at the external inguinal ring, to become inserted into the labium majus.

2. The *ovaries* are two in number, and correspond to the testes in the male; they are of a flattened ovoid form, vertically placed in the posterior part of the broad ligament. By its anterior border the ovary is connected to the broad ligament, and by its lower pole to the uterus by a proper ligament, extending to the superior angle of the uterus, and called the *ligament of the ovary.* The lateral surfaces and posterior borders are free. The superior pole and posterior border are embraced by the Fallopian tube; on its inner surface it is in relation with small intestine in Douglas' pouch, and externally lies in a peritoneal fossa between the external and internal iliac vessels as they diverge. The vessels enter the hilum at the attached anterior border.—(*Aids to Anatomy.*)

3.

SUBSEROUS UTERINE FIBROID.	HEMATOMA AND HEMATOCELE.
1. No history of recent pregnancy.	1. Frequently history of previous pregnancy.
2. Slow, continued development.	2. Sudden development.

SUBSEROUS UTERINE FIBROID.	HEMATOMA AND HEMATOCELE.
3. Consistency, firm, rarely soft.	3. Consistency at first fluctuating, later doughy.
4. Sharply circumscribed tumor.	4. Ill-defined tumor.
5. Exploratory puncture negative.	5. Exploratory puncture —blood obtained.

—Findley's *Diseases of Women.*

4. *Amenorrhea* is absence of menstruation. It is *physiological:* Before puberty, during pregnancy and early-lactation, and after the menopause. It may also be due to: Absence or imperfect development of the generative organs; also to stenosis, obstructions, or atresia of the genital tract; also to operative removal of the uterus or its appendages. Other causative factors are: Acute infectious diseases, anemia, chlorosis, obesity, drug habits, alcoholism, overstudy, lack of exercise, exposure to cold, and various emotional causes.

5. CARCINOMA OF UTERUS. *Pathology:* Cancer of the body occurs in less than 2 per cent. of all cases. It is more frequent in nulliparæ than carcinoma cervicis, and tends to occur rather later in life than cancer of the cervix. The disease begins superficially or deeply in the mucosa. Epithelioma, malignant adenoma, adeno-carcinoma, and pure carcinoma are found, the latter being of the scirrhous or medullary type. In the malignant adenoma there is an atypical proliferation of the glands; they become folded up irregularly; the intervening connective tissue may be very scant, and the gland spaces may touch at points. They are lined with a single layer of columnar epithelium. In the adeno-carcinoma, parts may show the structure of the malignant adenoma, and parts that of the ordinary cancer where the loculi are filled with epithelial cells. These growths form swellings in the wall. When near the cavity, the mucosa may ulcerate over them. Gradually the uterus becomes excavated. Adhesions may form with adjacent structures, and secondary deposits develop in the peritoneum, ovaries, tubes, vagina, etc. The epithelioma may grow diffusely through the whole cavity, or as an isolated fungoid growth, which may become polypoidal. Metastatic nodules may form in different parts of the uterine wall. These tumors are covered with layers of polyhedral cells; very rarely pavement epithelium is found like that in ordinary epithelioma. The mucosa of the body gets thinned."—(*Webster.*)

Etiology of cancer of the uterus: "The causes of cancer are unknown; the predisposing or favoring conditions are as follows: (1) *Age*—the disease occurs most frequently between forty and fifty. The extreme limitations are between eight and seventy-six. (2) *Heredity*—an apparent predisposing cause. (3) *Social state*—more frequent among the poor and ignorant. (4) *Race*—relatively rare among negroes. (5) *Trauma of labor*—laceration of the cervix a possible predisposing cause. (6) *Endometritis* and *endocervicitis* are said to be favoring conditions."—(Dudley's *Gynecology.*)

SURGERY.

1. *Popliteal aneurysm* "occurs almost invariably in men, constituting a pulsating tumor in the ham, rendering the knee painful and stiff, and so much do the symptoms resemble those of chronic rheumatism that in every such case the popliteal space should be examined. The limb is usually kept semiflexed, and the aneurism often increases rapidly in size. If the main swelling is situated to the front of the vessel, there is some likelihood of the knee-joint becoming implicated, and neighboring bones carious; when it extends posteriorly, diffusion is not uncommonly followed by gangrene, on account of the pressure exercised, not only upon the vein, but also upon the articular branches of the popliteal artery, which are most important factors in maintaining the collateral circulation. The *diagnosis* has to be made from chronic enlargement and abscess of the popliteal glands, but in these there is less disturbance of the circulation in the foot; from bursal tumors, by their want of mobility and pulsation; or from solid tumors, *e.g.* pulsating sarcoma of the femur or tibia, by attention to the general principles already enunciated."—(Rose and Carless' *Surgery.*)

2. In the fracture of the neck of the femur, the head of the femur will be found in the acetabulum; in dislocation, the acetabulum will be empty, and the head of the femur will be found elsewhere, e.g., on the dorsum of the ilium. In the fracture, crepitus *may* be elicited; in the dislocation, never. In the dislocation, there is inversion and a fixed position of the limb, both of which are absent in fracture. In fracture there is shortening and outward rotation.

3. Acute intussusception is most common in children. It begins suddenly with severe abdominal pain and vomiting. Blood-stained mucus is passed, perhaps with tenesmus. Collapse soon comes on, and may be fatal in twenty-four hours; otherwise death occurs in a few days from peritonitis. In most cases a "sausage-shaped" tumor can be felt, usually along the course of the colon, but lower down, or just above the pubis. The right iliac fossa feels empty. A natural cure may follow, but rarely, from sloughing of the intussusceptum, whilst the peritoneal cavity is protected by adhesions uniting the entering and ensheathing layers.—(*Aids to Surgery.*)

4. CEREBRAL ABSCESS. — *Etiology:* "Pyogenic infection is the cause in all cases, and the commonest method is by spreading from chronic otorrhea. Other cases are traumatic in origin, as in septic compound fractures and penetrating wounds, the frontal and parietal lobes being then chiefly affected. The commonest seat of abscess in the brain, due to middle-ear disease, is the cerebellum. The next most common seat is the temporo-sphenoidal lobe. The suppuration may extend directly through the tegmen tympani, the membranes and brain becoming first adherent to it; but usually there is a healthy area of brain intervening, so that the extension of infection has been along the course of vessels and lymphatic sheaths running between the brain and the middle ear. Similar abscesses rarely follow suppuration in the frontal, sphenoidal, and ethmoidal sinuses, and thrombosis of the cavernous sinus. Pyæmic and chronic tuberculous abscesses also may occur. An abscess in the brain is usually chronic, but terminates in compression, either from the onset of spreading œdema or rupture into one of the lateral ventricles.

"The *symptoms* in traumatic cases are acute and, as there is usually diffuse meningitis, there is intense pain, fever, and rigors, coma quickly supervening. In the more common chronic cases the symptoms are often vague in the early stages, but when well marked consist in signs of intracranial pressure. 1. The *headache* and tenderness are severe and localized to the site of the abscess. 2. The *temperature* is subnormal, unless there is associated meningitis. 3 The *pulse* is markedly slowed, even down to 30 or 40. 4. The patient is quite intelligent, but *cerebration* is very slow; vomiting and optic neuritis are usually present. 5. *Motor symptoms* may occur if the abscess is in the anterior part of the temporo-sphenoidal lobe, either irritative or paralytic. If the cerebellum is affected, there is giddiness both while walking and lying down, together with weakness of the hand grip and increase in the knee jerk on the side affected. Lateral nystagmus often occurs.—(*Aids to Surgery.*)

5. ACUTE INFECTIVE OSTEOMYELITIS.—"*Symptoms:* The disease begins with a rigor, high temperature, and severe pain. The part becomes swollen, infiltrated, and congested, with distended veins over it. The pulse is rapid and small and the tongue dry, and delirium soon comes on. It should be distinguished from acute rheumatism by the fact that the interarticular and not the articular region is affected. Fluctuation can be detected if the bone be superficial, or the abscess may burst on the surface. The bone is then found to be bare over the extent of the abscess cavity. When the bone is deeply seated or the disease confined to the medulla, the swelling is later in evidence, but the pain and toxemia are very severe, and the child may die from this before local signs show themselves. When the epiphysis is attacked, septic arthritis often quickly follows, and a loose flail joint may result."—(*Aids to Surgery.*)

6. *Conditions which justify amputation of a limb* are: "Any injury, disease, or malformation rendering reten-

tion of the limb incompatible with life or comfort; avulsion of limb; compound fracture; compound dislocation; fracture with great comminution of bone; laceration of important vessels; extensive contusion; extensive laceration; gunshot injuries; aneurysm; effects of heat and cold; gangrene; extensive bone disease; tumors; elephantiasis; tetanus; snake bite; deformities."—(Bickham's *Operative Surgery.*)

7. *The sources of wound infection*, are: The clothes, skin, hair, and sweat glands of the patient; the hands of surgeon, nurse, or friends; the dressings and instruments which come in contact with the wound; the mouth, teeth, intestinal, respiratory, and genital tracts of the patient.

8. An *enterocele* is a hernia which contains a part of the intestine.

An *epiplocele* is a hernia which contains omentum.

9. *Hemorrhoids are due* to dilation of hemorrhoidal veins, pressure, constipation, pregnancy, pelvic and abdominal tumors, stricture of rectum, cirrohosis of liver.

10. *Nonunion of fracture is caused by:* Ill health, want of approximation of the end of the bone, want of blood supply in the bone, defective innervation of the bone, disease of the bone, lack of rest, and immobility.

HYGIENE.

1. *To prevent the spread of smallpox in a hotel:* The patient should be isolated and strictly quarantined. All who have been in contact with the patient since the eruption must be vaccinated unless they have been vaccinated within one year. Those who refuse to be vaccinated must be quarantined for 20 days. The case must be reported to the Board of Health, and its orders must be carried out.

2. *To prevent the spread of whooping cough:* "The prevention of the disease consists in keeping the sick at least five feet away from the non-immunes. There is only a slight chance of infection after a patient has been isolated three weeks. The disease is not extremely infectious, and less than a third of exposed children catch it. The complete prevention depends upon the recognition of all cases before the whooping stage, for the bacilli are expelled for days before the whooping begins. When whooping cough is epidemic, it is necessary to isolate every child with a cough or apparent cold in the head."—(Overton and Denno's *Health Officer.*)

3. *"The contraindications to the high altitude resorts* are: (1) Advanced age; (2) the septic state, in which the disease is active and pyrexia constant; (3) double cavities with or without pyrexia; (4) cases in which there is great irritability of the nervous system; (5) diseases of the liver, kidney, or heart; (6) diabetes; (7) great loss of pulmonary tissue; (8) emphysema." (*Reference Handbook of the Medical Sciences*). The atmospheric pressure is diminished, and the air is rarefied.

4. *Physical conditions that make the practice of taking a hot bath inadvisable:* Organic diseases of the heart and brain, aneurysm, acute inflammations, and tuberculosis.

5. *Diseases which are communicable to man through cows' milk:* Typhoid, tuberculosis, scarlet fever, diphtheria, and septic sore throat.

MEDICAL JURISPRUDENCE.

6. *Causes for which a license to practise medicine can be revoked, in New Jersey:* "Chronic and persistent inebriety, the practice of criminal abortion, conviction of crime involving moral turpitude, or for publicly advertising special ability to treat or cure chronic and incurable diseases, or where any person shall present to the board any diploma, license, or certificate that shall have been illegally obtained or that shall have been signed or issued unlawfully or under fraudulent representations."

7. *The Harrison Act, as it applies to the practice of medicine*, provides that physicians must keep a record of all drugs dispensed or distributed which contain opium or coca leaves or their salts or compounds or derivatives or preparations; this record must show the amount dispensed or distributed, the date, the name and address of the patient, except in the case where the physician is personally attending such patient at the time; these records are to be preserved for two years; and the physician must be specially registered under the Harrison law.

8. *Vital statistics* is the science of figures applied to the health history of countries, and the study of the laws that govern the physical conditions of mankind. It deals with births, marriages, and deaths, the diseases from which people die or suffer; and it takes into consideration age, sex, and occupation of individuals. It gives information as to the health of the people and the good or evil conditions affecting them; it shows the fatality of different diseases at different ages; and it indicates the influence of professions, trades, locality, and age on the well being of a community.

9 By the term *Quarantine* is understood "the adoption of restrictive measures to prevent the introduction of disease from one country or locality into another."

10. It may be impossible to determine whether the woman had died from the effects of a criminal abortion. The vagina and uterus should be examined for marks of injury by the use of instruments. Wounds on the walls of the vagina would indicate the use of instruments, most probably by an inexperienced hand; while perforations of the neck of the womb, and sometimes of its fundus, indicate the use of pointed instruments, very possibly in the hands of a professed abortionist. In some instances a blunt instrument, such as a catheter, is employed; and the instrument may pass up between the membranes and the uterine walls, and tear the placenta, producing internal hemorrhage, and ending fatally. In cases of instrumental violence there will frequently be discovered marks of metritis and peritonitis. The stomach and bowels should likewise be carefully inspected for signs of irritant poisons (abortives), such as redness and the remains of the various reputed abortives, as powdered cantharides, savin, ergot, etc.; also for the oils of savin, tansy, pennyroyal, etc.; the latter may sometimes be recognized by the odor, or they may be separated by distillation or by ether.—(From Reese's *Medical Jurisprudence.*)

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

NEW BOOKS AND OLD.

XIX. MISS BRIGHTWELL'S LIFE OF LINNÆUS.

BY JOHN RUHRÄH, M.D.,

BALTIMORE, MD.

ALL of us, I suspect, have our intellectual Yarrows yet unvisited. I have many, but up until late two in particular obsessed me. One, Linnæus, whose abbreviated name is so familiar to everyone doing any scientific reading whatever, and the other Plimsoll, not a physician at all, but the originator of the loading lines so fascinatingly displayed on the sides of freight-carrying vessels and so familiar to all travelers by sea. Of the second gentleman who was not a physician I shall have nothing to say, but concerning Linnæus my curiosity got the better of me and I turned to a short biography written by Miss Cecilia Lucy Brightwell of Norwich, and published in 1858. This little volume was written for the layman rather than the physician, and it is small enough to be read in an hour or a little more. It gives one a very good idea of the botanist-physician whose name is well-nigh imperishable through the many plants which he named during his long years of botanical investigation.

Carl Linnæus descended from a line of peasant ancestors whose name is reputed to have its origin in the name of a remarkably fine linden tree growing near their native place. His father was a minister in Stenbrohult on the banks of Lake Möklen. Carl was born in 1707 and was destined for the ministry, but his strong love of botany, which developed in early childhood, led him to prefer scientific studies. While still a student of the gymnasium he started a library on his favorite subject, and he mentions owning at this time *Chloris Gothica* of Bromelius and Rudbeck's *Hortus Upsaliensis*. His father was in despair and was on the verge of placing him as an apprentice to some tailor or shoemaker when a conversation with Dr. Rothman, the provincial physician and also a lecturer in physics, led to young Carl's entering the doctor's house for the remaining year of his studies.

In 1727 Linnæus entered the University at Lund, where he lodged in the house of Dr. Stoboeus, professor of medicine, where he was soon accorded many favors. During the summer vacation his former benefactor, Rothman, persuaded him to quit Lund for Upsala, much to the disgust of Dr. Stoboeus. Without a protector and always very short of funds, he was reduced to great poverty. Chance led to an acquaintance with Dr. Olaf Celsius, who soon after offered him board and lodging in his own house and allowed him the full use of his library, which was very rich in botanical books. When he was about twenty-two the idea of a systematic botanical classification dawned upon him and gradually was worked into a state of high perfection. An essay on the sexes of plants led to his being appointed to lecture in the botanical garden as an assistant to Dr. Rudbeck, who afterward engaged him as a tutor to his children. Here he began his *Bibliotheca Botanica*, *Classes Plantarum*, *Critica Botanica*, and *Genera Plantarum*. These works were completed some seven years later and published during his stay in Holland.

His way, while smoother, was not without its difficulties, and certain enmities and rivalries led to his undertaking a journey into Lapland. Rudbeck, his benefactor, had made one scientific expedition into Lapland, but the results of his work were destroyed in the fire at Upsala in 1702. Early in 1732 Linnæus started on his perilous journey, traveling over the greater part of Lapland, following the boundaries of Norway and returning to Upsala by the eastern side of the Gulf of Bothnia. This was a journey of nearly four thousand English miles, which he covered chiefly on foot, suffering untold hardships and privation, but from a scientific standpoint it afforded him most satisfactory results in that he collected about one hundred plants which he described for the first time. He gave an account of this expedition in a work entitled *Lachesis Lapponica*, which was subsequently translated into English and which contains graphic accounts of some of his adventures.

Linnæus had a habit of affixing the names of his friends to various plants. His own name he gave to a modest little flower found in great abundance in West Bothnia, which he called "Linnæa borealis."

On this journey he learned the art of assaying from a chance companion and on his return to Upsala started a private course of lectures on this subject which secured him a number of pupils.

His old enemy, Rosen, again used his interest to thwart the endeavors of Linnæus, so that he later turned his attention to mineralogy with such zeal that he was chosen by the Governor of Dalecarlia to head a commission to investigate the products of that province.

About this time, when he was twenty-nine, he became betrothed to the daughter of Dr. John Moroeus. The young lady's father made the young couple wait three years rather than have the girl marry a penniless student.

He now decided to study medicine, and, having procured about £15, set out on his way to the University of Harderwyck. He journeyed through the southern provinces of Sweden, thence to Lübeck and to Hamburg, thence to Amsterdam and he finally reached Harderwyck, and, after undergoing the necessary examinations, he obtained his degree on June 23, 1735, at which time he published and defended a thesis on the "Causes of Intermittent Fever." This he dedicated to his friends, and, remarkably enough, added among the names that of his old enemy, Rosen. While in Holland he met Gronovius, who was so delighted with his *Systema Naturæ* in manuscript that he had it printed at his own expense. On the advice of Gronovius, Linnæus called on Boerhaave, who, in showing the botanist his garden, was so struck with his knowledge of botany that he advised him to remain in Holland. Through Boerhaave he met Burmann, professor of botany in Amsterdam, and remained as his guest until the following year. During this period he printed his *Fundamenta Botanica*, thirty-six pages in the form of aphorisms. While the guest of Burmann he met Clifford, a wealthy banker, who possessed one of the finest gardens in the world. He employed Linnæus to arrange and describe his collection, and during the period which he remained with this patron he lived, as he himself

stated it, "like a prince." In 1736 Linnæus, still in the employ of Clifford, paid a visit to England for the purpose of securing botanical novelties for the collection. At Oxford he met the botanist Dillenius, with whom he spent a month, after having first met with scant courtesy.

Linnæus possessed singularly agreeable manners and a personality which enabled him to make friends. It is a mystery how he managed to get along so well, for he knew only his own language, did not learn Dutch, though he lived in Holland three years, and had to depend upon Latin for his intercourse with his scientific friends. But, despite this fact, he had a large circle of friends and correspondents, including Miss Jane Colden of America.

On his return to Holland he superintended the production of *Hortus Cliffortianus*. This was a magnificent work, describing the Clifford possessions. During this time he also saw some of his other works through the press. Overwork so undermined his constitution that he was taken with homesickness and decided to leave for Sweden, but before returning he paid a visit to Paris and on his journey he traveled through various parts of Germany and paid a visit to Haller at Göttingen. He went to Stockholm in September, 1738, and there he started the practice of medicine and underwent the usual painful period of probation, but soon, through a fortunate cure, he was introduced into a remarkable practice which kept him busy from four in the morning until late in the evening. During this time he was made a member of the Upsala Academy, the only one then existing in Sweden, and he was one of the founders and first president of a literary society in Stockholm. Through the interest of Count Tessin a salary of two hundred ducats per year was given him, with the understanding that he was to give public lectures on botany and mineralogy. This same generous person obtained for him, as Linnæus himself states, "a salary from the states, the appointment of physician to the Admiralty, the professorship of botany at Upsala, the title of dean of the college of physicians, the favor of two kings, and recommended me by a medal to posterity." Emboldened by his unusual success, he now persuaded Moroeus to consent to his marriage, which took place in 1739.

With Haller he had had some correspondence and he learned that this worthy scientist was about to oppose his new system. Linnæus, therefore, wrote to Haller, begging him to desist. Part of his letter ought to be placed on the desks of all the medical controversialists:

> What man (he asks) was ever so learned and wise, who, in correcting others, did not now and then show he needed correction himself? Something always sticks to him. I dread all controversies. Who ever fought without some wound or hurt? Time is too precious; and can be far better employed by us both. Besides, the serious contentions of our time may, fifty years hence, seem to our successors no better than a puppet-show; let there be peace between us!

Shortly after his marriage the death of Rudbeck vacated the chair of botany at Upsala. Linnæus was a candidate for the position, but it was given instead to his former rival, Rosen. Shortly after, however, Linnæus was appointed to the chair of medicine in the same university and made a private arrangement with Rosen by which he obtained charge of the Botanic Garden and the whole department of natural history. The Botanical Garden had fallen into decay. Formerly it had been in the most flourishing condition, but the fire of 1702 had almost entirely done for it. Under Linnæus it became the equal, if not the superior, of any botanic garden in Europe, and it was here that Linnæus lived in the old house that had been built by the Rudbecks. In 1745 he published the first edition of his *Flora Suecica* and in the following year the *Fauna Suecica*.

Linnæus as a lecturer attained great success; his hall before many years was filled to overflowing. He lectured on natural history, the medicinal properties of plants, dietetics, and, of course, botany. He attracted large numbers of students to the university, and its fame spread throughout Europe and even to America. During the period preceding his residence the average number of students was 500. This was increased to 1,500, but subsequently, after the death of Linnæus, the number gradually fell off to the usual 500. Through his interest a large number of young men started out on scientific expeditions, but misfortune and death attended almost all of these adventurers. His fame now spread through the entire scientific world, and he was made a member of most of the learned societies of Europe. In 1746 a gold medal of him was struck by some of his friends, and the year after he was made Dean of the College of Physicians.

His medical writings consist of a *Materia Medica*, published in 1749 for the use of his students, and two other works, the *Genera Morborum* and *Clavis Medicinæ*. An attack of gout, which he attributed to fatigue from overwork, led him to write the *Philosophia Botanica*. He believed he was going to die, and dictated this volume to a pupil who sat by his bedside ready to write down whatever the master had to say between his attacks of pain. He recovered, however, and continued his work in a most indefatigable manner.

In 1754 he published a large folio volume containing descriptions of rareties from the king's collection, which led to his being given the Order of the Polar Star, the first time such an honor had ever been conferred for literary merit. Shortly afterward the King of Spain invited him to Madrid, with the offer of pension for life, letters of nobility, and the free exercise of his religion. After he received his patent of nobility in Sweden he changed his name to Von Linné. The helmet which surmounted his crest was adorned with a spray of his own flower, *Linnæa*, and the motto on his coat-of-arms was "*Famam extendere factis*."

His masterpiece, the *Species*, was published in 1754, a remarkable work which contains a description of every plant known at the time it was published, arranged according to his own classification.

During the last fifteen years of his life he resided in summer time on an estate which he purchased at Hammarby in the environs of Upsala. In many ways a modest scientist, as Miss Brightwell says: "Linnæus's foible was vanity and inordinate desire of fame. This is nowhere more strikingly seen than in the pages of his diary . . . drawn up by him for the use of his intimate friend, Dr. Menander, Archbishop of Upsala, to serve as materials for a history of his life."

In 1764 he had an attack of pleurisy for which he was treated throughout by his old enemy, but now friend, Rosen, but he recovered from this, though he gradually began to fade, and some years later, in 1772, he resigned his office of rector of the university. On this occasion he gave an oration "On the Delights of Nature." In the spring of 1774 he had an attack of apoplexy, while lecturing in the Botanic Garden, which led to his giving up all active duties. Two years later a second attack paralyzed his right side and left him very much impaired as to his mental powers, but he lingered on until January 10, 1778, having rounded out a little more than the three score and ten.

His library and museum were eventually sold as a whole by his widow to Sir J. E. Smith for the sum of £1,029. This happened while the King of Sweden was away, and it is recorded that a vessel was dispatched by the Swedish Government to intercept the ship which was carrying away the treasures. The collection, however, reached England in safety, where it was eventually turned over to the Linnæan Society.

Such is the story of the father of botany, a life that is a record of great achievement and an inspiration for all followers of science.

The "Vinegar of the Four Thieves."—Boinet gives a brief account of this ancient remedy in *La Presse Médicale* for July 30, 1921, xxix, 61. Attention had recently been called to it in connection with the anniversary of the plague of Marseilles in 1721 which destroyed 50,000 citizens. Despite this fearful mortality the vinegar obtained considerable repute as an antipestous remedy. The formula given by the author of the article in question was not authentic. He took it from the Codex of 1758 which gives a formula entitled *"Acetum antisepticum vulgo des quatres voleurs."* This comprised wormwood, rosemary, rue, lavender, and numerous other aromatics. But this is not the true and original formula. Boinet is able to quote the earlier and authentic one as used in the Marseilles epidemic. It is indeed not so dissimilar to the one already given; some ingredients are identical while others belong to the same general class. The authentic formula orders a handful each of wormwood, queen of the meadow, wild marjoram, and sage, fifty cloves, two ounces each of elecampane, angelica, rosemary, and hoarhound, and one ounce of camphor. These are digested for 15 days in three pints of strong white wine vinegar, strained, and tightly bottled. When one is about to be exposed to the plague the vinegar should be rubbed on the temples, neck, ears, and hands. The Codex of 1758 modified the formula, adding rue, garlic, and other substances and omitting some. The name was derived from the fact that four thieves as a result of the use of this preparation, became immune enough to steal right and left from the houses of the plague-stricken. While they originally might have sung "we are four," their numbers were soon greatly augmented. It is quite obvious that the benefit was obtained by keeping away the infected fleas which are now known to transmit the disease. The formula was officially made public at the time of the epidemic by the alderman of Marseilles.

Ancient Lyons Surgeons.—The city of Lyons was during the Middle Ages the gateway between Southern France and Italy, and as such became a good town in which to practise medicine, despite the absence of a university. When the great Lanfranc was banished from Milan in 1280, he went first to Lyons where he practised surgery for a considerable period. Two hundred years later, or soon after the invention of printing, his book on surgery was first translated into the French idiom by a local surgeon, Maitre Yvoire.

The justly celebrated successor of Lanfranc, Guy de Chauliac, practised medicine and surgery in Lyons for the greater part of his life. He only left, in 1348, to accept the appointment of first physician to Pope Clement VI, at Avignon. He died in his home town in 1368, leaving the reputation of being the "Father of French Surgery," a title also conferred unofficially two centuries later on Ambroise Paré. He fought always for the betterment of surgery.

The barber-surgeons were most contemptuously regarded by the physicians of the day, and the latter cunningly saw an opportunity for nonattendance on plague cases by throwing the work upon the barber-surgeons. During the epidemic of bubonic plague in 1628 the physicians stated in substance that since the victims required venesection and the lancing of buboes, it was clearly a case for the barber-surgeons, who normally attended to these minor interventions. The result was that of the 150 barber-surgeons of Lyons at least 70 perished from the disease during the space of two months. In the same year the master surgeon Louis Panthiot, performed a cesarean section and saved mother and child. In doing this operation he faced excommunication, but seems to have escaped it. The other surgeons of the day, even Paré, had pronounced the operation invariably fatal.

This case did so much to raise the status of the surgeon that it was not long before the position of chief surgeon to the Hotel-Dieu came to be regarded an honor.—*Le Progrès Médical.*

History of the Paris Medical Faculty.—Charlemagne originated a movement for medical instruction, evidently on a very small scale, and the original faculty was established in 1270. Originally both teachers and pupils were ecclesiastics. The dissociation of Church and State was not complete until 1452 when medical men were for the first time allowed to marry. For centuries there were no special buildings. Students sat on the ground or on bundles of straw while the teachers interpreted Hippocrates and Galen. In the XVIII century arose the College of Surgeons, a body of workers which was a distinct advance over a body composed of mere rhetoricians. A fierce quarrel arose between these factions and persisted until the King gave the precedence to the medical faculty by lowering the grade of the surgeons, the latter having the status of "demonstrators" and being forbidden to wear the gown. In the Revolution both bodies were suppressed and the *École de Santé* was created, which included both medical and surgical professors. Napoleon changed the title of the school to Faculty of Medicine. The 12 chairs of 1808 have now increased to 42.—*Gazette des Hôpitaux.*

CASES OF GALL-BLADDER LESIONS STIMULATING OTHER AFFECTIONS OF THE DIGESTIVE TRACT.*

BY MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE AT THE NEW YORK POSTGRADUATE MEDICAL SCHOOL.

GALL-BLADDER lesions have been of late more frequently recognized than formerly. This is due to our advanced methods of diagnosis.

In gallstones a typical history (short severe attacks of pain in the upper abdomen, usually radiating to the back and the right shoulder with long intervals of freedom) is of prime importance and frequently sufficient to make a probable diagnosis. An *x*-ray picture of the gall bladder and discovery by it of shadows in this region is of great assistance. The newest aid is the direct examination of the bile as obtained from the duodenum in the fasting condition. In most instances of a pathological gall bladder abnormal conditions will be discerned in the bile bearing testimony of disease. The main features are turbidity of the fluid and (microscopically) mucus, pus corpuscles, bacteria, numerous cholesterin and calcium bilirubin crystals.

Some of the gall-bladder lesions run in disguise and simulate other affections. In this paper I shall describe three cases, one that resembled cancer of the stomach, another that typified duodenal ulcer, and a third in which a diagnosis of intestinal obstruction had been made, by competent physicians. In all these cases the correct diagnosis had been established before the operation by the direct examination of the duodenal contents, showing the importance of this method of examination.

I may be allowed to describe these three cases which I have observed within the last six months:

CASE I.—March 20, 1921. Mrs. Louise C., 50 years old, complains of epigastric distress and vomiting. The previous history is as follows: In November, 1920, the first symptom was rather sudden vomiting of food almost immediately after taking it. There was very little nausea preceding the ejection of everything that was taken. After the stomach was empty the patient could return to the table and eat food which at times was retained. At the beginning the patient was awakened frequently with a sudden desire to vomit—liquids only, but not food. The patient usually vomited a tumblerful of liquid. This brought immediate relief and the patient went back to sleep at once. After being placed upon a diet for two to three months, the symptoms were alleviated somewhat but vomiting persisted at intervals. Later on the patient developed a gnawing sensation when hungry, which was relieved by drinking hot milk (hunger pain). At times there was a feeling as though the food was not passing down properly, and a sensation of a lump in the chest. These symptoms persisted until the patient was admitted to the hospital. The loss in weight was 30 pounds in five months.

Present condition: The examination of the abdomen reveals a somewhat dilated stomach and slightly enlarged liver. The swallowing sound is absent. Examination with a bougie (43 F.) reveals a resistance at 16 inches from the lips.

A diagnosis of stricture of the cardia was made, and it was necessary to ascertain whether we had to deal with a neoplasm or with a spasmodic contraction of the cardia.

In order to elucidate this point the duodenal bucket was given after previous administration of atropine. The bucket passed the cardia and pylorus, showing bile at the string from 24 inches downward and no blood stains.

Patient was put on belladonna medication and subjected to the routine examinations.

The gastric contents, after an Ewald-Boas test breakfast, revealed: HCl =0; acidity = 4; rennet absent, no blood, no lactic acid; in the fasting condition the stomach was empty.

The duodenal contents obtained in the fasting condition on April 9, were dark yellow and slightly turbid; they contained cholesterin and calcium bilirubin crystals, mucus, bacteria, and all the pancreatic ferments.

The *x*-rays showed a dilated stomach and a filling defect in the pyloric portion.

The urine was negative and the blood showed a secondary anemia.

Taking into consideration the comparatively short period of disease about 4 or 5 months, the steady persistence of symptoms, and the great loss of weight (30 pounds), the possibility of malignancy had to be thought of. The dysphagia, although due to cardiospasm, did not exclude a neoplasm of the stomach—which is rather a frequent occurrence in the latter condition. The *x*-ray, likewise, did not exclude malignancy. The duodenal contents examination and the gastric analysis rather pointed toward a benign condition, namely: cholecystitis with the possibility of stones and achylia gastrica and cardiospasm as secondary conditions.

An operation for the removal of the gall bladder and a thorough exploration of the abdominal cavity appeared to be the correct procedure to pursue. After a consultation with Dr. Hynes, who kindly referred the patient to me and Dr. Willy Meyer, we all agreed on the above procedure.

Dr. Willy Meyer operated upon the patient April 9, 1921. The gall bladder was found adherent to the liver and duodenum, and contained very turbid bile and innumerable small, black stones of poppy-seed size. The latter could not be discovered by palpating the bladder with the fingers.

After opening the vesicula fellea these tiny stones were discovered (see Fig. 1). No neoplasm was found, and patient made an uneventful, smooth recovery. She enjoys perfect health now.

CASE II.—July 2, 1921. Fred. K., 51 years old, complains of epigastric pain.

Previous history: Had "inflammation of the bowels" fifteen years ago; otherwise no serious illness or operation.

Present illness began two years ago. Patient has

*From the Lenox Hill Hospital, New York.

had since then attacks of pain two or three hours after meals. These attacks would come periodically, varying from once a month to two or three times a week. The pains were located in the epigastrium and were relieved by taking food or bicarbonate of soda. The past three months the patient has been getting worse and

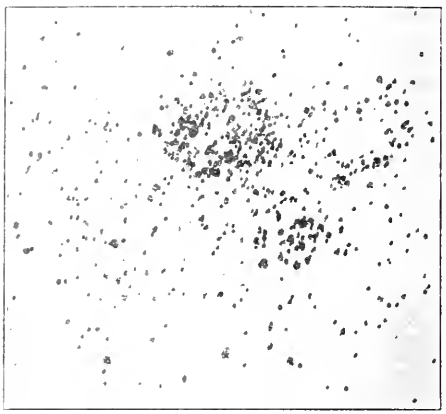

Fig. 1.—Small black poppy seed-sized concretions found in the gall bladder of Mrs. Louise C. 1½ natural size.

the attacks became more frequent. Patient was usually awakened at night by the pain. He never vomited, but belched gas continually. No blood was ever seen in the stools. The patient noticed his skin was yellow tinged before having the pain.

Physically the man was very well developed. Examination of the head, neck, heart, and lungs was negative. There was slight rigidity over the abdomen. There was no mass palpable and there was no tenderness over the gall-bladder region. The liver was slightly enlarged. At times McBurney's point was painful on pressure.

Gastric contents: HCl-; acidity =30; duodenal bucket test negative. There is bile on the string

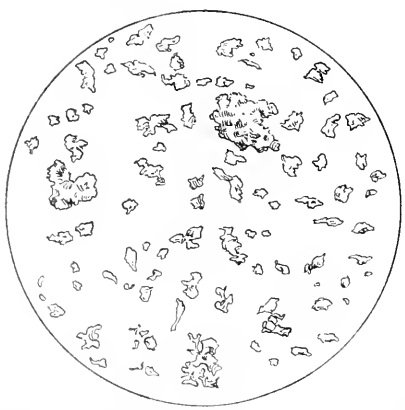

Fig. 2.—Harry B., March 24, 1921. In the fasting duodenal contents were found numerous cholesterin crystals of small and large sizes.

below 23 inches and no blood stains, indicating permeability of the pylorus and no signs of ulceration. The duodenal contents were examined on August 18, 1921, in the fasting condition, with the following result: Dark green, yellow, turbid; fatty acid and cholesterin crystals, mucus and pus cells; alkalinity =25; A = 6; S = 1; T = 2. The blood showed a leucocytosis of 10,000 white blood cells and 79 per cent polynuclears. The patient has lost considerably in weight (about 25 pounds).

Before he consulted me a diagnosis of duodenal ulcer had been made by his previous physician, principally

Fig. 3.—Big stone found in Harry B. on March 23, 1921, tightly closing up the cystic duct. Natural size.

based on the symptoms of hunger pain a few hours after meals. Taking into consideration the severity of the cramps at definite long intervals, and the result of the direct examination of the bile, a diagnosis of a severer form of cholecystitis, with the possibility of stones, was made. A chronic appendicitis was also assumed to be present.

Dr. Semken operated upon the patient August 22, 1921. The stomach and duodenum were thoroughly explored, and no evidence of ulcers or any other gross pathology was found.

The gall bladder was small, walls thickened, neck strictured; the mucosa showed a few superficial ulcers covered in places with yellowish looking dots of poppy-seed size, which were soft in character; in other places the mucosa was covered with mucus. The appendix was strictured and contained a few fecal concretions. Both appendix and gall bladder were removed.

A particle scraped with forceps from the roughened surface of the mucosa of the gall bladder showed cholesterin and calcium bilirubin crystals and mucus.

The patient made a good recovery.

Case III.—March 9, 1921. Harry B., 39 years old, was taken ill seven days ago with a severe attack of abdominal pains, accompanied by nausea. The attack lasted ten hours and was followed by vomiting for a whole hour. The pain was cramp-like in the abdomen and radiated posteriorly. There was also constipation, and the abdomen was considerably distended. There were repetitions of these symptoms extending over the seven-day period. The patient had never had any similar attacks before. The physician in charge made a tentative diagnosis of intestinal obstruction and sent

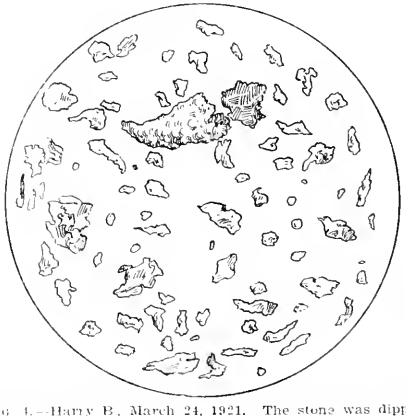

Fig. 4.—Harry B., March 24, 1921. The stone was dipped in water and drawn under some pressure over an ordinary slide. Microscopically big and small cholesterin crysta's were found resembling in detail those shown in Fig. 2.

the patient with this diagnosis to Dr. Willy Meyer's ward at the Lenox Hill Hospital. This eminent surgeon was not satisfied with the above diagnosis, and asked me to investigate the gall bladder and the gastro-intestinal tract.

I found the following: Abdomen slightly distended;

liver somewhat enlarged; lower border painful to pressure; McBurney's point likewise was tender to pressure; no muscular rigidity. The gastric contents revealed: HCl=46; acidity =81. The blood count did not show anything abnormal.

The duodenal contents were obtained in the fasting state on March 21, 1921: Pea soup appearance, yellow, turbid; alkalinity =10; 20 c.c. Microscopically, numerous cholesterin crystals of small and large sizes were found (see Fig. 2).

A diagnosis of cholecystitis, most probably due to stone, and chronic appendicitis was made. The patient was operated on March 23, by Dr. Willy Meyer. The cystic duct was tightly closed by a big stone (see Fig. 3), so that nothing could leave or enter the gall-bladder. After opening the latter the contents were found to have a reddish appearance and consisted of pus and red blood corpuscles mixed with mucus, without any bile.

A cholecystectomy and appendectomy were performed.

The pathological diagnosis was: Chronic hemorrhagic cholecystitis, cholelithiasis, chronic appendicitis. Culture of the bile was sterile.

The solitary stone was dipped in water and then drawn under some pressure over an ordinary slide. The microscopical examination showed big and small cholesterin crystals (see Fig. 4), resembling in almost every detail Fig. 2.

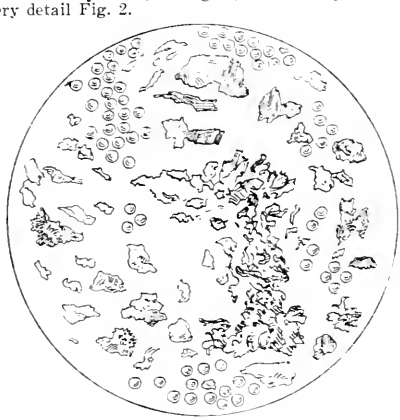

FIG. 5.—In the fasting duodenal contents of Morris E., March 3, 1921, were found numerous small and big cholesterin crystals and some pus corpuscles.

This shows the great importance the microscopical examination of the bile occasionally has with regard to diagnosis.

Although already mentioned in another place' I would add here that this particular case furnished a direct proof of the incorrectness of Lyon's theory that the dark bile frequently appearing after magnesium sulphate injection into the duodenum is "gall-bladder" bile. For in this particular case on March 21, two days preceding the operation the magnesium sulphate had been instilled into the duodenum and after a while a very dark bile was obtained, which looked characteristic of "gall-bladder bile." As it is evident from the findings at the operation the gall bladder did not contain bile at all, and was filled merely with pus, mucus, and blood. The dark reaction, therefore, was not due to the gall bladder but to the liver.

I speak of it here again, as it shows the importance of the examination of the fasting specimens, in preference to magnesium sulphate instillation.

Remarks.—Case I, Louise C., resembled cancer of the stomach in a great many aspects. The examination of the bile, however, in conjunction with the duodenal bucket string test pointed toward a gall-bladder lesion, which proved to be correct.

A few years ago I observed a similar case in whom in one of the best hospitals in New York City a diagnosis of cancer of the stomach had been made. A renewed examination under my care in the Post-Graduate hospital showed, however, that we had to deal with a gall-bladder disease and probably stones, which an operation by Dr. Willy Meyer revealed as correct. The gall bladder was found filled with over 200 small stones. No other disease was discovered at the operation, and patient made a good recovery and is still enjoying good health, five years after the operation.

Although cancer of the stomach is pretty easily recognized, the possibility of gallstones masquerading in disguise must be thought of, especially if there is no distinct tumor present and other signs of a neoplasm of the stomach are lacking.

Case II., F. K., resembled a case of duodenal ulcer; recurrent pains a few hours after meals, "hunger pains"; frequent attacks of gastralgia at midnight; the pains frequently of a severe character; long periods of intermission. Both the string test and the direct examination of the bile pointed to a diseased gall bladder. The operation fully confirmed this diagnosis.

Case III., H. B., likewise, did not present any distinct symptoms of gall bladder disease. As mentioned above, intestinal obstruction had been diagnosed by the family physician. The direct examination of the bile, however, indicated that the gall bladder was the seat af the trouble, which the operation confirmed.

All three cases then show the great importance we must attribute to the direct examination of the bile. The essential points are, if I am permitted to repeat it again, turbidity of the fresh bile, and the finding microscopically of mucus, pus corpuscles, numerous bacteria, and considerable quantities of cholesterin and calcium bilirubin crystals.

The presence of numerous large cholesterin crystals seems to indicate the presence of stones. In some of the cases slight scraping of the stone found at the operation gives a microscopic picture resembling very much the results encountered in the duodenal contents.

The question arises, are these numerous and considerably large cholesterin crystals a positive proof of gallstones or can they be met with without the actual presence of stones?

Before answering this question the following case may be briefly sketched:

CASE IV.—Maurice E., about 45 years old, was troubled with recurrent attacks of pains in the epigastrium, late after meals, relieved by the ingestion of food, for periods of four to six weeks' duration, with intervals of euphoria extending over six months, for the last six years. In addition he would also be seized about once every few months by very severe abdominal cramps radiating to the back and right shoulder, lasting six to twelve hours, and requiring hynodermics or morphine.

The examinations during the month of March, 1921, revealed a dilated stomach, hyperchlorhydria, a swollen liver, and very turbid bile, with numerous small and large cholesterin crystals, an exact sketch of which is given in Fig. 5.

A diagnosis of probable duodenal ulcer and cholecystitis with stones was made, and the patient was first treated with duodenal alimentation. When, however, after the course of treatment a new attack of cholecystitis appeared he was advised to be operated. Dr. I. F. Frost of Morristown, N. J., who kindly had referred patient to me, performed the operation. The findings I give in Dr. Frost's own words:

"Yesterday morning we operated on Mr. Maurice E. and found the following: Exposing the gall bladder, we found it to be firmly adherent to the duodenum by adhesions which were well organized, and extended to the extreme tip of the gall bladder, kinking the latter, as well as binding it to the duodenum. No gall stones were found, but the foramen of Winslow was completely blocked. A thorough investigation of the posterior surface of the duodenum revealed the site of an old ulcer entirely healed. After the adhesions had been separated we transferred a piece of omentum which entirely covered the raw area, thus separating gall bladder from stomach. The appendix was chronically inflamed and was therefore removed. Mr. E. is doing nicely."

It is evident that the above picture of numerous cholesterin crystals can occur in a case of cholecystitis without stones. The probability is that in the latter instance the concretions are small (sand like) and constantly leave the gall bladder and form again, so that they do not reach the dignity of a stone.

The last case mentioned is also of importance in showing the coexistence of duodenal ulcer, cholecystitis and appendicitis, an association not so rarely met with.

WRITERS' CRAMP AND ALLIED AFFECTIONS: THEIR TREATMENT BY MASSAGE AND KINESITHERAPY.

BY DOUGLAS GRAHAM, M.D.,

BOSTON, MASS.

PRESIDENT OF THE MASSACHUSETTS THERAPEUTIC MASSAGE ASSOCIATION.

"A damn'd cramp piece of penmanship as ever I saw in all my life. I can read your print hand very well, but here there are such handles, shanks and dashes that one can scarcely tell the head from the tail——

"It's very odd I can read the outside of my letters where my own name is well enough, but when I come to open it—it's all buzz. That's hard, very hard for the inside of a letter is always the cream of the correspondence."—*She Stoops to Conquer.*

OVERUSE of any group of muscles and nerves, especially in fine work requiring a high degree of delicate coordination of individual movements and voluntary impulses, as in writing, sewing, knitting, watchmaking, playing the piano, harp or violin, etc., gives rise to similar disturbances. So does also, but less frequently, excessive use of muscles in heavier occupations, such as painting, telegraphing, tailoring, shoemaking, blacksmithing, milking, etc., occasion like troubles of motion and sensation. Predominance of symptoms may be of spastic, tremulous, or paralytic form, with extreme fatigue pain, formication, hyperesthesia or anesthesia, and thrills like electricity. There may be total inability to perform the accustomed movements, or if they be attempted for a few minutes, the symptoms just named appear. The spasms may be of flexors or extensors; there may be rigidity or contraction of the muscles, local or general tremor. No two cases are exactly alike, as these symptoms are variously combined and usually only called forth on attempting the work that has brought them on, while for all other purposes the hands and arms are well. As I predicted some time ago, we can now add another form of cramp to the list, namely, manipulators' cramp, as the penalty for those who try to do massage without knowing how, and the sufferer supposes that the trouble in his arms is owing to his having imported so much "magnetism" out of them to his patients—his conceit not allowing him to think that he is only suffering from an unnatural, constrained, and awkward manner of working.

We see but few cases of writers' cramp nowadays and hear very little about it. Sufferers from this consider it a foregone conclusion that nothing can be done for it, and some learn to use a typewriter or hire someone who can. Physicians by their disbelief in the efficacy of any treatment whatsoever have done much to foster this state of mind in their patients. We read in Scripture that on one occasion even Jesus Christ himself could not work many miracles on account of the unbelief of those around him; while in the absence of this unbelief we find no less than six references in the Bible to the devil and his emissaries working miracles. Saints or devils, we would all like to be able to cure writers' cramp and allied affections, and it is no miracle to do so in the absence of what is called organic disease of the central nervous system.

First and foremost, as to the predisposing causes of writers' cramp: It usually occurs in those who are somewhat neurasthenic, and who write in great haste from the wrist, using the hand and fingers almost entirely for this purpose, and not combining the forearm and upper arm in the side-to-side movements as they ought to. The fingers, hand, and arm are generally perfect and powerful for every other purpose, sometimes unusually so, and objective symptoms are said to be lacking. Are they? The writer has seen quite a few cases of writers' cramp, and in every one the space between the lower end of the bones of the forearm and the carpal bones has been unusually large—in other words, there has been too long a neck to the wrist. This favors the pernicious habit of moving the hand alone from side to side, thus obviating the healthful combination of fore and upper arm in these side-to-side movements.

In order to get a case of writers' cramp well, it is largely a question of removing the fatigue, the overexcitation, the irritability which accompany it, as well as are education in proper ways of writing. This involves a careful consideration of many things: the method of holding the pen, of forming the letters, the height of the desk and the position of the patient thereat, the state of the eyesight, of the nerves and muscles, etc. With some patients a long period of rest would seem to be necessary before commencing treatment; others can be kept at their writing and improve by the following methods: They should be taught how to hold the pen easily and not to grasp it tightly,

and be shown how to vary the methods of holding the same, if they have not already found out for themselves. Holding the pen between the fore and middle fingers is one of the best methods for relief. The pen holder should be of as large a size as will afford a comfortable grasp, and may be of cork or surrounded by a rubber pneumatic appliance at the lower end. The pen should be neither too soft nor too hard, the point of medium size, and the paper neither too smooth nor too rough in order that a proper resistance may be offered, so that the patient's attention may not be distracted thereby. The height of the desk should be on a level with the forearm when the upper arm hangs free by the side. It is often advantageous to change the angle of the paper from time to time, so that the patient may not get tired out from being too long in one position. Writing on a large book on the knee is sometimes easy as it forms a good automatic tip-table instantly adjustable in any direction. The light should fall upon the paper in such a way as not to cast a shadow, either from in front or on the right side.

Fine complex movements that are the last acquired are soonest lost. Therefore reeducation leading back to these should be gradually begun by teaching the patient to make long parallel lines from left to right and sometimes also from right to left. This is a good preparation of the upper arm for free-hand writing. After this the patient should be taught to make whole lines continuously of large *l*'s with wide interspaces, and also the reverse of these with equally as large spaces, *m*'s. These may be done either slowly or rapidly so as to break up the habit that the patient may have acquired. With improvement and facility in execution they should be gradually decreased in size. The advantage of this is that it trains the upper arm and forearm to cooperate with the hand in these movements that are so necessary for easy writing. Later a combination of letters and words must be devised to get the patient over any special "hitches" he may have. The word *legacy* offers a good combination for this purpose. After having made *l*'s for a while the patient can then practise *lelele* until it becomes easy; then *legleglegleg* continuously until this can be done with great ease, and so on to the end of the word.

When the patient has become somewhat proficient in writing, an excellent exercise is to write the capital letters of the English alphabet connectedly as far as he can. He can usually go from *A* to *I* without a break. The writer, after having devised and employed this combination for years, found that Professor Zabludowski of Berlin had independently and unknown to either of us been doing the same thing. Exercises of flexing and extending and separating the fingers, gradually increasing in vigor and frequency, should be done three times daily, and for any one predisposed to writers' cramp these exercises form a good preventive measure.

Careful and skillful massage of the fingers, hand and fore- and upper arm, and also of the upper part of the back, should be done daily for a while at first, and later every other day. It should not be that kind of massage that is so prevalent and consists mainly of allowing the hand and fingers to slip on the surface, but deep and searching and gentle, without chafing the skin or bruising the muscles. Alternating with the massage every five minutes should be given resisted movements of supination of the forearm, of extension of the hand and of each finger separately. Much tact, skill, and practice are required to adapt these resisted movements to the strength of the patient and no novice had better undertake them. When done properly they are restful and invigorating in place of annoying and fatiguing.

The writer, in an article on "Writers' Cramp and Allied Affections" in the MEDICAL RECORD of April 28, 1877, said of these movements that they tend to restore a harmonious distribution of will, nerve, and muscular effort by counteracting the motions that have produced the trouble. Dr. George W. Jacoby said of this suggestion that it was of more real value than all that Julius Wolff, the so-called inventor of the cure of writers' cramp, had ever done. It was in 1882 that Mr. Wolff and the distinguished Drs. Schott of Nauheim got into an unseemly squabble as to priority of the use of massage and exercises in the cure of writers' cramp, five years after the publication of my article on the same subject. Wolff had the best of the argument.

The indications for the use of massage in these or any other cases could not have been better laid down than has been done in the following words: "really effective treatment of scriveners' palsy must be an agent which is at the same time both tonic and sedative in its neural effects, which must have the power of restoring the circulation of the blood in the suffering parts to its proper condition, which is capable of promoting the absorption of serous effusions, and will thus cause the nutrition of the maimed ganglia to be raised to a normal standard." "By stirring up the nerves and muscles of a limb you may, says Russell Reynolds, "to a certain extent, act upon the other ends that are in the brain and spinal cord and so improve the nutrition of the brain and spinal cord."

CASE I.—F. K. A., aged twenty-four years; weight, 138 pounds; in good general health, and has excellent muscles; came to me on the 3rd of May, 1915. For about five months he had suffered from almost total inability to write, which came suddenly after a hard day's work of eight or nine hours at his profession as assistant editor on one of our large monthly magazines. His usual day's work was four or five hours of writing, often stopping to think between times. After signing his name a few times he had pain in the interosseous spaces between the metacarpal bones. He had no cramp, no tremor. Tried writing with his left hand, which soon brought on pain in the region of the musculospiral nerve and insertion of the deltoid. Playing the piano or using the typewriter soon brought on the same disagreeable symptoms. Hands and arms were perfect for every other purpose. A few days of rest afforded him temporary relief. His physician had told him that he was suffering from neuritis, and that it would take him a year to get over it. Under the plan of treatment above outlined the patient made a good recovery with variations. Sixteen days after he began treatment he wrote 300 words with ease, and two months after he started he could write 1000 words without any difficulty, and no more fatigue than any one might feel.

May 19, 1917. This patient returned to Boston from another city, where he had been practising his profession for the past two years. He reports that he had continued well for writing in spite of the fact that before—six weeks—he had the grip, which was followed by hives, acute indigestion, and jaundice. He still

writes all he wishes, 1000 or more at a time if necessary, even though his general health is not yet to par. He came to me again for neuromuscular pains in back and legs, which are so common after the grip, and for which massage is so beneficial.

CASE II.—H. W., aged twenty-five, enjoyed good health and had strong muscles; by occupation a pianist and astronomer. For a year his wrists had been weak and lame, which he attributed in great part to the frequent and forced efforts required in elevating and changing the direction of his large telescope, which strained the extensors of his hands very much. He could play but fifteen or twenty minutes on his piano before his fingers and wrists gave out from fatigue and ache. No visible or tangible defect could be found save a somewhat constrained stiff-bent position of the fingers, making voluntary extension difficult and disagreeable.

The treatment for several months had been half a dozen layers of bandage wound around each wrist and rubbing with liniments, without any improvement. These were left off when massage was begun. The first four visits were devoted solely to manipulation of the fingers, hands and arms. I find my notes quote Mr. A. as saying that his hands and arms felt stronger after the first handling. At the fifth and subsequent massages I added percussion and resisting motion to all the natural movements of the fingers, hands, and arms, but more particularly to extension of the fingers and of the hands on the forearms, and this was carefully kept within the limits of the patient's strength, so that at no time should he be made painfully conscious of his disability, as this would have frustrated the object of the treatment. In thirteen days from his first visit to me he had eight massages, at the end of which time I again find my notes quote him as saying that "If anyone had told him that his wrists and hands could have been made so much stronger as they now were in so short a time, he would not have believed him." He could then elevate and move his telescope about with ease, and play on his piano for an hour at a time before fatigue came on. Massage was continued for a few weeks longer and the patient got quite well, so that he could use his upper extremities ad libitum for any mortal length of time. He continued well, and for his scientific attainments was employed by the United States Government in a situation requiring a man physically perfect.

He had been suffering from muscular asthenopia (fatigue of vision) for a long time, which is quite analogous to writers' cramp. Under massage of head, face, and eyelids, he recovered so that he could read whole pages of the Beecher trial in the newspapers, and see stars in the daytime without falling on the sidewalk.

CASE III.—Mr. A. J., thirty-one years of age, was referred to me by Dr. George W. Gay. He was in good general health, and his muscles were well developed. It was two years before this that he first observed that he was not writing with his usual ease and accuracy, as if out of practice. He is a professor of writing in a commercial college. He gradually grew worse, so that he had to use a larger penholder and grip it harder and harder. Occasionally there were days when he could write well and easily. It was just after doing some very fine writing that had to be reproduced, and which he first outlined in pencil that his difficulty began. When he first came to me he could write a few lines well and naturally, then the hand and arm became tired, the hand jumped and trembled, he grasped the pen more firmly, and as the fingers contracted he lost his grip altogether; so that he presented three phases of writers' cramp—tremulous, spastic, and paralytic—in one or more of which it usually occurs. When well he wrote with his hand in the so-called regulation position, resting on the tips of the little and ring fingers, but gradually he had to let his hand descend so as to write while resting it on the whole of the middle phalanx of the little finger, and using the muscles of the forearm rather than those of the hand and fingers. At times the forefinger alone would jump from the penholder, and then he would hold it down with the thumb and endeavor to continue writing.

Examination of the hand revealed almost nothing—apparently slight stiffness of motion in the interossei between the metacarpal bones of the index and middle finger, but not more than is often met with in those not troubled with writers' cramp. There was, however, not full strength in extending the fingers, which would point to overuse of the flexors and the need of the extensors to counteract this.

It was not till after I had seen the patient a few times that he told me that nine years previous he had sprained his back by attempting to shut a heavy trap-door in a steamboat. He was beneath it, with his hands and arms extended over his head, when the boat gave a lurch and he was suddenly thrown backward. For this he had constantly worn a corset which enveloped his whole trunk in order to support his back. With this he was comfortable, and did not require to lie down to rest during the day, but without it he drooped and sagged down and soon a burning spot appeared about the middle of the dorsal region. Examination proved that there was nothing at all the matter with his back unless it were muscular weakness, due to having worn the corset too long. After two massages the patient felt as if he had a new back and could go for half a day without his support, and in the course of two or three weeks it was laid aside entirely. If the condition of his back had anything to do with his trouble in writing, the latter ought to have appeared much sooner. Neither do I think that imagination had anything to do with his writing, for he did not know what was the matter with him until the day he was sent to me.

To keep the patient at his work, and at the same time attempt to get him well was the problem to be solved. For home exercises I prescribed at first active extension and separation of the fingers, and later the same against resistance by means of rubber bands and tubes, so many movements at stated times, in order to bring into greater action the less used extensors, and also to give a change of exercise to the interossei, and thus help to restore the lost equilibrium of will, nerve, and muscle. But to prescribe writing exercises for a patient whose chirography was like copper-plate did not seem so easy a matter. However, I had no difficulty, for it was evident that he was painfully slow and particular, and when fatigue came on after a few lines he had hitches in rounding the backs of left lower curves of his *l*'s and *e*'s and in making the upward stroke of the leg of his *g*'s. Therefore, for home exercises in writing I directed large *l*'s made quickly and continuously, followed by the reverse of these, making *u*'s, so as to compel him to write from the upper arm and shoulder. As time went on we gradually reduced these in size, so as to bring more into play the muscles of the forearm and hand. When he had become proficient in these, the next exercise was a little more difficult, and consisted of *lelelelel*, large and rapid at first, then gradually diminishing; and later the exercise was *legleg*, practised in the same manner, many lines at a time, and in this way he soon got over his hitches and halts.

But calisthenics and elementary writing exercises, though helpful, have never been known to cure a case of writers' cramp without other assistance. For this purpose I gave the fingers, hand, and arm massage, deep manipulation, almost daily for four weeks. After the first two massages the patient wrote with unusual facility, but tired as soon as usual. After the third massage he was fatigued at the end of the first line, and it is a wonder he did not give up treatment then, as these cases are apt to do. After four massages he wrote with greater ease, and made delicate movements of fingers and thumb which he had not been in the habit of doing, and he was but slightly fatigued with ten lines. After the third massage, which included the back, he was almost faint with hunger, though he had just had dinner before coming to me. I have observed the same effect in other cases, in one a physician, from percussion alone for a few minutes on the back. At the fifth visit there was some lameness of the muscles of hands and arms from the manipulation, which had not been rough, and this is generally a good omen. He thought the writing exercises which I prescribed were excellent practice to train his boys at the com-

mercial college to write a free, easy, and rapid hand, so he used them for that purpose. After the fifth and sixth massages he wrote still more easily, and for an hour and half each time, stopping occasionally to explain to his students. At the end of nineteen days he had no difficulty in grasping his penholder, and he could write with ease for three hours, and at the end of twenty-eight days he wrote with ease and fluency and animation. And thus he improved with variations, but all the time making a better average.

At times we had to call a complete halt for a few days in his home exercises, when it was evident that he was overdoing and getting his nerves and muscles into an irritable condition, which was relieved by massage alone. But when this condition has arisen of its own accord or from writing, in other cases, it might be an indication to urge them on with exercises in order to tire out the affected nerves and muscles and their central connections, and thus allay overexcitability. The same means incite nerves and muscles that are inactive, but here, in order to be of benefit, must stop short of overexciting them.

Our patient might have been discharged at the end of four weeks, but this was not in accordance with his wishes, for he did not then feel safe without the aid of massage, so he continued to visit me two or three times weekly for several weeks longer. At the end of six weeks, though he was generally fatigued from sickness and death in his family, he had not the slightest difficulty in giving his writing classes full instruction from 9 to 12 o'clock, and it was during the last ten days of this time that I thought it well for him to have a tonic, consisting of 5 minims of tincture of nux vomica, 20 minims of cascara cordial, with 35 drops of elixir of calisaya, three times daily. He called upon me again ten weeks from the time I first saw him to report that he had attained perpetual motion, for the longer he wrote and the more he exercised, the easier it became and the better he felt. I have heard from him recently and he has continued well. Without the patient's hearty cooperation he would doubtless have sunk into the slough of despond.

From 1877 to 1882 Julius Wolff, of Frankfort-on-the-Main had treated by massage and gymnastics in all two hundred and seventy-seven cases of writers' cramp and such troubles. Two hundred and forty-five were writers' cramp and one hundred and thirty-two of these were said to be radically cured, twenty-two improved, and ninety-one without result. Thirty-two were pianists', violinists', telegraphers', and painters' cramp, and of these twenty-five were said to be cured. In all, one hundred and fifty-seven were cured, twenty-two improved, and ninety-eight not cured. Of the one hundred and thirty-two cases of writers' cramp cured, one hundred and eight were men, twenty-four women; eighty-eight of the men were married and twenty single. Most of the women with writers' cramp were widows. Wolff usually gave his patients two séances a day for a month.

The advantages of massage and gymnastics in the majority of cases of writers' cramp and allied affections would seem to be removal of painful fatigue, spasm, tremor, weakness, incoordination of motion, feelings of constriction, of tension, and disturbances of sensation. Hence, so far as we can judge, this method is capable, in many cases of fulfilling therapeutic indications of the utmost importance, such as removal of increase and decrease of resistance in the paths of conduction, excitation, and motion; restoration of harmonious coöperation of individual movements, of natural conductivity and excitability, as well as of muscular sense and muscular effort; in a word, correction of underaction and overaction of muscles, nerves, and their central reflex apparatus. Impalpable trophic disturbances of the coordinating machinery in the central nervous system are regarded as the origin and predisposing cause of writers' cramp and such maladies. If massage excels galvanism in correcting these disturbances, as would seem to be the case, it must indeed be a remedy of rare value and worthy of being used by the most skillful physicians.

It is astonishing how well patients suffering from Parkinson's Disease (paralysis agitans) can sometimes write, notwithstanding their tremor; thus showing how voluntary motion can be made to control involuntary, and passive motion has a still greater inhibitory effect even permanent. These facts are often overlooked and not even sought for.

A patient of mine suffering from paralysis agitans, who was improving under massage, passive motion, and resisted exercises, parathyroid extract, and home baths, consulted the best known neurological surgeon in Boston, who did not take the trouble to inquire what treatment he was under nor the effects of the same, and who after an hour's examination told him he had Parkinson's disease and that there was no cure for it; thus throwing a *wet blanket* over the progress of the case, and stopping subsequent procedures in the strait and narrow way of orthodox medicine. A year later this patient wrote to me telling me he was having treatments twice a week from a "magnetic healer," and he thought he felt better for a time, thanks to the good surgeon for shaking his confidence and throwing him into the broad road that leadeth unto the everlasting destruction of legitimate medicine.

A glance at Shakespeare's signature will convince anyone that he never could have written the plays ascribed to him, thus throwing the balance of the argument in favor of those who claim that Bacon was the author of them.

520 Boylston Street.

REPORT OF A CASE OF TUBERCULOSIS OF THE SPINAL CORD.

By CHARLES C. BROWNING, M.D.,

Los Angeles, Cal.

Professor of Diseases of the Chest, College of Medical Evangelists; Professor of Medical Diagnosis College of Dentistry, University of Southern California.

THIS case in which there also existed tuberculosis of the adrenals and of the mitral valve, and the left kidney was congenitally absent, is reported because of the comparative rarity of similar instances in the literature examined.

The most exhaustive report which I have found is that of Dr. Peter Bassoe[1] of Chicago. He had collected 74 cases and added two to that number, bringing the total to 76. Apparently Dr. Bassoe had not seen the report of the case by Dr. Elsberg[2] of New York, and of the one reported by Dr. Starr.[3] The addition of these two would make the total number reported to this time 78. Dr. Herman Kretschmier[4] of Chicago has since reported one case of what was apparently multiple tuberculous foci of the spinal cord. This, with the case herewith reported, makes the total of 80.

Diagnosis.—Signs of progressively developing tumor of the spinal cord with clinical history and

differentiation from other than tuberculous conditions.

Prognosis.—The prognosis is very grave, in part, at least, because of the extensive tuberculous activity in other parts of the body. I find reported four cases operated upon, with encouraging results in three.

Treatment.—The only treatment which offers hope for this condition is surgical. Two of the cases so treated are reported in the paper by Bassoe,[1] one by Drs. Veraguth and Brun, and one by Drs. Krauss and McGuire, to which article I would refer those interested in this subject.

The following are brief reports of the other cases:

Dr. Harry L. Elsner, writing in "Monographic Medicine," under Diseases of the Spinal Cord, dismisses the subject with the statement:

Starr[2] reports a case in which a single tubercle nodule was easily removed from the cord by McBurney. The patient developed general tuberculosis and spinal meningitis two months after the operation.

Dr. Elsberg[3] presented a patient who had been operated upon two years before on account of loss of power in the lower extremities; bladder and rectal disturbances and severe pain in the abdomen. At the operation the arches of the ninth, tenth and eleventh dorsal vertebræ were removed. A small tumor measuring 1½ by 1 centimeter was easily extirpated from the substance of the cord, after incision. The pathological report was tuberculoma.

On account of the spastic paraplegia, posterior root section was done three months later. The patient had improved markedly, had regained control of the bladder and was able to walk around without any support. There has been only one similar case in the literature—the case of Veraguth and Brun, in which a conglomerate tubercle was removed from the substance of the cord.

Dr. Herman L. Kretschmier[4] of Chicago presented a case of a patient who had been ill about three weeks with symptoms of meningitis. Tubercle bacilli were not found in the spinal fluid. In the autopsy inquest it is stated that: "In the section from the lumbar portion of the cord there was a dense, small round cell infiltration of the meninges and large areas of caseation, surrounded by epitheliod cells. In the sections stained for acid bacilli there were found a few typical acid fast bacilli in the sections of the cord. No bacilli were demonstrated in the sections from the brain."

REPORT OF CASE.—The patient was a white male, aged 30, who entered hospital October 9, 1919.

The history was similar to that of many advanced cases of ambulatory tuberculosis, with the additional history of gradually increasing weakness of the left leg.

Physical examination revealed a well advanced case of pulmonary tuberculosis, with cavities in both upper lobes. The sputum examination was negative to tubercle bacilli on the 9th, positive on the 10th, and again on the 22nd of October. The temperature on admission was 101.4°.

On October 11, 1919, the physical examination revealed the left lower limb paralyzed. Sensation normal. Left knee jerk exaggerated. Right side normal. Babinski positive both sides, more so on left. No ankle clonus. Abdomen very rigid and tender. Questionable nodular mass palpated in umbilical region, extending toward right and left iliac fossae. A diagnosis of beginning peritonitis, with spinal involvement, was made.

On October 13 there was paralysis of the right limb similar to that of the left. Bladder palpable. Patient catheterized regularly thereafter. Radiograph of spine negative. Ten cc. of fluid, which was under considerable pressure, was withdrawn by lumbar puncture. The laboratory examination of the *spinal fluid* was as follows: Clear, 3 cells to the field; Nogouchi negative; no tubercle bacilli found; Wassermann negative, and remained negative after administration of 0.6 gm. neosalvarsan.

The *blood count* was as follows: Hemoglobin, 90 per cent.; erythrocytes, 4,900,000; leucocytes, 11,800. Differential: Small mononuclear, 2 per cent.; large monoculear, 12 per cent.; polymorphonuclear, 86 per cent. Blood Wassermann was negative.

October 14.—Abdominal rigidity has entirely disappeared. Patient passed urine involuntarily, notwithstanding catheterization, which continued until the end, November 7, twenty-seven days after the patient entered the hospital. A bed-sore began to develop on the back. Both lower limbs were completely paralyzed until October 25, when a slight return of motion was noted. The bed-sore at this time had greatly increased in size, and the patient's heels were becoming gangrenous. The temperature gradually rose from 101.4°, on admission, to 104.8° on the 17th, and gradually dropped to subnormal with a final rise the day before death.

The patient died on November 7, 1919.

The autopsy was performed forty-eight hours after death by Dr. H. E. Butka, White Memorial Hospital, Los Angeles.

The microscopic examination was by Dr. Newton Evans and Dr. H. E. Butka, Loma Linda.

Abstract of Findings: Only those conditions are

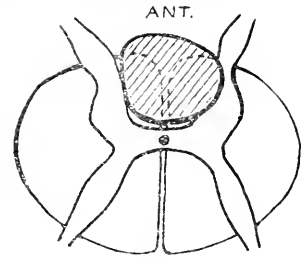

FIG. 1.—Cross-section of the spinal cord at the level of the tumor.

mentioned which are applicable to the subject under consideration.

The *peritoneal cavity* contained about 300 cc. of dark fluid. There were numerous recent adhesions about the bladder and loops of intestines adjacent. There were numerous enlarged glands in the mesentery. The left *adrenal* contained two small nodules, white in color, firm in character, with no marked degeneration or necrosis of central portion. The left *kidney* was congenitally absent. The right weighed 330 gms. Cortex was wide, vessels injected. One area extending from cortex to pelvis near the lower pole, about 2 cm. in width, was filled with numerous gray tubercles of moderate size.

Vascular System.—The pericardium contained about 30 cc. of clear fluid. The heart weighed 240 gms. and was flabby, the walls being rather thin. The mitral valve contained three small white hard nodules resembling tubercles. The aortic valve showed fibrous changes about the bases of the cusps.

The head was closely examined. No tubercles revealed. Section of the brain tissue revealed marked congestion. The choroid plexuses were also markedly congested and contained several small crypts.

The *spinal cord* was exposed and removed from the seventh cervical to the twelfth dorsal vertebra. Upon external examination there was found to be an enlargement at the level of the 8th dorsal vertebra, covering about one segment of the cord. The cord was removed and exposure of the enlargement revealed the cord at that level to be destroyed, and for some distance above and below to be in a semi-fluid condition. However, a grayish nodule about the size of a small navy bean was found compressing the cord substance, just

beneath the meninges anteriorly, extending further to the right of the midline than to the left. This tumor was firm, hard, and shelled out easily from the cord, and resembled very closely the tumors found in the left adrenal body. (Fig. 1.)

Microscopic Examination.—Sections of the tumor

FIG. 2.—Showing the tubercle bacilli among the cells. From a drawing by Dr. Newton Evans.

from the spinal cord revealed tuberculous granulation tissue, with much fibrous tissue, and cells about the periphery of growth composed of numbers of lymphocytes, fibroblasts, plasma cells, and polynuclears.

There was complete absence of typical giant cells usually found in tuberculous granulation tissue. However, upon staining for acid-fast organisms, numerous well stained tubercle bacilli were found, interspersed among the cells. (Fig. 2.)

The tumors of the adrenal body were identical, except that central necrosis was present. Appropriate stains demonstrated tubercle bacilli to be present.

PRINCIPLES OF THE PIRQUET METHOD OF FEEDING.*

BY CHARLES F. FISHER, M.D.,

BROOKLYN, N. Y.

ASSOCIATE ATTENDING PHYSICIAN, DEPARTMENT OF MEDICINE BROWNSVILLE AND EAST NEW YORK HOSPITAL; CHIEF OF DEPARTMENT OF PEDIATRICS, BIKUR CHOLIM HOSPITAL, BROOKLYN.

I HAVE been asked to read a ten-minute paper on the Nem system, or Pirquet's method of feeding. To cover this subject in so short a time is a physical impossibility, and to attempt to crowd the subject-matter into a few minutes would neither do justice to Pirquet nor leave you any wiser than before. This method as applied to infant feeding alone could not be described in the few minutes allowed me, so I thought it best to limit myself to an explanation of the subject and to omit answering any objections which may have already been raised.

*Read at a meeting of the East New York Medical Society, June 22, 1921, and of the Williamsburg Medical Society, November 14, 1921.

This subject is practically unknown in this country, and in order to master the details one must have a speaking acquaintance with the principles involved, and these I will attempt to explain to-night. If the topic interests you enough, and you will permit me, I should be very glad to go into details and show you its application in everyday practice at some time in the near future.

The subject-matter of this paper is based upon (1) the Lehrbuch der Volksernährung by Mayerhofer and Pirquet, (2) Das Pirquetsche System der Ernährung by Schick, and (3) the personal experience I have had with the system under Pirquet in the Kinderklinik in Vienna, in the American Convalescent Home for Vienna's children, and in private practice.

I wish to emphasize this point about the Nem system of feeding, notwithstanding any objections which may have been raised against it, and that is that the Nem system, as it is called, is neither a theory nor an experiment, but a method of feeding which has been in operation for over five years in Vienna, and has proved both practical and scientific, and has shown wonderful results. This method of feeding was considered to be of such great value by the American Relief Administration that Mr. Hoover consented to supply food to Austria for another year when relief by this Government was discontinued to all other European countries; and this was done for no other reason than because of the great esteem in which the Pirquet method of feeding was held by it.

One of its greatest advantages is its simplicity as applied to infant feeding. By Pirquet's method of feeding the general practitioner can in a few minutes and without hesitation prescribe a formula which would give the desired results. When applied to feeding large numbers, as in schools or other institutions where cost is a great factor, it is found most economical. Above all, it is exact, and one can figure out mathematically just how much food the individual requires, whether in health or disease, and whether he is fed correctly, underfed, or overfed.

The Pirquet method of feeding was born during the war. At that time there was the greatest necessity for utilizing all available food and eliminating all possible waste, because the cost of food was excessive, and also because it was difficult to obtain. Pirquet also realized that there was the greatest necessity for popularizing a scientific system of infant feeding to insure for each infant a quantitatively and qualitatively adequate food supply. This was made necessary because there was an insufficient supply of milk available, and it was not generally known at that time what foods could be substituted for milk, nor the quantities of such substitutes needed.

The caloric system could not be used, because it was too difficult to understand, and cooks and housewives would not adopt it. As a result of all this, Pirquet set his fertile brain at work and the Nem system of feeding came into being.

The main points of Pirquet's method of feeding are, first, the calculation of the daily food requirements of an individual from the sitting height—sitzöhe, as he calls it—and, secondly, the conception of the idea of a calory, through an easily

understood physiological measure of the value of milk.

I wish to explain in detail what is meant by this sitting height, and easily understood physiological measure of a calory. The sitting height is the measure from the crown of the head to the end of the spine, the patient being in the sitting posture. In other words, you measure the patient as you would any animal, from head to tail. Pirquet uses this measure in computing the daily quantity of food necessary in feeding an individual, and does not take into consideration the age, weight, or any other factor. This does not mean, however, that there is no relationship between body weight and length, for there is, as we shall see later. But this sitting height is the criterion in determining the daily quantity of food needed. By Ruebner's method the individual's daily food requirements were calculated from the external surface area of the body. By the Vierordt-Meeh formula the external surface area was calculated from the body weight. This, as you can readily see, is rather complicated and not practical.

In 1881 Henning, in his most interesting work, showed that the absorptive portion of the gastro-intestinal tract—that is, that part of the gastro-intestinal tract in which absorption of food takes place—always bears a definite relation to the sitting height, or "sitzhöhe." This absorptive tract is ten times the length of the sitting height, or vice versa, the sitting height is one-tenth the length of the absorptive tract. Pirquet went further and demonstrated that the square of the sitting height is also equal to the square area of the absorptive tract. For example, if you were to split open the bowel and lay it out flat like a tape, the width multiplied by the length of this tape would equal the square area of the sitting height. He proved, further, that the cube root of ten times the body weight of normal individuals also equals the sitting height. So because of these facts—the relation of the absorptive tract to the sitting height, the relation of the body weight to the sitting height, and that it is logical to measure man, like other animals, from head to tail to determine their length—Pirquet decided that this sitting height must be the only measure for determining the daily food requirements in any system of feeding. That it is logical we can readily understand. The methods previously mentioned are too complicated and impractical. To use the body weight as a guide in order to determine the daily food requirements of a person, as is still the case in this country, is illogical because of two given children of the same age, the one weighing more would get the greater amount of food. But in reality which one needs more?

Now, the second point upon which this system depends is the conception of a calory through the physiological measure of the value of milk. In other words, Pirquet uses mother's milk of a definite composition which has a physiological caloric value of 667 large calories per liter as a standard by which the caloric value of all other foods is measured. For all practical purposes Pirquet considers mother's milk and cow's milk as having the same utilizable caloric value. The caloric value of one gram of mother's milk he calls a Nem—and for this reason this system is called the Nem system. The word nem is formed by taking the initial letters of the words Nahrung-Einheit-Milch, meaning in English the nutrition-unit-milk.

The Nem, then, is the utilizable caloric value of one gram of mother's milk of a definite composition, and is the standard of measure for comparing all other food values. In short, one nem equals the caloric value of one gram of milk. Based upon this, Pirquet has worked out a table of the nem value of the most important foods.

He has also devised a table of measure for this method of feeding, based upon the metric system and using the word nem for gram or c.c. For instance, one-tenth of a nem equals a decinem, 10 nems equal a dekanem, 100 nems equal a hektonem, 1,000 nems equal a kilonem, etc.

In considering the relative value of the proportions of fat, protein, and carbohydrates necessary in feeding, Pirquet, contrary to all other teachings, denies the existence of a fat minimum. He has come to this conclusion after feeding infants for twelve months on skimmed centrifugalized milk—fat-free milk — without causing any deleterious effects. He contends that fat is only a fuel food elaborated by nature for the sake of compactness, and is not an essential article of diet. It can be replaced by carbohydrates without injury to the organism. It is, however, necessary in the art of cooking and in the flavoring of foods.

With protein, on the other hand, it is quite different. Protein is not only necessary to supply material for new tissues to replace worn-out tissues, but it is also necessary in supplying an adequate amount of digestive ferments. So that there must be a protein minimum. This minimum must be not less than 10 per cent. in order to sustain an individual. Pirquet considers this amount sufficient because in mother's milk there is only 10 per cent. protein; this is sufficient for all the needs of an individual during its greatest growth, and so it ought to suffice in later life. Too much protein is harmful and can cause disturbances of metabolism, such as gout, etc. He considers 20 per cent. as the maximum.

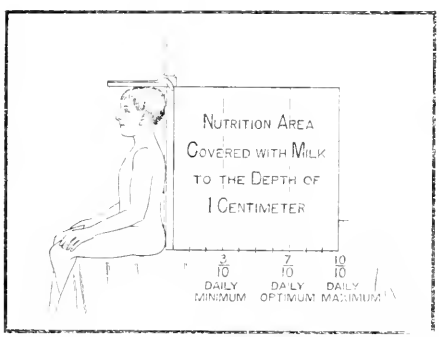
I wish to emphasize this point a little more—that is, the protein minimum. You can feed your patient fats, carbohydrates, and some protein, but if there is less than 10 per cent. of protein your patient will not gain; on the contrary, he will lose weight and strength. I have in mind a case in the medical service of one of our hospitals—a cardiac with polyarthritis. This patient has been in the hospital for several weeks, and, besides the occasional relief of pain in the joints, is getting weaker, more anemic, and the heart, to say the least, does not improve. This patient gets no meats; eggs are also restricted, and the total protein allowed is too small. In our eagerness to do something for the disease we are forgetting our patient. We forget that the heart cannot improve without general body improvement, and this cannot be accomplished by starving the patient—as you do if you give less than the required protein minimum. I do not mention this in the light of a criticism, but to call your attention to the fact that the proper understanding of feeding is absolutely essential and plays a most

prominent rôle in successful therapeutics. You do greater harm by treating the disease than by treating both the patient and the disease. That we must keep up the patient's resistance we know, but this fact is lost sight of in our eagerness to treat the disease. It must be remembered that there is a protein minimum which cannot be ignored if our patients are to be treated intelligently. As soon as this patient was allowed a greater amount of protein she began to show marked general improvement.

Carbohydrates cannot be replaced by other foods, and are essential in the body economy. They can be given in rather large amounts without gastric disturbance. This fact is corroborated by many observers in this country, especially Faber of San Francisco. He has given infants as much as 14 per cent. carbohydrates without causing any ill effects.

To go back to the sitting height and its application in feeding. Older children and adults are measured by an upright scale—while infants are measured in a sort of crib with a slide working on a scale.

The square of the sitting height represents the



largest number of nems that can possibly be required during the most strenuous physical exercise and is called *maximum*. For example, if the sitting height of an infant is 40 cm., its maximum would be 1,600 nems. This means that the greatest amount of food that this child could possibly require under the most strenuous kind of work could not exceed 1,600 nems.

This maximum is divided into tenths, and (according to the metric system) each tenth is one decinem, or one-tenth the total number of nems (of maximum). Three-tenths of maximum, or three decinems, is called *minimum* and represents the least number of Nems that the body requires when in absolute rest, not even digestion taking place. This is the number of Nems that the body requires for internal combustion. To compute the number of nems required in feeding a given case, besides the three decinems allowed for internal combustion, that is minimum, two decinems are added for exercise, one decinem is allowed for growth, and one decinem is allowed for storing up glycogen —reserve force. This gives a total of seven-tenths of the maximum, which is called the *optimum*, and represents the total number of Nems that the body requires for all normal functions and to sustain a normal individual.

Five decinems will sustain life, but the body does not gain on that amount. A healthy newborn baby requires only five decinems for the first two weeks of life, but after that and until the end of the sixth month it requires six decinems. From then on a normal individual requires seven decinems, which is optimum. In disease the number of Nems necessary in feeding a given case varies from minimum to maximum. Thus in myxedema, where metabolism is retarded, only three decinems, minimum, is sufficient. But when thyroid is administered we all know that a loss of weight takes place due to increased metabolism, and to allow for this increased body activity the number of Nems must be decreased accordingly. I have watched myxedematous children in Pirquet's Klinik keep their weight for a long time on three decinems, but upon the administration of thyroid this had to be increased to optimum—seven decinems—in order to make the weight curve go up. On the other hand, in hyperthyroidism where there is a great increase of metabolism, due to increased heart rate, tremors, etc., seven decinems, or optimum, is insufficient. Here we hade to increase the decinems to eight or nine and in some cases even up to maximum. In fever where there is much oxidation the patient needs plenty of food. Thus in typhoid, dysentery, etc., food should be given in large quantities but of a kind easily digested and of high caloric value. So that instead of cutting down the number of Nems you can give optimum or even more. However, in fevers of short duration, such as measles or diphtheria, five or six decinems will be sufficient to keep up the body weight and can be increased to optimum when the disease is over.

Now I would like to say one word about the relation of body weight to the sitting height. If you recall, Pirquet brought out the fact that normally the sitting height was equal to the cube root of ten times the body weight. This relation of body weight to sitting height he calls the "pilidisi." A pilidisi of 96 or over means a well-nourished person, while a pilidisi of less than 96 spells malnutrition. This computation is done very quickly in the fraction of a minute by using a slide rule, and no one need be a mathematician or need paper and pencil to do it. This fact is of very great importance in determining the status of individuals for armies, industrial plants, etc.

Because of the lack of time I cannot now show you the practical application of this method of feeding, but if you have grasped the meaning of the terms nems, minimum, optimum, maximum, etc., you have acquired the fundamentals and are in a position to master the practical side easily.

In conclusion, I wish to say that Pirquet's method of feeding is (1) scientific and practical, (2) the simplest and most rational system of feeding so far devised, (3) based upon two factors: (*a*) the sitting height is used as a basis of measure for determining the daily *amount* of food required in feeding a given case, and (*b*) milk is used as a standard of measure of the value of a calory, with which all foods are compared.

315 Pennsylvania Avenue.

TUBERCULOSIS: ITS CLIMATOLOGY AND SOCIOLOGY.

C. OWEN PAGET, M.D.,
PERTH, WEST AUSTRALIA.

THERE is a cynical humour in nature paraphrased by the itinerant showman's remark, "What's lost on the rounds is made up on the swings;" or again by the fashionable physician who considered death due to a single cause, for his private patients died from overeating, and his hospital cases as a result of starvation.

The incidence of tuberculosis is dependent upon the existence of tubercle bacilli and the efficiency of the nose. In other words on the attacking force and the capacity for defence.

Although tuberculosis is a universal endemic disease, its local potency must vary considerably from time to time. In the open air, conforming to other forms of vegetable life, it is checked in growth by excessive cold, aridity of soil, and glaring sunshine. Warm, shaded and moist places favor its development. Cultivated for instance in ill-ventilated, gloomy, dirty, and heated rooms it is likely to be more virulent in character than in clean walled lofty chambers exposed to the sunlight. Again, though other factors must be taken into account, its malignancy in a hot dry climate like that of West Australia is probably somewhat lower than in many other parts of the world. This is confirmed by general experience, Alps and deserts being regarded as localities beneficial to tuberculosis.

The tubercle bacillus is capable of periodical enhancement of virulence. This phenomenon is common to many varieties of vegetable life all over the world. For example in England mushrooms are some years very prolific. In Australia periodically large areas of country are invaded by such growths as Scotch thistles. In India and the East, bubonic plague and cholera are endemic. At times they assume not only epidemic proportions locally, but spread far beyond their usual confines, in vast waves of devastation.

In a former paper (MEDICAL RECORD, March, 1919), I pointed out some reasons for my belief that the European influenza epidemics of 1918-1919, of which I had considerable experience, were in fact no other than epidemics of tuberculosis. My opinion was strengthened by experience on my return to Australia in 1919, which was then suffering from an epidemic similar in character. The lengthy West Australian summer (8-9 months) of sun and cloudless skies causes a general lowering of tone in the health of the community. The first rains, often light and intermingled with further sunshine, are succeeded by violent winds and in some places by vast clouds of dust, which seem to fill the streets and houses. The dryness and the sandy nature of the soil are further climatological contributory causes. Under these conditions a low form of epidemic pneumonia springs to life. This disease commonly called "influenza" is, I am now convinced, an epidemic of tuberculosis of slight virulence. The lack of malignancy is probably due to the tone of the bacillus being lowered by the lengthy summer, aridity of the ground, and all pervading sunshine.

The clinical features of this disease, when it assumes the pneumonic form, are debility, vague physical signs, occasional hemoptysis, low temperature, slight mortality if any, but frequently remarkable subsequent asthenia; often not recovered from for months, and requiring a change of environment, such as a sojourn in the hills or a sea voyage. So far as physical signs are concerned, its exact counterpart was found in the acute epidemics of "Spanish influenza" in 1918-1919.

In the gold fields, too, with large mining dumps, a longer, hotter, and drier season than on the coast, and with winds producing vast and sometimes constant clouds of dust, pneumonia is very prevalent. It is evident that the natural physical, botanical, and biological laws governing the incidence of tuberculosis are intricate, interwoven, and probably to a considerable extent, unstudied and unknown.

The social fabric of civilization is dependent on production, transportation, manufacture, and exchange. Of these factors, production and manufacture have a considerable influence on tuberculosis.

In certain forms of mining, where rock is drilled and a fine hard dust is produced the disease pneumonoconiosis or miner's phthisis arises. The action produced by such dust is different from that produced by coal dust, inasmuch as it excites pulmonary catarrh and fibrosis. In my opinion the original catarrh, by irritating and causing exfoliation of the bronchial epithelium, diminishes the resisting power to tuberculous infection. For the existence of a pure pulmonary fibrosis, without tubercle infection, is open to grave doubts. That it is usually low in virulence is probably due to the general aridity of the surroundings in the neighborhood of mines.

Writing without personal experience, I yet believe myself correct in saying that the conditions as to mortality, physique, longevity, and incidence of tuberculosis in the cotton and woolen districts of Yorkshire and Lancashire are very bad. An insufficiently ventilated factory, full of light and floccose dust, with air warm and moist, and employees underfed, produces the ideal conditions for the spread of tuberculosis.

The world, except in savagery supporting itself by artificial expedients, expressed by the term civilization, is always confronted by difficulties, economic, hygienic, and social. But such troubles must be faced, and cannot be overcome by ranting philosophy.

To those with war experiences, or who have seen the hardships and vicissitudes of opening up new countries, and who have had practical knowledge of conditions under simple civilizations, native and otherwise, the shortcomings of our social system, though admitted, are not so apparent as they are to the armchair pedants, jaundiced too often by feeble health or inactive existence.

Even as steam and oil engines made possible the emancipation of slaves, so must science by discovering new truths inaugurate eras more cheerful, kindlier, and healthier for mankind.

In so far as tuberculosis is concerned, nature has forestalled our wishes, by providing us with an organ, the nose, amply capable of protecting us from the attacks of the tubercle bacillus. To elaborate fully all the causes of the nose's inefficiencies would require a text-book. It will be sufficient to indi-

cate a single condition, common amongst the white races, and dependent on false ideals and faulty doctrines.

As a student in London, we were taught that adenoids were due to the dampness and mugginess of the atmosphere, associated with the effects of poverty and want of good food. Yet 20 years ago adenoids were as common in West Australia as in London, and that in spite of the dry and sunny climate; whilst poverty and hunger amongst children were unknown. On investigation it was found that many West Australian and London babies were bottle fed, brought up largely on patent foods, and kept on soft foods during their early infancy.

In the Australian *Medical Gazette* (January 31, 1914), I pointed out that the effect of these factors is to produce (1) Adenoids, (2) poorly developed teeth and jaw, (3) a laterally compressed nose with weak cartilages; a sure precursor of tuberculosis.

The reasons for these mothers artificially nourishing their children, for they were poor people or of moderate means only, were as follows: In England the mothers were exposed to the blighting effects of overcrowding under poverty-struck conditions. Whole families lived and slept in a single room. Food was poor in quality and small in quantity. Parents were too often of stunted growth, of tuberculous and syphilitic stock and were engaged in monotonous and unhygienic employment. Such mothers are unable to furnish milk of sufficient quantity or proper quality for any length of time.

The exact converse existed in the case of the West Australian mothers. These were largely pioneer women, who helped to build the houses, nursed husbands and children with typhoid fever, and worked hard all day in a climate which, however salubrious, causes abundant perspiration. And although meat, bread, and tea were abundant, fruit and vegetables were difficult to obtain and often prohibitive in price. Such women either broke down in health, or became wiry; and usually their milk dried up very early. Both sets of women had their natural breast development compressed, and often their nipples malformed and stunted as a result of mid-Victorian corsets.

Thus neglect of the welfare of women, either by the too strenuous life of pioneering, or the too confined life of overcrowded poverty, ultimately has an enormous effect on the general welfare of the community, and is a primary factor of the utmost importance in diminishing our natural capacity to resist tuberculosis.

To this must be added the adherence to fashions and customs, often originally esthetic, but degraded into foolish fetish worship by our inability to appreciate the sensible and the beautiful. This is no fantastic chimera, for most practitioners have seen a binder tightly wound round a baby's stomach, strong enough to hold on the saddle of the wildest bucking horse; and are acquainted with the frail and peevish children of the conscientious Mrs. A., who is always making pap food; and the sturdy youngsters, playing in the gutter and scrapping for a crust, of the neglectful Mrs. B.

The man who does not use his arms and legs develops a liver and a flabby heart. The baby who eats soft foods develops weak jaws and inefficient nose and dies of tuberculosis. How well this is shown in nature! The too finely bred and delicately nurtured racehorse becomes at best a five-furlong sprinter.

Perhaps one of the most extraordinary developments of modern times is the worship of the cow.

Physicians, priests, and women vie with each other in extolling the virtues of milk. Even at military messes it has in some places become *de rigueur*; and, well, I remember feeling almost an outcast on refusing this beverage at a neighboring medical mess, to which I had been invited.

To those suffering from the glamour of delusions, I suggest a walk along the country lanes of merry England, where the chilly evening is ushered in by the distant coughing of tuberculous cows. If the charms of city life are preferred, then in a London bun and milk shop watch the lugubrious countenances quaffing their brimming goblets of solutions of tubercle bacilli.

Apparently the word "milksop" is no longer a term of contempt as in Shakespeare's time, but is emblematic of virtue. Hippocrates, the father of medicine, advocated in tuberculosis the milk of the goat, freest of all animals from disease. The modern "sanatorium cum milk" physicians prefer the tuberculous cow. There is only one time in life when a man should drink milk, and that is when he is too feeble to be capable of anything better.

The accusation of iconoclasm or heterodoxy cannot be made against the advocate of the reasonable use of wine and beer in cases of tuberculosis. Able physicians of all ages and climes have shewn the inhibitory action and increased tendency to fibrosis, produced by gout in tuberculous cases. With a reasonable knowledge of the clinical side of the disease my experience has never discovered a case of tuberculosis brought on by drinking or even drunkenness. But unquestionably patients with tuberculosis have harmed themselves by drinking, especially spirits. And this occurs in the following manner: Large numbers of people suffer from tuberculosis which is not diagnosed by physicians for times varying from two to seven years. I have treated cases not diagnosed after 15 years.

These patients, during the period that their disease is unrecognized, suffer from all the accompaniments of tuberculosis, such as anemia, fatigue, want of balance, loss of appetite, and general capriciousness. Many find that alcohol, temporarily at all events, relieves their symptoms. With complete rest it is usually in proper quantities distinctly beneficial, but if, on the other hand, work is continued, and the spirit merely employed as a stimulant to further exertion, then truly it is a bad remedy, and the final breakdown, by being postponed, is probably worse and more difficult of treatment than if the disease had been allowed to take its natural course. Nevertheless, more human beings have been maimed and killed by drinking the milk of tuberculous cows than ever died from alcoholic poisoning.

Though the poor by their surroundings are more exposed to infection, they are, on the other hand, by the rigour of their upbringing, more likely to develop good resisting powers in the form of a stalwart nose.

The child fortunately born into healthy surround-

ings, but pampered by soft food, an indulgent mother, and taking insufficient physical exercise for his general development, is liable, when exposed to severe infection, to succumb through inadequate resistance.

The pretentious title of this paper must be excused. At best it is indicative of various intricate issues, with which such a disease as tuberculosis is entwined.

34 St. George's Terrace.

THE BOSTON DISPENSARY HEALTH CLINIC;*

A REVIEW OF THE FIRST 400 CASES.

By LESLEY H. SPOONER, M.D.,

Boston, Mass.

This clinic was instituted in the fall of 1919 to provide a routine physical examination by a group of four specialists—the internist, nose, throat, and ear, eye and laboratory specialists—to working people of rather scanty means, who were presumably well. The fact that this work is performed in the evening renders the economic saving a great feature for the working people. Although these four departments are used as a routine, consultation is afforded, when additional information is required, by other evening clinics at the dispensary: namely, the genitourinary, the dermatological and syphilis, and the gynecological departments, without additional cost to the patient. Assistance from other and larger clinics of the dispensary, which bear the brunt of overhead expense, enable us to offer a most complete examination which costs the dispensary less than the admission fee of $5. The *x*-ray and the more complicated laboratory investigations are carried out when required at a minimum fee fixed at the cost of such work.

Other organizations providing routine physical examination have been in existence for many years, but the outstanding feature of ours lies in the utilization of specialists for the purpose of group diagnosis and in the personal review and advice by the internist who is the natural referee, whose judgment should be unbiased by diseases of special organs.

Since the aim of the work lies in diagnosis, it is essential to render no treatment to the individual, but to refer him to his own physician, who receives a carefully prepared personal letter detailing the diagnosis and the more intricate matters of treatment advised. When no physician has been in attendance, as is found in 48 per cent. of our first 400 consecutive admissions, the individual is referred either to a competent physician, or, where finances do not permit, to the proper departments of our evening clinic.

The great danger to be avoided is a change from the original purpose to the establishment of a Diagnostic Clinic. Such an organization as the latter fills a perfectly well-recognized need, but is quite apart from the object of this project. To show that such a change has not taken place to any appreciable degree I have taken as a criterion of health the time the individual loses from his work during a given period.

Although most of our patients admit some symptoms, not necessarily of organic disease, but at least causing mental anxiety, 71½ per cent. showed a maximum loss of time from work of one week during the two years prior to consultation and 78¼ per cent. were incapacitated for two weeks only over the same period. From this I conclude that almost four-fifths of our patients are, in their own opinion, well. This is a fact of importance in showing that the original purpose of our work is being maintained, but also should be borne in mind later when the physical findings are to be discussed.

Mention of the scope of the work should be made. Although the Boston Dispensary is considered a local institution—only 46½ per cent. of our cases came from within the city—50½ per cent. from Massachusetts outside of Boston, ¾ per cent. from without the State, and one from without the country. Twenty-two per cent. were foreign-born.

In considering our findings, to be mentioned later, age is a matter of importance. Twenty-five per cent. were under 31 years of age, 53 per cent. under 41 years, and 79 per cent. under 51 years of age.

As one would expect, the intelligence of our group is far above the average of that of the ordinary dispensary case. A review of occupations bears out this point. The more miportant, expressed in percentages, are as follows:

Housewife (occasionally housework)	23
Clerical	19
Skilled labor	17
Professional	11
Business	9
Unskilled labor	7
Public service	4
Scattering	10

From a public health viewpoint a brief review of the patient's history might be of interest. In regard to previous diseases, measles is, of course, the most prevalent, being found in 78 per cent. A history of tonsillitis was encountered in 37 per cent. The other more common affections occur in the following order, expressed in percentages:

Scarlet fever	20
Pneumonia	13
Gonorrhea	13
Rheumatism (acute articular)	11
Malaria (often unsubstantiated)	10
Typhoid fever	10
Suppurative ear	8
Influenza	8

Of the operations, tonsils and adenoids had been removed in 7 per cent. and the appendix in 6 per cent. The remaining operations were well scattered and of little interest.

Our statistics seem to show that heredity of degenerative disease of the cardiorenal and vascular system is often over-estimated, since we found such history in 47 per cent. of the series; a figure far out of proportion to our physical findings. A similar conclusion might be drawn between heredity of tuberculosis and the incidence of the disease, although the difference is not so striking when the matter of contact is considered in addition.

Errors in Hygiene.—Excesses seem to be relatively infrequent in this group. Only 7 per cent. indulged to an excessive extent in tea, 5 per cent. in coffee, and only 3 per cent. in tobacco. A very

*Read before the Medical Section of the New York Academy of Medicine, Oct. 18, 1921. (See page 1053.)

small number admitted a previous over-indulgence in alcohol, which has stopped in every instance, presumably in large part because of the difficulty of securing it.

Although such a good record would indicate a model life, such optimism is dispelled by a review of other personal habits. Meat was taken in excess by 31 per cent. and fluids in diminished quantity by 37 per cent. The latter no doubt accounts in considerable degree for the constipation which is encountered so frequently.

Indigestion in its various forms was found in 40 per cent. Forty-one per cent. were found to be rapid eaters, and 45 per cent. were constipated. Of the cases showing indigestion, the last two factors played an important part, for of the 40 per cent. giving a history of indigestion, 85 per cent. were either rapid eaters or constipated, or suffered from both complaints.

Many conclusions in regard to disturbed bodily functions can be drawn from a review of these and other figures, but it is sufficient to state that 18 per cent. indulged in an insufficient amount of exercise and 26 per cent. in inadequate recreation. The latter seems of great importance as a predisposing factor of bodily as well as nervous disorders. It is a regrettable fact that in this group of 400 seemingly very intelligent people, 50 per cent. bathed inadequately.

Factors Predisposing to Organic Disease.—The two important factors in this group are the excessive features of weight. Malnutrition, often to the extent of emaciation, was found in 26 per cent. and obesity in 20 per cent. This reduces the normal fat disposition to only 54 per cent., a rather surprising fact. Slight differences from the normal scale are not rated in either of the first-mentioned classes. Caries of the teeth, substantiated in the majority of instances by the *x*-ray, was found in 25 per cent. and pyorrhea in 13 per cent. Either or both of these conditions were encountered in 30 per cent.

Organic Disease.—General or constitutional diseases were found in the following proportions: Goiter, simple, 3 per cent., associated with hyperthyroidism, $1\frac{1}{2}$ per cent.; syphilis, 8 per cent.; secondary anemia, $3\frac{1}{2}$ per cent. Single cases of the following were discovered: Acromegaly, dwarfism, anatomical elephantiasis, and myxedema.

Cardiovascular disease (including nephritis): Valvular disease of the heart was discovered in 7 per cent. Arterial degeneration appeared in 11 per cent. Hypertension was found as an entity, often, of course, associated with other conditions, in 18 per cent. Renal disease appeared in 3 per cent. On the other hand, functional cardiac murmurs were discovered in 12 per cent. This figure shows the importance of careful study in all cases suggesting cardiac disease. Three-quarters of these functional murmurs were found in females. Hypertension, arteriosclerosis, and chronic nephritis are considerably more prevalent in males, and the other cardiovascular changes about evenly distributed between the sexes. Of the venous diseases hemorrhoids were found in 9 per cent. and varicose veins in 13 per cent. Strangely enough, the latter were found more frequently in males.

Diseases of the respiratory system are far less common in this group. Phthisis, arrested or active, was found in $3\frac{1}{2}$ per cent. and emphysema, generally of the senile type, associated with arteriosclerosis and other degenerative changes, in 4 per cent. Asthma was seen only twice. Chronic bronchitis and chronic pleuritis appeared each three times among the 400 cases.

The gastrointestinal tract seems even less frequently involved. The incidence is as follows:

Gastric ulcer	3	
Duodenal ulcer	1	total 4
Gall-bladder disease	6	
Visceroptosis	3	
Fissure in ano	2	
Fistula in ano	1	
Carcinoma of Liver	1	
Mucous colitis	1	
Appendicitis	1	

Those conditions less closely associated with the intestinal tract are as follows:

Hernia—Inguinal	6 cases
Umbilical	6 cases
Into scar	3 cases

The routine examination demonstrated palpable kidneys in 38, or $9\frac{1}{2}$ per cent.; three-quarters being found in women. In only two instances was the left kidney demonstrated, and in only one of these the left kidney alone. It was impossible to show any organic significance in any of these findings. The liver was found palpable in 7 per cent. and an organic basis was discovered in only half of the cases.

Disease of the urinary organs (exclusive of nephritis) and of the male genitals shows, among 400 cases:

Varicocele	11
Phimosis	6
Atrophied testicle	3
Hypertrophied prostate	3
Hydrocele	2
Renal calculus	2
Epididymitis	1
Hypospadias	1
Cystitis	1
Tuberculous kidney	1
Pyelonephritis	1

Acute gonorrhea was never observed.

The female genital organs were involved in the following order:

Retroversio uteri	3
Menopause pathological:	
Natural	2
Artificial	1
Fibroid uteri	2
Chronic salpingitis, atrophic vaginitis, gonorrheal vaginitis, gonorrheal urethritis, tumor of breast, procedentia uteri, and lacerated cervix	1 each

Diseases of the bones and joints are far more prevalent. The total represents 38 per cent. of our cases. They fall under the following classifications:

[illegible]	[illegible]2 cases
[illegible] disease	4 cases
[illegible]	15 cases
[illegible]	12 cases
[illegible] disease	2 cases
[illegible] not included above	26 cases

These figures are even more striking when one considers that the orthopedic examination was conducted by an internist. For fear of repetition of figures, the following are not included in the above group:

Faulty [illegible]	20 cases
Valgus	23 cases—the latter most often associated with pronation.

Diseases of the nervous system were not com-

mon. Tabes and epilepsy occurred each in three cases, cerebral syphilis in two cases, and general paresis, psychosis, sexual neurasthenia, masturbation, chorea, hysteria, flaccid paraplegia, and occupational neurosis each once.

Diseases of the skin were as follows: Acne, 17 cases; eczema, 8 cases, and pruritus ani, epidermophyton, pedidulosis capitis, and psoriasis each one case.

Affections of the special systems, the nose, throat, and ear, and the eye were the most prevalent. Of the former chronic infection of the tonsils, of any degree of severity, and deviated septum were found each in 36½ per cent. of the cases. Chronic rhinitis appeared in 15 per cent., spurs in 10 per cent. and hypertrophied turbinates in 5 per cent. Chronic catarrhal ears were found in 26 per cent. Those presenting no pathological process in ear, nose, or throat amounted to only 21 per cent.

A review of the eye condition shows the bulk of pathology lying in errors of refraction. They are divided as follows:

Astigmatism	90 cases
Hyperopia	73 cases
Hyperopic astigmatism	33 cases
Myopia	24 cases
Myopic astigmatism	19 cases
Presbyopia	22 (6 counted previously)
Anisometropia	2 (2 counted previously)
Amblyopia	3 (2 counted previously)
Refractive error (unclassified)	30 cases

The following diseases of the eye were noted:

Conjunctivitis	21 cases	Vitreous opacities	2 cases
Corneal scars	6 cases	Choroiditis	1 case
Cataract (mixed)	10 cases	Chororetinitis	1 case
Optic atrophy	3 cases	Scleritis	1 case
Retinitis	3 cases	Others	7 cases

The cases presenting normal external eyes, fundi, and refraction represented only 25 per cent. of this group.

Fully as important as the detection of organic disease is the recognition that certain pathological findings have no organic bases. Albumin in the urine was detected in 116 cases, or 29 per cent. Of this large number definite organic basis for the albumin could be demonstrated in only 43. A pathological sediment of pus, possibly due to urethritis, prostatitis, or vaginal secretion, might be considered as a cause for 33 others. In 40 instances, or nearly 35 per cent., no possible explanation could be found for the albumin, which was transient in a large majority of cases. Of the unexplained cases almost twice as many occurred in women as men.

A general survey of the laboratory findings, in addition to this consideration of albumin, is of interest. Sugar was detected in the urine of seven; of these a true diabetes was demonstrated in only two cases.

Positive Wassermann reactions were considered diagnostic of syphilis only when subsequent tests substantiated the findings. Eighteen cases showed such reactions, representing 4.5 per cent. of all cases examined. Secondary anæmia was demonstrated in 14 and a distinct eosinophilia in 8, six of the latter being unexplained. A positive gonococcus fixation reaction was found in one case. When the clinical findings and the history of the patient are considered, the following survey represents the incidence of syphilis in the 400 cases:

	Cases	Positive Blood W. R.
Neurosyphilis	6	3
Syphilitic history	15	4
Persistently positive W. R without history or signs	11	11
	32 (8 per cent)	18 (4½ per cent)

A summary of these findings shows that definite organic disease, exclusive of that of the eye, ear, nose, and throat, was demonstrated in 79 per cent. of all of this group. In the case of the cardiorenal and vascular diseases marked increase in economic efficiency can be expected from proper supervision and treatment. The same may be said of the affection of the respiratory system. Those of the gastrointestinal, urinary, male and female genitals are most amenable to, if not curable, by appropriate treatment. Considerable improvement results from proper management of the diseases of the nervous system. The affections of the skin were, for the most part, curable. The greatest benefit from an economic standpoint would be found following systematic treatment of the diseases of the bones and joints. Including the diseases or affections of the special senses only 4 per cent. of this group are normal men and women.

Conclusions.—1. A health clinic, conducted along the lines of group diagnosis, can operate without great expense to the individual and, in our case, none to the institution.

2. Such a clinic can cooperate with the family physician to the benefit of him and the patient.

3. It reaches well beyond the limits of the city where it is established.

4. The second, third, and fourth decades appreciate best the need of such service.

5. The occupations indicate a high grade of intelligence of this clientèle.

6. Physical defects, exclusive of the eye, ear, nose, and throat, were demonstrated in 79 per cent. of a group of 400 individuals, of whom nearly 80 per cent. were presumably well.

7. Faults in habits and hygiene were shown in percentages ranging as high as 50.

8. Factors well recognized as predisposing to organic disease were shown in as many as 30 per cent.

9. A large percentage of cases showed signs which might erroneously be considered of organic significance. Rectification of such errors is of nearly the same value to the individual as the demonstration of positive facts.

10. The faults in habit and hygiene can be eliminated, the factors predisposing to disease almost entirely corrected, and the organic disease nearly always modified and in the majority of instances definitely cured.

520 Commonwealth Avenue.

Sympathetic Algia in a Melancholic.—Laignel-Lavastine and Delmas relate that a woman of 35 with melancholia tried suicide by strangulation. She was prevented but thereafter was wont to constrict her neck with any convenient object at very short intervals, stating that this act relieved her anxious state. In this way she induced what appeared to be a vasomotor neuralgia of the left arm and hand, which subsided under the use of vasodilators.—*La Presse Médicale.*

HYOSCINE AND MORPHINE AS A PRELIMINARY TO LOCAL ANESTHETICS.*

BY LEE M. HURD, M.D., F.A.C.S.,

NEW YORK.

IN 1914, after using this method for nearly two years, I made a report (*Laryngoscope*, Nov. 1914). Now, in the eighth year, stimulated by the findings of your Committee on Local Anesthetics reported before this Section last year, I am prompted to take up this subject for a second time. Anything that adds to the comfort of the patient, lessens, shock, and reduces risk of local anesthetic intoxication, is surely worth while.

In the report of your Committee on Local Anesthesia the answers received to the question "What toxic effects have come under your notice?" thirty-seven in number, detail the symptoms of syncope or phrenic irritation. I consider all were shock except two or three. The fatalities, excluding the mistakes in dosage and those in which the anesthetic was injected into a vein, appear to me more like mental shock death and not like fatality from local anesthesia.

The experiments on lower animals except for toxic dosage are of no help, because animals experience no apprehension or fear. In the human, especially the nervous type which are in the great majority, apprehension and fear play a very important role in shock, even more important than the shock of operative trauma. For this reason not only should the operative field be anesthetized, but the contact ceptors and the special sense ceptors should be blocked.

I wish to state again that the preliminary administration of hyoscine hydrobromate and morphine sulphate has eliminated the unpleasant features of local anesthesia which I experienced in the past, and given me a confidence that, no matter how nervous or apprehensive patients may be, there will be no trouble with them at the time of operation.

The operations of otolaryngology usually done under local anesthesia are expanded by hyoscine and morphine to the major group, such as mastoidectomies, laryngectomies, resections of jaw, etc., when general anesthesia is not desired.

Though nearly all cases are ready forty-five minutes after receiving hyoscine and morphine, some require a longer time to settle down and some require two or three doses. This makes it impossible to appoint a definite time for the operation, as is required in reserving the operating room in a busy hospital. I have had a delay of over two hours in some instances.

The routine dose is morphine 1 4 grain, hyoscine 1 100 grain. This is usually given after a light meal, administering a second dose, if necessary, after forty-five minutes, usually half of the first dose, though this depends upon whether the patient reacts to one drug more than the other. If so, less of the drug to which the patient reacts more readily, and more of less active drug is used in the second dose. In 300 consecutive cases a second dose was given in 42 cases, a third dose in 5 cases, and a fourth dose in 2 cases. The third and fourth doses were usually given for long major operations. One of my first patients, a woman, became suddenly very hysterical when I was half way through operation and was noisy, laughing and crying, but mainly laughing, for several hours. In this case I had been forewarned of the hysteria and the next day she did not remember the hysterical outburst, or any part of the operation. Four other women showed some hysteria when the first tonsil was removed, but made no complaint when the second came out. I had misjudged my patients and had not given enough hyoscine and morphine. They probably would have been all right after a second dose.

Of my early cases, two which were mentioned in my previous report, while I was using the sitting position, had marked drop of blood pressure to 90 mm. systolic; otherwise their condition was good and the operation was finished. In the first case I gave a hypodermic of adrenalin and placed the patient in a recumbent position. In the second case after operation, the recumbent position promptly raised the blood pressure. For the past three years all cases have been kept recumbent during the operation and, even if the dose is not sufficient, syncope and lowered blood pressure do not occur.

Previous to three years ago, the hyoscine I was using did not act as consistently as that which I am using now. There were more cases of delirium, coma, prolonged effect, etc. The hyoscine must be pure; especially, it must not contain apoatropine as an impurity. For the past three years the action of the hyoscine which I am now using is quite as consistent as is the action of morphine. The tablets must be kept dry and fresh solution made at the time of operation, as hyoscine in solution will break down into impure and poisonous by-products in twenty-four to forty-eight hours.

The patients were nearly all good risks, though the poor surgical risks did equally as well. When patients are ready for operation, their pulse rate is reduced, they are sleepy or sleeping and do not want to be disturbed, speech is slow and somewhat thick, cerebration is slowed, they may be somewhat confused, and in moving from bed to operating table they have a staggering gait. The pupils may be contracted (morphine), or dilated (hyoscine). The ideal is midway. The face usually itches; the color is good.

The pulse is taken at time patient enters office for operation, again when the operation begins, and immediately after it is finished. The average pulse rate in 50 cases was 99 at the time of entering office, 85 at the beginning of operation, and 85 at the end of operation. This, however, does not show the whole picture, for example, 128-88-84 in a highly nervous patient, and 76-76-72 in a phlegmatic one might be taken as extremes.

The blood pressure taken in a few cases a day or two before operation, at the beginning and at the end of operation, showed:—

Before Operation		Beginning of Operation		End of Operation	
Systolic	Diastolic	Systolic	Diastolic	Systolic	Diastolic
122	76	110	70	124	74
170	100	180	100	200	110
150	100	150	100	162	84
132	84	120	80	150	100

*Read before the Section on Laryngology, Otology, and Rhinology at Boston, June 8, 1921.

The age groups are:—

11 to 20	50 cases	16+ per cent
20 to 30	75 cases	25 per cent
30 to 40	93 cases	31 per cent
40 to 50	50 cases	16+ per cent
50 to 60	18 cases	6 per cent
60 to 70	14 cases	5 per cent

Hyoscine and morphine work well at all these ages.

Having had the usual run of syncopes and varying degrees of psychic shock before I began the use of hyoscine and morphine, I now have none with its use. The patients have a steady pulse which tends to pass the anesthetic which is being absorbed, on to the liver for elimination, preventing intoxication.

Morphine can be used in larger doses if cocaine is used in conjunction with it, and the reverse is true. Hyoscine has the same physiological action as atropine plus blocking of the mind. Blocking the sensory nerves with morphine and hyoscine prevents shock and, though more local anesthesia can be used, as a matter of practice less anesthetic is necessary.

In the production of local anesthesia I have used novocaine hypodermatically, cocaine and alypin topically,

Cocaine	29 times
Novocaine	41 times
Alypin	223 times
No anesthesia	2 times

Alypin and novocaine are quickly eliminated and are, therefore, better than cocaine. Alypin which is equally as anesthetic as cocaine and much less toxic, I prefer, though it is unobtainable at present.

Patients are kept in the office two or three hours after operation during which time they are asleep. They are awakened then and are usually in condition to be taken to their homes or a hotel.

Since the previous report, I have extended the use of hyoscine and morphine to all cases operated upon under local anesthesia except very minor and short operations regardless of age or surgical risk. Whether the patient appears nervous or phlegmatic, I feel confident that, if this method is used, you will not have the symptoms attributed to anesthetic intoxication, and fatalities with the proper use of the local anesthetic will be greatly reduced.

39 East Fiftieth Street.

WERE THEY WRONG DIAGNOSES OR NATURE CURES?

By C. A. BRYCE, M.D.,

Richmond, Va.

Most of us who have seen long service in the profession can recall mistakes in diagnoses, and even worse ones in unfavorable prognoses. Some of my experiences with supposed cases of cancer of the stomach and hopeless prognoses are interesting to me now that time has proven my mistakes.

Case I.—Many years ago I was called to attend an old lady between sixty-five and seventy years of age, who presented every symptom of cancer of stomach. She had fallen off to a mere skeleton, had long standing aggravated dyspetic symptoms, pain after taking any food, a flaming glazed red tongue, and a big hard lump near the pyloric end of the stomach as well as I could make out from external manipulation. With her age and these symptoms I made out a case of cancer of stomach, and concluded that her days were numbered. My dear friend and able physician, the late Dr. R. A. Lewis, saw the case with me and fully agreed with my diagnosis and unfavorable prognosis. We advised the old lady to "go to the country" for a while. This is a very convenient procedure for getting hopeless cases off a doctor's hands. The old lady took our advice, went to a niece's in the mountains, got a complete change of environment, water and diet, and cheerful company. In six months she returned home absolutely well and without having used any medicine of any kind whatever. I was surprised to see her once more, and more surprised to see her looking so well; indeed, at first I failed to recognize her. She said to me: "You thought I was going to die and that is the reason you sent me away, but you doctors don't know everything, and I thank God that you quit the case and gave me a chance for my life." She shook herself and looked so "sassy" about it I almost wished my prognosis had been right.

Case II.—Twenty years ago a gentleman of about thirty-five years, a farmer, came to consult me about a chronic stomach trouble that had persistently resisted all measures employed by two very good physicians of his neighborhood. He was very much emaciated, vomited almost everything he ate almost as soon as it entered the stomach, and he had lived on small quantities of milk and other semi-liquid diet for months. He had much pain after the ingestion of anything. He was seen by several good surgeons, and all of us feared malignant disease of the stomach. It was finally agreed that we would operate upon him for supposed cancer and if such did not exist, to find out what was the trouble. He went home to arrange his affairs, promising to return in two weeks to undergo the operation. The weather was warm, and before leaving town he went into a restaurant and ate a pint of ice cream. It felt good in the stomach and was retained without giving him any pain. He was surprised at its retention and at the comfort it gave his stomach, and just before taking his train he ate another pint, which behaved as the first did. He shipped the best freezer he could buy to his farm, and being a man of means, his fine herd furnished him abundantly with the best cream. His wife kept a good supply of ice cream in that freezer all the time, and for two months he lived absolutely on nothing but ice cream—not a mouthful of anything else. Within the two months he gained twenty pounds, had no trouble with his stomach and cautiously returned to his usual diet without any inconvenience, and has remained well ever since. He was in my office this summer and looked well and felt fit—twenty years after his cure.

Case III.—Within the past five years a lady about forty-five years of age, consulted me after having been x-rayed and pronounced suffering with an inoperable cancer of the stomach, by a leading surgeon of this city. She was told that nothing could be done for her through surgery, and she drew the inference that she could live but a few months. She was placed upon a milk diet principally, and as she did not get worse she kept on and gave up the idea of dying from cancer, and today is looking and feeling as well as she ever did in her life.

It is bad to make a diagnostic mistake. It is infinitely worse for patient and physician to labor under an unfavorable prognosis, which may not be correct, and always lessens the chances for recovery.

516 North Tenth Street.

Acute Miliary Tuberculosis Mistaken for Typhoid Fever.—Caussade and Doumer describe a case which had all the symptoms of Landouzy's classical picture—fever curve, dissociation of pulse and temperature, pronounced leukopenia, enlarged spleen, etc., slight bilateral serous pleurisy being a complication. The patient was a diabetic, but sugar left the urine during the acute disease. Autopsy showed no Peyer's patches or other lesions of typhoid, but instead miliary tuberculosis. There is no mention of negative serodiagnosis or hemoculture and it is not to be inferred that a mistake in diagnosis was made.—*Le Bulletin Médical.*

A CASE OF CHRONIC ERYTHEMA NODOSUM, WITH RECOVERY.

BY WILLIAM W. CADBURY, M.D.,

PHYSICIAN TO THE CANTON HOSPITAL.

CANTON, CHINA.

ERYTHEMA Nodosum is one of those clinical entities whose etiology is still very obscure. Most authorities believe that it is rheumatic in nature, while others claim that it is generally associated with tuberculosis. According to Stelwagon in his "Diseases of the Skin," the disease is more common in females than in males, and at from ten to thirty years of age.

The inflammatory swellings usually do not last more than two weeks, and the patient generally makes a good recovery in a month or so. Sodium salicylate and quinine are recommended for treatment.

The following case of unusual severity and prolonged course will be found of interest:

T. T. S., Chinese, male, aged eighteen, a farmer by trade, was admitted to the wards of the Canton Hospital January 28, 1920. (Hist. No. 20,209.) The patient complained of painful swellings on the face and four extremities. The family history was negative. Patient is unmarried, neither smokes nor drinks alcohol, and has had no serious previous illness.

The present illness began five years ago. Tumors first appeared on the face and then on the forearms and legs. Occasionally the thighs and upper arms were the seat of the lesions and rarely the trunk.

A tumor begins as a small hard swelling of the skin. It gradually enlarges and becomes exceedingly painful and tender. The color becomes dark red and the surface is hot. If several swellings mature about the same time the patient has chills and fever. The swellings gradually decrease in size; the entire cycle of development and recession of one lesion is about a month. At the maximum there is generally fluctuation, but the tumor seldom breaks down. If this does occur a small amount of fluid escapes. The sites of the old lesions remain pigmented after the removal of a small scab. Sometimes the skin is also pitted at the site. Lesions are generally round, but sometimes elongated. New ones tend to appear at the margins of old ones. There is no itching and no numbness, only tenderness and pain.

Physical examination: The boy appears no more than fourteen years of age, though he says he is eighteen. There are numerous swellings on the face and four extremities. The anterior surface of both legs is smooth and shiny, the result of many tumors. They have always been more numerous on the legs.

The appetite was fair. The heart, lungs, and liver appeared to be normal. The spleen was enlarged and palpable.

July 29, 1920: Hemoglobin, 60 per cent.; leucocytes, 23,600; red cells, 4,750,000. Urine, dark yellow, acid. Sp. G., 1,020, no albumin no glucose. Feces: Ascaris ova present.

The temperature on admission was 38.7° C. the pulse 108, and respiration 18.

The treatment consisted in calomel and saline purgatives as required, and a course of santonin for the ascaris. Yeast was given for the first week and also chloride of iron solution with Fowler's solution. An antiphlogistic paste was applied to the most painful lesions. Quinine was given for three or four days.

Stock typhoid vaccine was injected intravenously as follows: January 30, 20,000,000; February 11, 10,000,000; February 23, 20,000,000.

The temperature fluctuated from 36.9° to 38.7° C. for the first three days until the vaccine was given on the 30th. This was followed by a severe chill and a temperature of 40.6° C., which fell to 38.7° the next day, and fluctuated between 38° and 40°, but gradually falling until the 10th of February, when it did not rise above 37.6°. After the second dose of vaccine on the 11th there was a milder reaction, after which the temperature varied from 37° to 38° until February 20th, after which it remained normal. The injection on the 23d was followed by a more severe reaction and a return to normal the next day. The course of the lesions was as follows: Slight decrease of pain by February 4; February 13, condition still better.

Patient was discharged on February 25. The temperature was normal. No new lesions were developing, and the old ones had healed and were painless.

On February 7 the leucocytes were counted again and there were but 10,500.

Considering the protracted course of the disease, the marked improvement during one month of treatment was considered quite remarkable.

Medicolegal Notes.

Evidence as to Death from Ptomaine Poisoning—Invading Province of Jury.—In an action on an accident policy where it was claimed that the insured's death was caused by ptomaine poisoning, the defendant objected, on appeal, that physicians were permitted to state what caused the deceased's death, as this was invading the province of the jury. The court found no testimony in the record where the doctors were asked or permitted to state in positive terms what caused the deceased's death, except where the defendant's counsel asked a medical witness, on cross-examination, if he was certain as to what caused the deceased's death. It was held that if defendant's counsel asks questions of this character, or makes no proper objections to those asked by counsel for plaintiff, he cannot be heard to complain on appeal.

Three doctors testified that there is such a thing as ptomaine poisoning, and that, in their opinion, this caused the deceased's death. Two doctors testified that under the facts disclosed at the trial this would be almost impossible. It was held that this made a disputed question of fact for the jury, and there being substantial testimony to support their finding that the deceased came to his death by ptomaine poisoning, the court would content itself with "refusing to disturb the verdict of the jury, rather than to declare as a matter of law that deceased could not have died from ptomaine poisoning, and thereby settle judicially this disagreement between members of the medical fraternity."—O'Connor v. Columbian Nat. Life Ins. Co. (Mo. App.), 232 S. W., 218.

License to Practice—Right to Adjourned Hearing.—The Colorado Supreme Court holds that, under Laws 1917, p. 359, § 11, providing for thirty days' notice to an applicant for a license to practice medicine after an adverse finding by the board, to appear before the board in person, an applicant who has appeared in person and introduced his evidence on the hearing four months after the filing of his application is not entitled to have a further hearing on thirty days' notice or otherwise.—State Board of Medical Examiners v. Brown (Colo.), 198 Pac., 274.

Privileged Communications — Prohibition Surviving Patient's Death.—In a suit to set aside a will on the ground of undue influence and mental incapacity, the Mississippi Supreme Court holds that the prohibition of the Mississippi statute against the disclosure by a physician or surgeon of communications made to him by a patient, except at the instance of the patient, survives the patient's death, and cannot be waived by the patient's heir, executor, or administrator.—McCaw v. Turner (Miss.), 88 So., 705.

Province of Medical Witnesses and of Jury in Injury Cases.—In an action for benefits under a health and accident policy, where the plaintiff's finger was accidentally injured by being mashed in turning a wagon, resulting in blood poisoning, a physician who subsequently attended the plaintiff testified that he found him suffering from diabetes, which might have been, and, in his opinion was, the direct result of the injury to the finger and the resulting blood poisoning. It was held that the question whether the diabetes was the result of the accidental injury was for the jury.—Anderson v. Mutual Benefit Health & Accident Ass'n (Mo. App.), 231 S. W., 75.

BOWEN'S DERMATOSIS.

DESCRIBED for the first time by Bowen, of Boston, this dermatosis has given rise to much study in France, especially by Darier. This process is characterized by the insidious appearance somewhere on the cutaneous surface—trunk, limbs, face, genitals—in adults or elderly subjects, of keratotic spots varying in size from a lentil to the palm of the hand, rounded, polylobate or irregular in shape, of a dull pink color, frequently more or less papular or vegetating and invariably covered with thick squamæ or crusts. The lesion may be single at the onset of the process, but usually there are from ten to twenty present. The principal characteristic of the lesions is to persist indefinitely and to resist all therapeutic measures, excepting destructive ones, while pruritus and pain are wanting. They extend slowly, but what is most interesting is that they undergo malignant transformation in a notable percentage of cases, hence they have been placed with precancerous affections, such as senile keratosis, radiodermatitis, nevi, xeroderma pigmentosum and, above all, Paget's disease of the nipple.

Malignant transformation makes itself manifest by the fact that the lesion develops vegetations or ulcerates. Sometimes the ulcer is irregular in outline with excessive granulations, an indurated base, and more or less keratotic edges. At others, a mammillate or papillomatous tumor develops, erosive, bleeding, and covered with a crust, so that the malignant character of the lesion cannot be overlooked. The adjacent lymph nodes are involved, form a bosselated tumor, which in turn ulcerates and invades the surrounding structures. Generalization of the neoplasia to the deep seated lymph nodes, and pulmonary and peritoneal metastases arise.

The gravity of this evolution necessitates an early diagnosis of the lesion. Darier points out that the epidermis of the lesions, which are distinctly limited on their edges, has undergone a profound change. A large number or even most of the Malpighian cells are increased in size, hypertrophied or edematous. The principal changes occur in the nuclei; these are unequal, some being small, others—and these are in majority—are giant, multiple, deformed or monstrous. It is to one of these vitiated processes or keratinization that Darier has proposed to give the name of dyskeratosis. One of the effects of this change is to permit the passage of condensed cells into the horny stratum, which assume the shape of rounded corpuscles, either nucleated or not. The horny stratum occasionally assumes the aspect of a true carapace more or less infiltrated with serum. In its *ensemble* the epidermis is thickened, the papillæ hypertrophied and more or less deformed, and the papillary body is the seat of a distinctly limited cellular infiltrate rich in plasmocytes.

Such are the clinical and histological character of this affection whose only remedy is excision, which should be done as soon as the diagnosis is made. Destruction of the process may be effected by radium, *x*-rays, carbonic snow, or cauterization. The essential is to know that over 50 per cent. of the cases undergo malignant transformation unless thoroughly dealt with, although at the onset the lesions look very benign.

THE PATHOLOGY OF FIBROMATA OF THE SPERMATIC CORD.

FIBROMA of the spermatic cord is usually single, though in one or two reported cases two tumors were present. In most cases the growth will have reached the size of a fist at the time the case comes to operation, but it may be much smaller. The site varies and if the cord be divided into two portions, the first extending from the tail of the epididymis to the external ring—which may be termed the scrotal portion—and the second comprising the entire inguinal course of the cord, it will be found that these growths develop much oftener in the scrotal portion, the ratio being 8 to 1. The tumor develops regularly, but slowly, and takes several years to reach the size of an orange. There is no spontaneous pain and none on pressure. No functional disturbances arise, but coitus may become impossible from the size of the neoplasm. The phenomena of discomfort are due simply to the weight of the growth.

Macroscopically, the tumor is a regularly rounded mass, smooth, hard, non-transparent, and without adhesions, surrounded by a dense thick fibrous capsule completely isolating it from the surrounding structures. The veins of the scrotum are hardly ever enlarged. The testicle and epididymis are intact and are normal in size. They lie against the tumor and often are adherent to it. They may lie in front, to the right or left, or underneath the fibroma. The cord is apt to be enlarged and its elements are spread out over the growth the vas deferens alone is comprised in the neoplasm and is difficult to dissect out. On section the neoplastic tissue is purely white, dry and hard, with concentric or interlaced fibers, while the intervals between the fibrous fasciculi contain a darker colored tissue. Occasionally, some cystic cavities may be met with.

Microscopically, the tumor is found composed of thick connective tissue fasciculi matted together, usually wavy, interwoven together or concentrically placed. This connective tissue contains cell elements in variable number. The vascular supply varies. Besides the vessels, lymphatic canals are found, containing coagulated lymph and leucocytes. Fat vesicles are quite numerous. Like all other fibroid neoplasms, fibromata of the cord may undergo mucous, serous, fatty, or even calcareous transformation. Non-malignant primarily, these growths may undergo sarcomatous transformation; they can also become inflamed and develop gangrene. The microscopic study of fibromata of the spermatic cord shows that there is always an abundance of connective tissue fibers and absence of elastic tissue. The cell elements vary in quantity. They are more abundant in younger growths which have not attained their final development. The vascularization of the growths is at times rich, at others poor, and this likewise applies to the lymphatic spaces. The fat vesicles invariably exist in very large number.

Now what elements of the spermatic cord give rise to these growths? The connective tissue uniting the various component parts of the cord has been supposed to be the starting-point of fibromata and it is beyond any reasonable doubt that this is true. In point of fact, if the envelopes intervened in the formation of the growth it would be quite impossible to isolate them. The fibrous capsule surrounding the tumor is perhaps nothing else but the membrane enveloping the cord, and under the influence of the irritation produced by the development of the tumor this membrane becomes thickened and united to the growth to which it intimately adheres, developing gradually along with the neoplasm.

SUDDEN DEATH.

THE dramatic nature of sudden apparently unmotivated death has made it a subject of perennial interest to medical men and especially to forensic practitioners. There is always a presumption of suicide or homicide until such a possibility can be excluded. The relationship between sudden death and the status thymicolymphaticus involves but one aspect of the problem, which should be dealt with separately. However, the enormous literature on this type of death is rather evidence against than for the existence of such a factor; and it is much sounder to analyze all of the cases of sudden demise without any prejudice in favor of so-called thymic death. This has been done by Thorner in the *Schweizerische medizinische Wochenschrift* for September 8, 1921, ii, 36. The writer first quotes from voluminous statistics which show the considerable predominance of males over females and the frequency of arteriosclerosis in the deceased, even when young. The relation between this vascular condition and sudden death is clear and arteriosclerosis is much more definite than the hazy status lymphaticus. The occurrence of sudden death after sharp physical overstrain can hardly be called a spontaneous phenomenon, although the author includes such in his quoted figures.

His personal statistics comprise nearly 300 cases recorded during a period of nearly four years in a definite area of Switzerland. Many came to autopsy in the Institute for Forensic Medicine of the Basle University. The annual figure is 77 deaths, and the percentage per 1000 of population appears to agree with that of other cities of Central Europe. The author was surprised to find that females predominate over males. Only 105 cases came to autopsy, and the author's analysis is based on this material. He makes three categories, in the first of which there was no discoverable cause of death, while in the second there were alterations which may or may not have been a factor. In the third class the causal factor was apparent in the presence of some lesion. When the cause was undoubted the heart was naturally the organ which had given out. The author lists 40 such cases, comprising 15 of valvular lesions, hypertrophy and dilatation, 7 of coronary sclerosis, 7 of myocarditis, and 7 of mesaortitis luetica, the remainder being scattered. Contrasted with this material there were but 4 cases of sudden death in which all the organs were intact and a number of others which cover deaths of tuberculous, cancerous, and other subjects in which the exact mode of death is not apparent.

In the 41 cardiovascular cases it is important to note that death was not the typical cardiac passing out, which is due to progression of the morbid state up to the point of cardiac failure. In many, if not most of the cases, the condition was at a standstill and death occurred in the midst of apparent health, as in the case of a youth of 20 who died in a game of football.

SPONTANEOUS COLIPROSTATITIS.

NUMEROUS recent writers on prostatogenic focal infection mention infection of that organ with the *Bacillus coli* as the source of one or more lesions in remotely seated organs, notably the joints. In such cases it is not necessary that prostatic abscess forms; on the contrary infection of the gland is usually discovered by milking it and examining the expressed secretion. In all cases there are local evidences of inflammation. Not a few writers ignore coli-infection and attribute practically all cases of prostatogenic infection to the gonococcus. In the *Schweizerische medizinische Wochenschrift* for August 11, 1921, li, 32, Suter presents a monographic study of spontaneous coliprostatitis, which naturally excludes all cases attributable to instrumentation, and relates a number of personal cases, claiming that the incidence is relatively common. Like most Continental writers he seems unaware of the existence of remote secondary foci. Focal infection is well enough known in Europe and infection in certain localities like the pararenal tissues is frequently particularized as a source of

miscellaneous metastases. The silence in respect to focal infection originating in the prostate and seminal vesicles may be explained by the fact that metastases from these structures are regarded as presumably gonococcic, despite the fact that the germ in question can no longer be found. In such a supposition the *Bacillus coli* and streptococcus would only mean mixture of infection. On the other hand in some of the American cases there is no history or evidence of old gonorrhea.

The symptoms of this affection suggest, according to the case, either acute or chronic cystitis and this diagnosis is almost always made when the prostate is not palpated. The urine often shows blood admixture. Palpation reveals an absence of type in regard to the size and site of the swelling, the consistency and tenderness. The amount of expressed secretion varies, as does the consistency. The *B. coli* is only directly in evidence in part of the cases. In the majority it is only brought out by cultural efforts. The posterior urethra is invariably diseased. Cystoscopy cannot be practised in these cases. Chills and fever are very common and are known to be common in all coli infections. No matter how acute the process the tendency is to subside without formation of a true abscess. The latter is very common in coli infection of the kidney and epididymis, so that this point is significant. In some cases pus escapes by the natural passages and in others there is no accumulation of purulent matter. Coliprostatitis is very prone to recurrence. The mechanism of infection is most obscure, and in an analysis of 89 cases of spontaneous prostatitis of all kinds collected by the author little light was thrown on the subject. A few seemed to have been due to influenza. The staphylococcus is the most common offender, followed at a considerable distance by the streptococcus and colon bacillus.

Studies of a Myxedematous Child.

The problem of thermogenesis in thyroidectomized animals has received considerable attention, and it has been ascertained that injections of thyroid extracts will raise the temperature in hibernating mammals. Cori, writing in the *Wiener klinische Wochenschrift*, October 6, 1921, xxxiv, 40, has recently made studies of a myxedematous child 4 years of age as follows: he immersed him in a bath at 25° C. and then in another at 40° C., the exposures being respectively 10 and 15 minutes. These experiments were then repeated with the same subject under thyroid feeding. Comparison of temperature curves shows that in the untreated child the temperature fell to 33° C. and that it did not behave normally until the lapse of 14 hours. Compared with several healthy children the latter showed an initial fall to 36° C. only, with but 1½ hours for readjustment. In the myxedematous child under thyroid feeding the behavior was nearly that of the normal child. Recovery was equally prompt although the initial fall was slightly lower. When the myxedematous child was placed in the warm bath there was no reaction—no reddening of the skin, no sweating nor acceleration of pulse or respiration. The child was then tested for protein fever by injecting milk parenterally. It has long been known that these children can develop fever in acute infections. The temperature promptly rose to over 39° C. and did not become entirely normal for 41 hours. Tests were also made for adrenaline, atropine, and pilocarpine reactions in the untreated and treated child. The administration of thyroid increased the response of the sympathetic and diminished that of the vagus to the action of these drugs.

Surgical Statistics of Mammary Cancer.

Apropos of the general discussion which followed the reading of papers by Forgue and Walther at the recent session of the French Surgical Society (*La Presse Médicale*), Alessandri of Rome mentioned a recurrence 14 years after removal of the breast; fortunately this was readily removed and there has been no second recurrence. Grenade announces 28 per cent. of 5-year survivals in a large operative material. Begoin has 20 5-year survivals in a material of 134 operations, equal to about 16 per cent. Apparently, however, but 78 cases were followed up so that the real percentage of his 5-year survivals is about the same as Grenade's. Delagenière has operated on 413 women in 3 years past and upwards. Only 159 were followed up, with 72 "long survivals"—considerably more than 40 per cent. Hartmann followed up 251 cases out of 331. He gives only his 3-year survivals—36 per cent. Auvray followed up 42 out of 82 operations, and found among them numerous prolonged survivals—one of 16 years, 5 of 10 years, another of 10 years including recurrences, and one each of 8, 7, and 6 years. Faure's Paris figures show 11 5-year survivors in 72 followed up. Lapeyre uses radiation of the ovaries in a sterilizing dose after operation. Reynes performs ovariotomy after Beatson's method. He has numerous cases of protracted survival—10, 15, and 20 years. Jemtel claims in 68 follow-ups no less than 17 10-year survivals. This, if not a misprint, must break the percentage record for protracted survival.

Experimental Yellow Fever in the Dog.

Doctor Lebredo completes his serial article on "Experimental Leptospirillosis" in dogs in the *Revista de Medicina y Cirugia de la Habana* for September 25, 1921, xxvi., 18. The organisms used for inoculation were of the so-called Merida (Yucatan) strain, obtained from Dr. Noguchi, of the *Leptospira icteroides*, which the latter succeeded in isolating. The author sums up the result of his investigation as follows: both pups and adult dogs were remarkably susceptible to this organism. The latter was introduced by the intraperitoneal, oral, and intradermic routes. The former exposure proved rapidly fatal—within 18 to 24 hours or before a typical disease picture could develop. When administered by the mouth the mortality was much less and some of the animals escaped infection altogether. Of most interest, paraphrasing mosquito transmission, was the intradermic method, which gave clean-cut disease pictures, comprising severe and fatal types. The icterus and

hemorrhagic lesions were typical of yellow fever. The author also succeeded in effecting mosquito transmission by means of *Aedes calopus* and he has shown that the dog may be a reservoir of infection, although this may not happen in natural yellow fever in man. In the author's research actual cultures were not employed but guinea pigs were first contaminated with the leptospira and the blood and viscera were then used in the canine experiments.

News of the Week.

St. Luke's International Hospital in Tokio to Be Made Health Center.—Tokio is desirous of creating a medical center like those of the large American cities, and has sent Dr. R. B. Teusler, director of St. Luke's International Hospital, to this country to interest Americans in a project to expand the institution. It is proposed to make St. Luke's Hospital the nucleus of a hospital of 250 beds, a training school for 150 Japanese nurses, a postgraduate department for training Japanese internes and for medical research work, a public welfare and health department to include medical social service, and a medical library for American and British medical literature and magazines. Dr. Teusler says that about $1,000,000 would be required properly to establish the proposed health center.

Health Week for Rotarians.—Rotary clubs are celebrating the week beginning December 5 as health week. During the week special attention has been given to spreading information with reference to tuberculosis. On Sunday, December 11, which is designated Health Sunday as well as Tuberculosis Sunday, instituted in New York State under the auspices of the Committee on Tuberculosis and Public Health of the State Charities Aid Association, there will be special talks in the churches on "Conquering the Great White Plague."

A Medical Unit for Russia.—The People's Commissariat for Public Health at Moscow has given permission to send an American medical unit to aid particularly in the famine regions of Soviet Russia. The unit is being organized in cooperation with the Russian Red Cross, at a cost of $150,000, and will be sent abroad by January 1. It is proposed to send at least twelve American physicians, several motor trucks, three or more motor ambulances, and hospital supplies and equipment.

Traffic Accidents in New York State.—A report of traffic accidents from January 1 to November 30, prepared by the National Highways Protective Society, shows that 1,741 persons were killed by automobiles and motor trucks in this State, as against 1,429 for the entire year of 1920. It is predicted that this year's record will be just short of 2,000 dead. During November 225 persons were killed from these causes in the State; in New York City 66 were killed by automobiles and motor trucks and seven by trolley cars.

The New York Hospital Immunization Clinic.—A clinic is being conducted at the New York Hospital for the immunological treatment of hay fever, asthma, eczema, and poison ivy, which is open Tuesday and Thursday evenings from 5 to 7 o'clock. Preventive inoculations against diphtheria and typhoid fever are also administered.

Suspected Food Poisoning Should Be Reported.—The New York City Health Department requests physicians who meet cases in which a suspicion of food poisoning is justified to report the facts to the Department of Health, so that the Bureau of Food and Drugs may make an investigation. Such illnesses are reportable in California and elsewhere, and as information accumulates in regard to their epidemiology will doubtless become generally notifiable maladies. In reporting suspected cases, physicians are requested to give information as to name, age, sex, occupation, residence, date of onset, symptoms, laboratory findings, treatment, present condition. As regards the food supposed to have caused the illness, information is wanted as to when and where the foodstuff was purchased, when eaten, by how many persons, number made ill, name and address of attending physician. Above all, the department desires to obtain a portion of the article suspected.

Medical Journal to Change Ownership.—The Southern Medical Association, at its recent meeting, held in Hot Springs, Ark., voted to accept the advice of its board of councilors that the *Southern Medical Journal* be purchased from its present owners for $55,000.

Shortage of Ambulances in New York City.—In connection with the campaign being conducted by the United Hospital Fund, Wiliam Fellowes Morgan quotes figures just compiled by the Public Health Committee of the New York Academy of Medicine showing that the ambulance service of the city is in a critical condition. Some hospitals have been forced to drop their ambulance service because of lack of funds, and other hospitals which are facing deficits fear they will be obliged to abandon this part of their work. The figures of the hospital survey of the Public Health Committee show that the ambulances of the city responded to 109,395 calls in the last year. Of this number only 3,100 were unnecessary. During the year ambulance surgeons treated 42,964 victims on the spot, a fact which shows the need of keeping up an efficient ambulance service. Of the 109 ambulances in the public emergency service the large majority belong to private hospitals.

Nursing Situation in New York Improves.—The shortage of nurses, which became acute soon after the war, is being remedied in New York City, according to an announcement made by the New York County Chapter of the American Red Cross. The Red Cross has maintained a traveling recruiting service for nurses for ten months and this, with unemployment which had led many girls into nursing who would otherwise have gone into business, has remedied the situation. The nurses' training schools in the hospitals of the city, which had only half their complement of pupils last year, are filling up, the report says.

Plan to Train Reserve Corps of Nurses.—Agitation is being carried on with the object of starting a nation-wide movement to interest cities in building up a reserve corps of nurses to cope with possible future epidemics. The idea is based on the work accomplished by Dr. John Dill Robertson, Health Commissioner of Chicago, who has developed a training course which not only costs the Chicago government nothing to give, but en-

ables the city to boast a nurse militia, as it is called, of 10,000 trained women ready to step in and aid in the event of an epidemic. Dr. Robertson, in commenting on his plan, says that as an economic problem the desirability of having in every family a trained member able to care for the sick needs no argument, and that is what he has set out to do. The Chicago attendance at the training school for home nursing from the start has averaged 700. It provides an eight weeks' course and charges a fee of five dollars. The Chicago school was financed in the main by a health exhibit, which netted sufficient funds to run a free hospital with twenty beds where the students could receive first-hand training. Graduates of this training school have aided in 12,000 homes besides their own during the past year.

The British Association for the Advancement of Radiology and Physiotherapy, which has been in existence for about four years, held its annual general meeting in London on September 30 last. Announcement was made at this time that the Society had secured its certificate of incorporation. The president, Dr. Robert Knox, in reviewing the work which the organization had accomplished since its foundation, outlined the causes which led to the formation of the Association. At the time of the outbreak of the great war in 1914 London at least was well provided for in radiological matters in so far as the purely scientific side of things was concerned. But when it came to be a question of corporate action, radiologists and physiotherapists found themselves without any organization capable of speaking and acting for these specialties as a whole. The University of Cambridge now recognizes the course of instruction organized by the Society in London as qualifying for admission to the diploma examination. In addition to educational activities, there has recently been initiated the policy of issuing authoritative statements on medical subjects to the daily press. A special committee is engaged on the matter of providing organization and training for lay assistants in *x*-ray and electrical departments. The activities of this committee have resulted in the founding of the Society of Radiographers, the aim of which is to see some day in London an Institute of Radiology and Physiotherapy housed in a building worthy of the extent and importance of these subjects, having its own museum and library, and perhaps its own clinic.

Third Harvey Society Lecture.—Dr. Clemens Pirquet, Professor of Pediatrics, University of Vienna, will deliver the third Harvey Society Lecture at the New York Academy of Medicine, Saturday evening, December 17, 1921. His subject will be "Nutrition Treatment of Tuberculosis in Childhood."

The Radium Institute of New York announces its removal on December 15 to 323 Riverside Drive at 104th Street.

Salvarsan Adulterators Receive Prison Sentences.—The salvarsan adulterations in Germany and other countries were recently taken up by the Criminal Court of the County of Hamburg. After a trial lasting fourteen days, in which many experts were examined, the manufacturer and his superintendent were sentenced to three and one-half years in prison and to five years disenfranchisement. Sixteen defendants received two-year prison sentences each, and sixty-two others who had conducted a flourishing business in adulterated salvarsan were fined 20,000 marks. Six persons were acquitted. Those convicted of adulteration had manufactured a yellow powder from substances which were not only worthless but dangerous to health. It bore a striking resemblance to the genuine salvarsan and the labels and packing were so perfect an imitation of the genuine product that it could easily be mistaken for it even by physicians.

Hospital Notes.—St. Louis is to be awarded a soldier hospital if Secretary Mellon approves the recommendation of the hospitalization committee, which has decided favorably on a hospital for that city.

The Beth Israel Hospital, Roxbury, Mass., has completed plans for the erection of a new building to replace the present institution. The new hospital is to have an out-patient department.

The new wing of St. Joseph's Hospital, St. Joseph, Mo., which was erected at a cost of $300,000, was opened formally on November 14.

By resolution of its hospital commission, the Texas conference of the Methodist Episcopal Church South has voted to raise $300,000 for the building of church hospital in Houston. A campaign to raise this fund will be started early in the next year.

Contract for the alterations and repairs to the out-patient department of the Boston City Hospital has been awarded. The cost of enlarging the building and making repairs will be $496,000. When these changes are made the hospital will be able to care for two hundred more patients.

Ground was broken in Minneapolis on November 16 for the first of the nine hospitals for crippled children planned by the Mystic Shrine. This hospital is to cost about $250,000 and will care for fifty or sixty crippled children.

The Lady of Lourdes Hospital, Pasco, Wash., completed several months ago by the Sisters of St. Joseph, will be formally dedicated on December 21.

A campaign to raise $250,000 for the erection of a new hospital building for the New Rochelle Hospital was recently launched at a mass meeting which was addressed by Dr. George E. Vincent of the Rockefeller Foundation.

Dr. Kenneth M. Lynch of Dallas, Tex., was awarded a gold medal for research and accomplishments in the study of tropical diseases by the Southern Medical Association at its recent meeting in Hot Springs, Ark.

Dr. Russell H. Chittenden, for nearly twenty-five years director of the Sheffield Scientific School, Yale University, has sent in his resignation to take effect next June.

Dr. Virgil Pendleton Gibney, who has just completed fifty years as surgeon-in-chief of the New York Hospital for Ruptured and Crippled Children, was tendered a testimonial dinner at the Hotel Commodore, on the evening of November 22, in commemoration of his long and faithful service to the crippled children of the city.

Dr. Richard A. Poole has been appointed superintendent of the Indianapolis City Hospital.

The American Academy of Applied Dental Science will hold its third annual meeting at the Stacey-Trent Hotel, Newark, N. J., January 9, 10, and 11, 1922. A cordial invitation is extended to all members of the medical and dental professions. Further information may be obtained by writing to the Assistant Editor, American Academy of Applied Dental Science, Yonkers, N. Y.

Vacancies for Physicians.—The United States Civil Service Commission announces an open competitive examination for medical interne to fill vacancies in St. Elizabeth's Hospital, Washington, D. C., at $1,200 a year and maintenance, and vacancies requiring similar qualifications. Applicants must show that they are graduates of a reputable medical college, or are senior students in such an institution and expect to graduate within eight months from the date of making oath to the application. The examination is open to both men and women. Applicants should at once apply for Form 1312, stating the title of the examination desired, to the Civil Service Commission, Washington, D. C.

Positions for Dietitians in the Public Health Service.—The United States Civil Service Commission states that there is need for a considerable number of dietitians in the Public Health Service at hospitals throughout the United States and that until further notice it will receive applications for such positions. The basic entrance salary offered is $960 a year with possible promotion to the basic pay of $1,344 a year. To all salaries there is added the increase of $20 a month granted by Congress. In addition, quarters and subsistence are furnished free by the Government. Applicants are not required to undergo a written examination, but are rated upon the subjects of general education, weighted at 30 per cent. and technical training and experience, weighted at 70 per cent. Full information and application blanks may be obtained by communicating with the United States Civil Service Commission, Washington, D. C., or with the secretary of the local board of civil service examiners at the post office or custom house in any city.

Medical Society Elections.—THE OHIO VALLEY MEDICAL ASSOCIATION, at its twenty-second annual meeting held in Evansville, Ind., Nov. 16, 1921, elected the following officers for the ensuing year: *President*, Dr. W. L. Bremerman, Chicago; *Vice-President*, Dr. S. J. Eichel, Evansville; *Secretary-Treasurer*, Dr. Benjamin Floyd, Evansville.

THE SOUTHERN MEDICAL ASSOCIATION, at its annual meeting held in Hot Springs, Ark., Nov. 14-18, 1921, elected the following officers for the ensuing year: *President*, Dr. Seale Harris of Birmingham, Ala.; *First Vice-President*, Dr. W. A. Mulherin, Augusta, Ga.; *Second Vice-President*, W. T. Wootton, Hot Springs; *Secretary-Editor*, Dr. W. L. Dabney, Augusta, Ga.

THE NEW YORK ACADEMY OF MEDICINE, at its stated meeting held Dec. 1, 1921, elected the following officers: *Vice-President, for 3 years*, Dr. Arthur B. Duel; *Recording Secretary, 3 years*, Dr. Royal S. Haynes; *Trustee, 5 years*, Dr. Charles L. Dana; *Committee on Library, one member for 5 years*, Dr. Jonathan Wright; *Committee on Library for 3 years*, Dr. Harold D. Senior; *Committee on Admission, one member for 5 years*, John J. Moorhead; *Committee on Admission, one member for 3 years*, Dr. Samuel A. Brown. The term of the President, Dr. George David Stewart, has not expired.

Obituary Notes.—Dr. FRANCIS D. BUCK died at his home in this city on Dec. 3, after a long illness. He was a son of Dr. Gurdon Buck, one of New York's most famous surgeons, and was born in this city on Oct. 11, 1850. He was a graduate of the Sheffield Scientific School in 1869 and of the College of Physicians and Surgeons in this city in 1876. Owing to failing health Dr. Buck had not been in active practice for several years.

Dr. WILLIAM S. HITCH of Laurel, Del., a graduate of Jefferson Medical College in 1869, died of cerebral hemorrhage on Nov. 11, at the age of eighty-four years.

Dr. NEAFIE RICHARDSON died at Philadelphia of heart disease on Oct. 30, at the age of forty-eight years. He was graduated from the Medico-Chirurgical College in 1906.

Dr. ROBERT WATSON MCCAFFERTY, formerly of Waymart, Pa., died at Montpelier, Ind., on Nov. 14, at the age of forty-three years. He was graduated from the Medical Department of the University of Pennsylvania in 1901. He was at one time physician to the Glen Mills Reformatory.

Dr. HENRY E. APPLEBACH of Philadelphia died on Nov. 16, at the age of fifty-eight years. He was graduated from the Medical Department of the University of Pennsylvania in 1889. He was for many years assistant chief surgeon to the Kensington Hospital for Women.

Dr. WILLIAM F. RUFF died in Philadelphia on Nov. 17, at the age of fifty years. He was graduated from the Medical Department of the University of Pennsylvania in 1893. He was a member of the Philadelphia County Medical Society, the Medical Society of the State of Pennsylvania, the Physicians' Motor Club and a Fellow of the American Medical Association.

Dr. HENRY WILLIAM FOX of Washington, D. C., a graduate of the George Washington University in 1884, died at his home on Nov. 3, at the age of sixty-four years. He was one of the founders of the Episcopal Eye, Ear and Throat Hospital, and one of its senior surgeons since 1897. He was a Fellow of the American Medical Society, the American Ophthalmological Society and the Washington Society of Ophthalmologists and Otologists.

Dr. JAMES F. YORK of Portsmouth, Ohio, a graduate of the Eclectic Medical College, Cincinnati, in 1895, died in Cincinnati on Nov. 2, at the age of fifty-five years. He was a former Mayor of Kenova.

Dr. WILLIAM STEVENS of Cairo, N. Y., a graduate of Albany Medical College in 1875, died on Nov. 7 after a long illness.

Dr. ABRAHAM S. BIENENSTOCK of New York, a graduate of New York University Medical College in 1891, formerly on the staff of Bellevue and of the Lying-in Hospital, died of heart disease on Nov. 27, at the age of fifty-four years.

Dr. WILLIAM H. MURRAY of Albany, N. Y., a graduate of Albany Medical College in 1869, died suddenly of heart failure on Nov. 29.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Nov. 18, 1921.

Post-Graduate Training in London.—I have been informed recently by Miss M. A. Willis, the secretary of the Fellowship of Medicine and Post-Graduate Medical Association, that, with the co-operation of various special hospitals, it has been arranged to hold a series of courses in general and special subjects during the forthcoming year, and the first of these, a six weeks' post-graduate course in general medicine, will be held from January 9 to February 15, 1922. The course will consist of a morning and an afternoon session and the subjects dealt with will include pulmonary affections, heart disease, disease of the nervous system, fever, lunacy, etc., and the program will be so arranged as to entail a minimum amount of traveling each day. The numbers attending the course will be limited and early application for further particulars as to syllabus, fees, etc., should be made to the secretary of the Fellowship, 1 Wimpole Street, London, W. This announcement affords evidence that those responsible for the organization and management of post-graduate training in London are actively bestirring themselves. Some of the progress made is due to the zeal and energy of the secretary. American medical men who are thinking of taking post-graduate courses in Europe will undoubtedly be greatly interested to learn that the scheme is taking coherent shape and that the almost boundless material in London for post-graduate training and study is to be employed to good advantage.

Presentation of the Jenner Medal.—In 1796 Jenner first performed vaccination on human beings and was the pioneer of this method for preventing disease. In 1896 the British Epidemiological Society instituted the awarding from time to time of a bronze medal to be known as the "Jenner medal," to a person who had distinguished himself in epidemiological research. The first to receive the medal in 1898 was Mr. William Henry Power, F. R. S., the then medical officer of the Local Government Board, and the latest is his lifelong friend, Sir Shirley F. Murphy, K. B. G. Sir Shirley Murphy is, perhaps, best known to fame as the first medical officer of health for the County of London, and the manner in which he performed the prodigious task of keeping this large and thickly populated area in a good sanitary condition is sufficiently evident in the state of the metropolis to-day. He has always shown himself to be a capable administrator and an authoritative writer on sanitary matters.

Vital Statistics.—According to the Registrar-General's return for the week ending November 5, 1921, the births registered in London and 95 other great towns numbered 7,439, corresponding to an annual rate of 20.8 per 1,000. The deaths numbered 4,040, equal to a death rate of 11.4 per 1,000, as against 10.4, 10.8, and 11.0 in the 96 great towns in the three weeks preceding. In London 1,813 births were registered, corresponding to a rate of 20.8 per 1,000, and 940 deaths, equal to a rate of 10.8, as against 11.3, 11.5, and 11.0 in the three weeks preceding.

Glasgow Women's Private Hospital.—This hospital was established in 1903, and the demands on it have become so great that larger premises are urgently required. To buy and adapt a suitable building a sum of £12,000 is needed. It is intended later to issue a public appeal for funds, but in the meantime the women doctors of Glasgow and neighborhood are endeavoring by private efforts to raise the first £1,000, and a successful beginning was made recently when £300 was realized at a sale.

A Different Classification of Pain.—At the meeting of the Section of Neurology of the Royal Society of Medicine on November 10, Sir William Thorburn of Manchester referred to the effects of treatment of pain. There was no accurate means by which the degree of pain could be measured. The mental effect of prolonged pain often caused the recurrence of pain sometimes in another part, after the original pain had been cured. Sir William Thorburn had seen recently two cases of pain due to cervical rib which had been cured by operation; the patients returned later complaining bitterly of abdominal pain associated with floating kidney. He divided cases into three classes: (1) Those in which there was a definite lesion, such as pressure on the brachial flexus. (2) Cases where the lesion was less definite and was possibly situated in the posterior root ganglia. (3) Those in which there was no definite lesion, and which he termed neuralgia. In the first class the only question was diagnosis and early diagnosis followed by prompt and adequate treatment was curative. In certain cases, however, where pressure had existed for a long time, a neuritis might be set up which caused pain even after removal of the original cause. This explained the failure in some cases of operation for cervical rib which had been too long postponed. In the second class of case the speaker included certain cases of painful amputation stump. Some of these were cured by removal of end-bulbs, but a percentage of cases remained where pain persisted after removal of the bulb and several inches of apparently normal nerve. These cases were, he thought, due to an ascending neuritis, and in some of them posterior rhizotomy was the only resort. In his opinion these bulbs were due to sepsis and did not occur if the nerves were cut sufficiently short. The discussion was opened by Dr. Wilfred Harris, who said that persistent deep-seated pain, if accompanied by failing health, would always suggest malignant disease. He then dealt with the causes of pain in the peripheral nerve endings, and sketched the various forms of disease of the nerve trunks, posterior roots, and their ganglia, the fillet or thalamus which gave rise to pain.

In the discussion which followed Dr. Gordon Holmes said that it was commonly taught that lesions of the central nervous system did not cause pain, but this was abundantly disproved by war experience. Injury to the tracts in the spinal cord undoubtedly caused pain. As was pointed out in an editorial on the above meeting in the *Lancet* of November 19, 1921, there are forms of per-

sistent pain in nervous disease that are not at all easily amenable to treatment, notably the variety described as central pain, of which at the discussion Dr. Gordon Holmes gave a diagnostic description. He alluded to the kind that sometimes occurred in cord lesions, an account of which he contributed to the Osler Festschrift; in certain types of thalamic lesion, also, it was pointed out central pain is an only too conspicuous feature in the clinical picture. The editorial ends with these true words, "Inability to ameliorate or relieve pain of organic central origin casts no discredit on neurological methods, for there is a limit to their applicability; but once diagnosis is satisfied with the non-organic nature of a particular pain its cure should be a matter of course."

Obituary.—Auguste Sheridan Delépine, professor of Public Health and Bacteriology and director of the Public Health Laboratory, University of Manchester, died on November 13, at the age of 66 years. His father was French and his mother Swiss, and he was educated in Paris, Geneva, and Lausanne. After going through the medical course at Edinburgh University, in 1882, he was graduated at M.D., C.M., with first class honors. After filling positions in bacteriolgy and pathology at Edinburgh and St. George's Hospital, London, in 1891, he was appointed the first Proctor Professor of Pathology and Morbid Anatomy in Victoria University, Manchester. He did excellent work on the bearing of food poisoning on the etiology of summer diarrhea and made valuable investigations into the general conditions necessary to ensure a clean milk supply. After having occupied the chair of pathology for twenty years he resigned and was appointed professor of public health and bacteriology and director of the public health laboratory. Delépine himself did good work during the war, and his only son was killed. It is believed that this tragedy shortened his life.

A QUESTIONABLE UNDERTAKING.

To the Editor of the Medical Record:

Sir:—During the past decade, the course of radium has been turbulent, and most of its tribulations have been due to over-enthusiastic statements of its friends. Of late, however, there have appeared throughout the country several questionable commercial enterprises that are attempting to reap a financial harvest by catering with "radium cures" to the last hope of an army of chronics. One of these, recently established, has issued a pamphlet extending an invitation to suffering humanity to come to the institution, where they will be treated by radium baths, pads, tampons and suppositories, and be relieved of arthritis deformans, various skin diseases, Bright's disease, pleurisy, bronchitis, gonorrhea, and other urinary troubles, high blood pressure, ulcer of the stomach, gallstones, hay fever, and disorders of the menopause. Among the diseases in which relief is promised is diabetes, which is interesting when records clearly show that every diabetic is made worse under radium therapy. Ulcer of the cervix uteri is another trouble to be treated by radium solution and vaginal suppositories. Whether the ulcer be malignant or otherwise makes no difference, apparently, but if it does not cure, evidently the case was too far advanced. The simple statement of such a list of indications suffices to discredit the whole enterprise.

It becomes necessary to warn the medical profession that they may fully understand that attempts to bring before the public the use of radium as a popular remedy may be productive of great danger to the patient. Radium is being studied exhaustively by many authorities, who recognize in it certain possibilities of great promise. Improper usage, however, may cause serious after effects, and therefore it will have but little place for use by the laity. Radium must, for many years, still be kept in the hands of physicians highly specialized in its usage. Its results are not remarkable nor miraculous—they all too frequently spell failure even in the hands of those of wide experience.

Those who are deeply interested in radium will welcome help from the medical profession, and particularly the medical press, in their effort to keep the remedy out of the hands of those who by improper usage will discredit it.

1. **Puerperal Sepsis and Its Prophylaxis.**—L. V. Friedman expresses the opinion that the various maternity benefit bills that have been proposed will, if enacted, do little to lessen obstetric mortality. He believes further that obstetric mortality statistics are by no means to be accepted at their face value, since they include deaths from criminal abortions and deaths in the hands of Christian Scientists and other irregular methods of treatment which cannot be attributed to the medical profession. Admitting, however, that there is room for improvement, he discusses means of improving obstetric results. Any attempt to lessen the amount of puerperal sepsis must depend primarily upon prophylaxis, which resolves itself into methods of asepsis. Since obstetric delivery should be organized, as in any well conducted abdominal operation, it is a logical deduction that only the rich can be delivered at home; the poor, if they are to secure adequate service, must be cared for in hospitals. But there is no doubt that hospital service without certain restrictions will tend to increase rather than diminish puerperal sepsis. Such restrictions are the isolation of the obstetric beds, and especially the obstetric operating rooms and the nurses serving them, from the general surgical work. It is not to be inferred from this that every woman is to have an operative delivery. The normal process well conducted does less damage to the pelvic fascia than a forceps or version by skilled hands; and the artificial dilatation of the primiparous os should be regarded as a major operation, requiring definite pathological indications. The decision when to interfere requires highly trained judgment and is to be made on the physical findings rather than on the desire to put an end to the patient's suffering. The writer finds in cesarean section another prolific source of obstetric mortality. The mortality from this operation may be kept down to a low figure by observing the following rules: The cesarean section should not be chosen after the patient has been in active labor more than a few hours. The operation ought to be refused when any considerable delay must occur between the rupture of the membranes and the performance of the operation. The operation should never

be done after a trial to deliver from below has been made, nor should it be done where any vaginal examination has been made. It is of great importance to limit the operation to the delivery of the child, not attempting to remove the appendix or palpate the gall bladder. After discussing the sources of infection he goes into the elementary detail of obstetric technique. He urges the use of properly sterilized gloves and calls attention to an advantage of the use of gloves often overlooked, namely, the diminished opportunity of abrasion or injury of the vaginal and cervical epithelium. There are only three conditions that justify the obstetrician for entering the birth canal after the child has been delivered: These are to repair a cervix torn so badly as to cause hemorrhage threatening the life of the patient; the manual removal of the placenta, which is rarely necessary, and for the purpose of checking postpartum hemorrhage.

1. Observations on the Effect of B. Acidophilus Milk upon Cases of Chronic Constipation.—Harry A. Cheplin and John I. Wiseman described a series of milk feeding experiments which have been conducted for several years at the Sheffield Scientific School, Yale University, on the implantation of *B. acidophilus* within the intestinal tract of both the albino rat and man. Throughout the investigation the favorable effects of the *B. acidophilus* lactose milk feeding on chronic constipation was quite apparent. In most of the cases the response was prompt and daily evacuations are recorded. Although in some cases the influence of the ingestion of the *B. acidophilus* milk in 500 c.c. quantities was less pronounced at the start, quite an appreciable difference in the effect on the bowel movements was noted when the amounts of *B. acidophilus* milk and added lactose were doubled. The *B. acidophilus* lactose milk diet effects a change in the intestinal flora. Within a few days after the ingestion of the sour milk and added lactose, daily stools are obtained and a transformation in the flora takes place in which the usual mixed bacterial types give away to a more simplified flora largely represented by *B. acidophilus*. It is to be assumed that the *B. acidophilus* milk has this influence in virtue of the large number of viable organisms which it contains and of the lactose present. This view is strongly supported by the extensive feeding experiments on clinical cases conducted by Cheplin and Rettger in which similar results were observed.

5. Measles, the Study of an Epidemic in the City of Watertown, N. Y.—Isaac Brewer describes an epidemic of measles, beginning in January and reaching its peak in May, 1921, during which 1,218 cases were reported to the department of health. During the year 1920 fresh importations of measles were frequently brought from a neighboring city, where a serious epidemic prevailed, but without inciting an epidemic in Watertown. He raises the question as to why the disease did not become epidemic in 1920 and whether a few cases in 1920 became carriers and paved the way for the serious epidemic of 1921. With a view of determining what might be done by early isolation of cases before the rash appeared, an effort was made to ascertain the interval between the appearance of the catarrhal symptoms, as observed by the family, and the rash which is the diagnostic symptom with the public. In 38.1 per cent. the interval was one day; in 25.7 per cent. it was two days, and in 10.6 it was three days. That is in 74.4 per cent. of the cases it might have been possible to have isolated the patient before the rash appeared. The writer is of the opinion that there is grave doubt if the measures usually adopted for the prevention of measles are anything but a public nuisance. The serious after-results of the disease demand that something must be done. Until such a time as a satisfactory vaccine is developed and the public educated to its use, the crux of the situation is the control of the "common cold." The isolation of cold will without doubt prevent measles and whooping cough and will also be the means of bringing many cases of tuberculosis under treatment at a time when they have a good prospect of being cured. Brewer is aware that the public will not take kindly to this proposition; he points out that from the economic standpoint the result will surely pay, for during this epidemic the children of the city lost thirty school years, a loss very costly in the long run.

2. Laboratory Findings in Early and Late Syphilis: Review of One Thousand and Sixty-four Cases.—John A. Fordyce and Isadore Rosen summarize their observations on this series of cases as follows: (1) Not only is thorough investigation of every syphilitic patient early in the disease recommended, but it is as imperative as the use of the dark field in making an early diagnosis of the primary lesion. (2) Probably not more than 25 or 30 per cent. of all secondary syphilitics show infection of the central nervous system. This can in the majority of cases be determined only with certainty by a lumbar puncture, as in the early months clinical signs are often negligible; and to wait until the latter appear usually requires a longer time to bring about negative reactions. (3) These statistics show that the incidence of syphilis of the nervous system is much higher in men than it is in women. (4) The statement is frequently made that neurosyphilis has increased since the use of modern antisyphilitic remedies. This increase, in our opinion, is more apparent than real, and is to be attributed to the more systematic investigation of patients and our more thorough knowledge of the disease. (5) We have no proof that arsphenamine adversely affects the optic, auditory or other cranial nerves. On the contrary, we have very definite data showing arrest of optic atrophy by the proper use of the drug. (6) In considering the problem of neurosyphilis one should always have in mind the general infection and especially the involvement by it of the cardiovascular apparatus and the eye. A persistent negative Wassermann reaction in the blood is frequently found with positive phases in the fluid and with an active process. A patient should never be discharged as cured without the information gained by lumbar puncture. When this has been neglected it has in many cases led to disastrous consequences and incurable conditions. (7) Pupillary anomalies and cranial nerve paralyses are often pathognomonic and are always suggestive of nervous syphilis. In papillitis and optic neuritis occurring in early syphilis, vision may be normal with only slight narrowing of the fields. The necessity for routine ophthalmological examination must, therefore, be emphasized so that the earliest changes may be detected before irreparable damage is done to the eye. (8) The absence of clinical signs and symptoms does not exclude syphilis of the central nervous system. The classical signs and symptoms of tabes may occur with a negative blood and spinal fluid. Likewise neurosyphilis of the vascular, gummatous and other types may present subjective and objective clinical symptoms with an excess of globulin only in the fluid. (9) The colloidal reaction has been employed by us for six years. We consider it of great value. A leutic curve enables us with almost absolute certainty to exclude paresis. A paretic curve is always present in paresis in untreated cases, but may be encountered in meningovascular syphilis and may disappear under treatment. A paretic curve is also found in some types of early neurosyphilis, and disappears as the other phases become negative.

4. A Study of Silver Arsphenamine in the Treatment

of Syphilis.—Mihran B. Parounagian presents this study from the department of syphilology of Bellevue Hospital, in the course of which silver arsphenamine has been administered 4,250 times to 756 patients. The patients received 0.15 of a gram of American made arsphenamine as an initial dose, and this was followed by an injection of from 0.2 to 0.25 of a gram for each succeeding dose, unless smaller doses were indicated by the character of the case. Injections were given every third or fourth day, eight injections constituting a course. A rest of four weeks without treatment, followed by treatment or a further rest as the serology or history indicated. The reactions were few and when they did occur were mild and evanescent. In this series of cases clinical manifestations in all stages of syphilis responded to treatment with silver arsphenamine with gratifying rapidity and thoroughness. The impression obtained is that the response begins more promptly and that the lesions resolve with greater rapidity than is the case with a similar number of treatments with other arsenical preparations. In this opinion Parounagian agrees with Kolle, Ritz, Galewsky, Hauck, and Gennerich.

5. The Management of a Diphtheria Outbreak in a Private School.—E. C. Fleischner and E. B. Shaw.—(See Medical Record, Vol. c. No. 15, p. 609.)

9. Phenolphthalein Dermatitis.—Samuel Ayres, Jr., reports seven cases in which an erupton of the skin has been associated with the oral administration of phenolphthalein for laxative purposes. The eruption in four of the seven cases has been of the same type, corresponding clinically, and in one case in which a biopsy was obtained, microscopically, to erythema perstans. These cases are of interest in view of the fact that most textbooks and most physicians regard phenolphthalein as a laxative as entirely lacking in toxic properties.

12. Report of Committee on Local Anesthetics in Ophthalmic Work.—Albert E. Bulson, Jr., William Zentmayer, Edgar Thomson, H. Maxwell Langdon, and Joel Whitaker, the committee appointed by the Section on Ophthalmology of the American Medical Association to investigate this subject, base the deductions submitted in this report on clinical and experimental observations, an analysis of the literature, and replies to a questionnaire sent to leading ophthalmologists. The conclusions reached are that for surface anesthesia cocaine in 4 per cent. solution, freshly made, possesses distinct advantages over all other local anesthetics, particularly operative work. In all instances the anesthesia is equal to and in most cases it is greater than that produced by any other local anesthetic. The use of stronger solutions than the one recommended is at the risk of seriously disturbing the nutrition of the cornea and interfering with the healing process. The efficiency of cocaine is not impaired by boiling or by the addition of epinephrin. Phenacaine in a 2 per cent. solution stands next to cocaine in efficiency. It has the advantage of producing a quicker effect than cocaine and a slight antiseptic action. It does not dilate the pupil, hence is valuable in producing surface anesthesia for tonometry, therapeusis, and removal of foreign bodies from the cornea. It does not produce desiccation of the cornea, or, so far as known, disturb nutrition. The solutions are not affected by boiling. Epinephrin does not add to its efficiency in any way. Alkalis should not be added to phenacaine solution, as they cause precipitation. Phenacaine offers the distinct disadvantage of producing more or less irritation. The use of glass vessels should be avoided in its preparation and porcelain used instead, as phenacaine is incompatible with the alkalis and their carbonate bases. Procain (novocaine) in 2 per cent. solution is the anesthetic of choice for infiltration anesthesia. Procaine should be injected slowly to aid in the avoidance of toxic effects. The efficiency of procaine solutions is not increased by the addition of alkalis. The committee believes that it is highly advisable to find, if possible, a synthetic anesthesia which will take the place of cocaine, one that will be less toxic, less expensive, nonhabit-forming, and equally efficient. The Research Committee of the Council on Pharmacy and Chemistry of the American Medical Association is experimenting with several new local anesthetics not yet on the market, one of which is especially promising, though it must be tested clinically before expectations are raised.

The Lancet.

[illegible] 1921, [illegible]

2. Mitchell Lecture on Tuberculosis: Its Relation to General Bodily Conditions and to Other Diseases.—E. Parkes Weber states that among civilized communities the mortality from tuberculosis seems to be gradually diminishing, apparently as a result of: (1) Relative immunity to "massive" infection, due to infection during early life with minor forms of the disease; (2) diminished frequency of "massive infection," a result of the modern application of preventive measures; (3) increase of the general standard of health, less poverty, less overcrowding, less overwork, better food and better air. Besides the general conditions of nutrition and specific immunity favoring or opposing tuberculosis, the latter disease may be influenced by other diseases. The condition of the blood in diabetes has been supposed to favor tuberculosis, and syphilis by producing a condition of cachexia is similarly supposed to favor tuberculosis. True syphilitic cachexia, however, is very rare nowadays, and Weber is not at all satisfied that it increases the gravity of tuberculosis when both diseases are present together. Septic counterinfections apparently favor the reawakening and dissemination of old tuberculous foci, and traumatism (contusions, etc.) may also do. In the writer's opinion, the presence of old quiescent pulmonary lesions of moderate degree does not greatly increase the gravity of attacks of pneumonia and the pulmonary complications of epidemic influenza, if the infection does not re-activate the tuberculous lesions. It is probable that tuberculosis, as well as many toxic conditions, especially those directly and indirectly due to alcoholism, favor the development of cirrhosis of the liver. But various forms of hepatic cirrhosis, with or without jaundice, may be the direct result of chronic tuberculous process within the liver itself, associated with tuberculosis in the region of the portal circulation or elsewhere in the body. A tuberculous cirrhosis may result when the tissues are very resistant toward the tubercle bacilli, or when the latter are few in number or of low virulence. In spite of the view that Hodgkin's disease is intimately and perhaps casually allied to tuberculosis, the obtainable clinical and pathological evidence and the ordinary experience of hospital physicians does not point to much real relation between the two diseases. Neither does there seem to be any special relation between tuberculosis and the various forms of carcinoma and sarcomata. The supposition that patients with congenital pulmonary stenosis who reach the age of puberty mostly die from pulmonary tuberculosis is probably incorrect. Active tuberculosis is seldom found in gouty subjects or associated with true granular kidney. In fact, it seems that a genuine antagonism between pulmonary tuberculosis and gout exists. Albuminuria, chronic renal irritation, and actual chronic nephritis may be due to the passage of tubercle bacilli and their toxins through the kidneys. Other results of tuberculosis may be termed "accidents"—for instance, intestinal obstruction due to adhesions or stenosis resulting from past or chronic tuberculous processes in the mesenteric glands, peritoneum, or abdominal viscera; attacks of pleurisy due to miliary pleural tubercles, and nearly all cases of so-called spontaneous or "idiopathic" pneumothorax arising in the apparently healthy, these should be regarded as the price which we may be called on to pay if our struggle against tuberculous infection is, on the whole, effectual.

3. Vitamine Deficiency and Factors in Metabolism Relative to the Development of Rickets.—Amy Hodgson, after having followed the recent controversy of the position of the fat soluble vitamine as a factor in the causation of rickets and having made observations concerning diets, reached the conclusion that while errors of hygiene and dietary and debilitating condi-

tions generally were incidental and probably predisposing to the development of rickets, there must be some common determining factor still to be found. This is probably to be traced to some error of metabolism, such as may be caused—possibly in common with other factors—by a vitamine deficiency in the diet. The hydrogen-ion concentration of the blood has been shown to be normal in rickets, but the assumption is that a compensated acidosis is present, in that there is a lowering of the alkaline reserve of the organism. With the object of deciding whether or no rachitic children were suffering from a lowering of their alkaline reserve, the writer decided to compare the urines of a series of rachitic children with those of normal children of the same age as to the proportion of nitrogen excreted as ammonia relative to total nitrogen excretion, and at the same time directly test the alkaline reserve, by the method of Sellard, Henderson, and Palmore. In all, sixty-five children were investigated, comprising thirty rachitic children, twenty-five healthy children, and ten unhealthy children of the same class not rachitic. In the control healthy children the ammonia ratio was roughly constant, approximating the adult proportion of 5 per cent., the average being 6.2 per cent. In the control list of unhealthy children there was a definite increase in the ammonia ratio, the average of all cases being 14.3. The alkaline reserve was reduced. The ammonia content was less constantly reduced following bicarbonate dosage. This suggests that a high ammonia formation was an essential of the metabolism present, even when additional alkali was supplied. The writer claims that there is sufficient indication of a lowering of the alkaline reserve in cases of active rickets for further work to be undertaken, more particularly on the alveolar carbon dioxide content. The ammonia ratio is a very variable quantity in rickets, according to the amount of reaction to the disease that is going on. Ultimately in healed cases of rickets the alkaline reserve and the ammonia ratio both became normal. The presence of acidosis in rickets calls for careful prophylactic measures, along lines likely to prevent such a condition, as well as the administration of calcium and cod liver oil, and a careful regulation of the diet.

4. **Cardiac Massage.**—A. G. Levy considers the term "massage" in this connection a misnomer and prefers the expression "mechanical stimulus." In the treatment of primary cardiac syncope from ventricular fibrillation cardiac massage finds its most urgent application. In animal experiments the writer has met with consistent success, but he acknowledges that in man the proposition is a somewhat different one and that failures must be expected. He thinks, however, that with a proper knowledge of the principles involved and their careful application, very much better results might be obtained in cases of massage than has hitherto been the case. The rules for performance of cardiac massage in chloroform syncope are as follows: In syncope from overdosage, partial inversion and immediate artificial respiration by the Sylvester method. If recovery does not occur within three minutes, proceed to perform intrathoracic massage with perflation of the lungs. In syncope from primary cardiac syncope, partial inversion for two minutes. If spontaneous recovery does not occur within two minutes, proceed at once to intrathoracic massage. In the interest of the nerve centers cardiac massage should be commenced within five minutes. Success depends upon proper access to, and the efficient compression of both ventricles, and an efficient system of artificial respiration. If continued rhythmic compression is not successful in five minutes, it should be intermitted for periods of up to forty-five seconds' duration. Massage should be continued, if necessary, up to one hour's duration before abandoning the case. It is advisable to rely throughout on massage alone and discard the use of drugs. If the circulation is feeble after recovery, an intravenous injection of pituitrin is desirable.

5. **Investigation of Gastric Function Before and After Gastrojejunostomy.**—T. G. D. Bonar concludes that, no matter what the type of operation, in prepyloric ulcers the curves obtained before and after operation differ in that the free hydrochloric acid is diminished, but the total acidity reaches roughly its previous level; bile enters the stomach during the meal, and the stomach is emptying more rapidly than before. Pyloric ulcers, after gastrojejunostomy, have the same type of curve as before operation. Duodenal ulcers have a highly acid resting juice, with a slightly diminished free hydrochloric acid, and the remaining part of the curve reaches about the same maximum as before, although it may be obtained quicker after operation. Carcinomata have a low free and total acidity both before and after gastrojejunostomy. In all cases the stomach is emptying quicker than before operation, a varying amount of bile gets into the stomach during some part of the meal, and when the gastrojejunostomy has been successful pain has been relieved. In most cases of simple ulcer weight has been put on.

British Medical Journal.

November 5, 1921. No. 3175.

1. **Causes and Prevention of Blindness.**—N. Bishop Harman, on the basis of an analysis of 4,288 cases of blindness studied in three groups—in infants, in school children, and in persons of all ages as ascertained in private practice—states that in infancy the causes of blindness are few, so the percentage of these causes is high. Congenital defects and conjunctivitis account for nearly all cases. Among school children other conditions come into account. First, the death rate of infancy will have reduced the number of cases of blindness in infants. Secondly, other causes of blindness will show their effects, particularly those arising from constitutional disorders. So that the startlingly high percentage due to ophthalmic neonatorum is reduced, and takes second place to the larger number of blind cases due to congenital syphilis. In the third group of persons of all ages, the greater number of adults reduces the infant population to its correct position, and correspondingly the incidence of the several causes of blindness. But other causes of blindness which affect adults mainly—accidents, vascular disease, glaucoma, gross myopia, and senile cataract—swell the total blindness and correspondingly diminish the blindness of infancy and childhood. The latter gives a fair picture of the causes of blindness, as they occur in the population under discussion. Examination of popular literature indicates that wholly erroneous beliefs are held as to the causes of blindness owing to the laxity with which statistics are quoted. Looking at the writer's returns, one would be justified in stating that 50 per cent. of the blindness of *infancy* is due to the preventable disease ophthalmia neonatorum, but wholly wrong in stating that 50 per cent. of blindness was due to that cause. Again, it would be correct to state that 50 per cent. of blindness in *school children* is due to parental venereal disease, but not that 50 per cent. of blindness is due to venereal disease. The true figures for all ages are 2.5 per cent. of blindness is due to gonorrheal disease, and 9 per cent. is due to syphilis. There are certain causes of blindness over which we have little influence, and others are well within our power of prevention, possibly of extinction. Among the preventable causes of blindness ophthalmia neonatorum stands first. Prevention of the disease can be secured by the treatment of vaginal disease in the expectant mother; this is the one and only certain means of prevention. In every convenient area there should be an ophthalmia neonatorum center where affected mothers and infants could be brought for treatment, and where accurate diagnosis could be carried out. Phlyctenular keratitis is certainly preventable and likewise syphilis. Much of the blindness from industrial accidents might be prevented by the use of goggles in all work where flying fragments are common. Where

accidents are common first aid stations should be established where foreign bodies could be removed and infection averted by irrigation. For children with a high degree of myopia special classes should be established which would meet two difficulties, namely, that these children can, even when provided with suitable glasses, see with difficulty both distant and near objects, and that there is an ever present risk of damage or degeneration of the retina and that this risk is increased by strain.

2. The Advisability of Early Operation in Strabismus Convergens.—W. B. Inglis, after trying medical methods of treatment, including training of the squinting eye, comes to the conclusion that early operation is the best preventive of amblyopia and ex anopsia. He has operated upon over 300 individual patients, and in most of them the earlier the operation has been done the greater the improvement of the vision in the squinting eye. Operation, he believes, is much wiser than the use of glasses, but the operation must be carefully done, because if there is only a partial success then there is no cure of the amblyopia. To obtain success it is necessary to get the eye perfectly straight, and in many cases it is advisable to occlude the good eye for three hours daily, or use other methods of orthoptic training.

6. Erythema Nodosum: An Acute Specific Fever.—J. Odery Symes reviews the evidence that can be adduced in favor of regarding erythema nodosum as an acute specific infectious fever comparable in every way with the zymotic fevers. He does not regard this evidence as conclusive. The strong points in favor of the theory that erythema nodosum is an infectious fever are the proof that it may be transferred from person to person and may occur in small localized outbreaks and in epidemic waves. Equally convincing is the evidence of a definite seasonal incidence and constant age incidence. The systematic distribution of the rash, the evidence of relapses, and conferment of immunity are also favorable to this view. On the other hand, one has to explain the constant association of erythema nodosum with other diseases, such as tuberculosis, measles, and minor conditions of ill health. The heavy incidence of the disease in girls at and about the age of puberty is difficult to explain on any ground of infection, and it is also necessary to decide whether erythema nodosum and erythema multiforme are but two phases of the same disease or whether they are two clear and distinct entities.

8. Eleven Thousand Cases of Spinal Analgesia.—Arthur A. Morrison records that in the past ten years he has performed 11,000 surgical operations under stovaine spinal anesthesia. The solution used is made up in ampoules containing 7½ c.c. to which ½ to 1 mm. of strychnine is added. This dose suffices for a prolonged operation. He finds that he has employed this method in 97 per cent. of all operations performed. The exceptions are made up of certain operations on the head and neck, for which spinal analgesia is neither easy nor efficient. Spinal analgesia he uses in all abdominal operations. Among the advantages claimed for this method are the rapidity with which the patient is prepared for operation; the fact that no anesthetist is necessary; the relaxation of the parts; the absence of vomiting and shock, and the safety from serious sequelæ. There is only one real disadvantage and that is a persistent headache, which occurs chiefly after minor operations, largely due to the fact that patients will sit up and jump about in bed. If they rest quietly there is absence of real headache.

1. Diagnostic Pitfalls in Gastrointestinal Diseases.—A. L. Levin emphasizes the fact that errors in the diagnosis of gastrointestinal diseases are often the result of laying too much stress on the stomach manifestations or misinterpreting them. Gastric analysis is by no means the tower of strength and the determining agent in locating the existing abnormality in the abdomen. A shrivelled up gall bladder, containing one or more stones lying hidden under a large liver and covered by a heavy garment of fat will often escape undetected even the expert palpating hand, but will often be suspected by an attentive ear and a vigilant eye. There are instances in which the clinical side of a case is of greater importance than the laboratory side. In the writer's experience the gall bladder is the commonest offender of the digestive apparatus. Patients, as a rule, cannot distract their attention from the stomach as the seat of their trouble. He also agrees with Fravel, who argues against the dogmatic teaching of our medical leaders that hyperacidity is the rule in gall bladder disease, and in a number of cases he has found subacidity more frequent than hyperacidity. The latter was present only when a chronic appendix was associated with it. The duodenal tap, which should be practised as often as gastric analysis, will be of considerable aid. He has noticed in a number of gall-bladder cases the following characteristics: A history of a more or less persistent nausea or sick feeling, drowsiness after a meal, and a low systolic pressure. He has noticed that low blood pressure in young individuals between the ages of thirty and forty, well nourished, with no cause to account for the low pressure but a probable absorption of infection from the gall bladder. With improvement in the gall-bladder symptoms the blood pressure rises. An overdistended gall bladder with a common duct outlet blocked by mucus or inflammatory exudates, will give rise to the same symptoms as stones. To differentiate gall-bladder pain from gastric or duodenal ulcer pain is quite a task. The persistence and regularity of nocturnal pain and the relationship to food, so strongly emphasized by Reisman, are not borne out in two cases reported by the writer, but rather serve to illustrate Rolleston's contention that pericholecystic adhesions lead to interference with the passage of food from the stomach and even to deformity of that organ, hence a misinterpretation by the *x*-ray. The gall bladder may be infected from septic foci elsewhere in the body, and from these sources the kidney may become infected, particularly the right kidney.

Anaphylactic Origin of Certain Crises of Nasal Hydrorrhea.—Pasteur, Valery-Radot, Haguenau, and Watelet refer to the hitherto inexplicable nature of these crises which are a burden to medical man and patient alike. They are not directly concerned with hay fever, as one might suspect in reading the above title, and in fact the authors barely allude to pollen sensitization. There is, however, the evidence that the latter is excluded, for they mention that the patient in question suffered her attacks in any climate and any season, and on sea and land alike. The habit of sneezing over a hundred times at a stretch with the crises of hydrorrhea was associated in the minds of the authors with a possible sensitization many years before with diphtheria antitoxin. The sneezing, hydrorrhea, and lacrymation were associated in the crises. The latter had persisted for ten years when asthmatic paroxysms were added. The nasal crises tended to appear after each meal and lasted as long as three-quarters of an

hour. The asthma, however, was nocturnal. Still later a rash of erythematous plaques would appear on the face and neck with pruritus each morning. This life proved unendurable, and all attempts at relief failed. The mystery was finally solved by tracing the entire picture to the ingestion of albuminous food, which produced a hemoclastic crisis and clinically the varied phenomena of anaphylaxis. By pursuing the method of Pagniez of giving peptones in cachets one hour before meals the colloidal shock due to the ingestion of albumins was prevented on the principle of antianaphylaxis.

Functions of the Lung.—Professor Roger, the internist, and Dean of the Paris Faculty of Medicine, believes that the lung has functions quite unrelated to the gas exchange. In 1898 he demonstrated that it could detoxicate certain poisons by an oxidation process. This is an intravascular phenomenon which occurs within the pulmonary capillaries. The method of demonstration is simple, for it is only necessary to inject a toxic solution in such manner that it reaches the nerve centers without first having passed through the lungs. Having thus established a toxic coefficient it is easy to repeat the experiment on other animals in which the blood must pass through the lungs and note the difference. Injections may be made into the superior cava or common carotid in the primary test. It may be readily shown by employing different solutions that oxidation is the agency which destroys or rather partly destroys the toxic substance, because if the latter is not oxidizable no detoxication results. Roger also regards detoxication by the liver as a matter of oxidation, although the two mechanisms are probably different. Naturally, the liver detoxicates the portal and the lungs the systemic blood. The author has experimented with extract of lung substance and finds it toxic but only as far as it is a colloidal substance. Dried lung substance is a powerful hemostatic and probably contains a thrombokinase. When the lungs are removed from a frog its blood coagulates very slowly. The albumin found in the sputum in pulmonary infections is hypotensive. In affections with sputum in abundance these albumins may in part be absorbed, but whether the low blood pressure of consumptives could in part be due to this property is not agitated. The author studied autolysates of lung tissue with the following results. The autolyzed lung tissue is found to have lost rapidly its toxic power to animals. But as its toxicity is lost hypertensive properties appear. The author sees evidence of some special power of lung tissue over the lipoids, destroying the latter. A storage is hardly possible. This lipolysis can also be studied *in vitro*, which argues for the presence of an enzyme of great power in the lung. But the significance of this lipase for the economy does not yet appear and not even a hypothesis can be advanced until the problem is studied from all angles.

Idiosyncrasies.—Doerr states that at first sight an enumeration of individual idiosyncrasies is confusing. The substances which give rise to them differ radically among themselves. A particular individual is hypersensitive toward a particular substance. Many idiosyncrasies are monovalent, while in others any member of a group may induce it. In the case of food idiosyncrasy in which many dishes may induce the same picture we do not speak of polyvalance because only the food protein in certain forms is the agent. In certain cases there is nothing specific, for it is not the quality but the quantity of protein which is at fault. Plant protein as a cause of idiosyncrasy is as well known as animal, but when we come to drugs as causal factors a different element enters. The content of nitrogen plays no rôle. The active factor is chemospecificity and there is a relation between the idiosyncrasy and the constitution of the molecule. In a large group of drugs which may cause idiosyncrasy it is the methyl group in the molecule which is actually at fault. Methyl specificity may be traced in a given individual through a number of substances. In certain cases of occupational idiosyncrasy the offending substance if traced may be found to contain the methyl radical and protein if present may be inert. Thus far the author has considered natural hypersensitiveness without reference to anaphylaxis. The relationship between anaphylaxis and idiosyncrasy is still somewhat obscure. In anaphylaxis the first step is the presence of a substance known as the antigen, which introduced parenterally causes the formation of an antibody. In a true idiosyncrasy the offending substance does not ordinarily come under the head of an antigen and no antibody is generated by it. Laboratory animals have no idiosyncrasies like mankind and anaphylactic behavior is constant for the species and in no sense an individual phenomenon. This is probably the chief distinction between the two. In practice, just as animals may be desensibilized to laboratory anaphylaxis man may be desensibilized to an inborn idiosyncrasy, but the process is more difficult and uncertain of result. In protein idiosyncrasy the subject may rarely show the presence in the blood of antibodies just as in anaphylaxis. In true protein idiosyncrasy the eliciting substance is of the same nature as the antigen which sets up anaphylaxis, although there has been no previous sensitization. This appears to be the bond or one of several bonds between the two processes. The active principle in both is an antigenic protein substance acting on different types of subject. But when we come to nonantigenic, chemospecific drug action, Doerr says, there is nothing in common with anaphylaxis.

Removal of Cancer of the Tongue and Pharynx Under Local Anesthesia.—Aboulker of Algiers publishes a remarkable record of cancer surgery. His material comprised twenty-eight cases, all of which were severe in type. Of this number, twelve were seated on the tongue. He regards the high operative mortality in these interventions as due to the general anesthetic and especially chloroform. He has been operating on the head, face, and neck under local anesthesia since 1912, and in 1914 reported a series of 150 cases. In cancer, however, he has until recently used chloroform anesthesia. In twelve cases of cancer of the tongue operated on under chloroform he lost five from one to twenty days after operation. In eighteen pharyngectomies under chloroform for cancer he lost 55 per cent. of his patients. He then operated ten times under local anesthesia without a death and has since added three more to the immune series. Thus far he has operated but once under local anesthesia for cancer of the tongue. He believes that thirteen consecutive pharyngectomies without a death is a record. In addition to local (novocaine) anesthesia, he adds methylene blue to the solutions in the interest of vital staining and operates only in the stained tissues. The operative field is inundated with the anesthetic solution. The author is not statistically interested at present in the remote survival of his patients and lets that be as it will, as it is as yet too early for remote statistics. His lingual cancer patients are all dead or have inoperable recurrence. His longest survival here is four and one-half years. We find no mention of the remote outcome of his pharyngectomies. But he is insistent on diminishing his operative mortality. Naturally under local anesthesia he has taken full advantage of the possibilities of serial interventions, such as preliminary tracheotomy and ablation of cancerous lymph nodes.

Fatal Diphtheria in a Patient with Negative Schick Test.—Blechmann and Chevalley report the case of a patient who had given a negative Schick test ten days before, yet had developed a particularly malignant case of diphtheria. The extreme youth of the patient, a nursling of one month, should have made it relatively immune. It had contracted the disease from an older nursling. It is so rare for nurslings to contract the disease before the age of two months that but seven cases have been recorded in the past twenty years, which makes the case doubly important.—*La Presse Médicale.*

Book Reviews.

OPERATIVE SURGERY: FOR STUDENTS AND PRACTITIONERS. By JOHN J. MCGRATH, M.D., F.A.C.S. Professor of Surgery, Fordham University; Consulting Surgeon to the People's Hospital; Visiting Surgeon to the Fordham, Columbus, and New York Foundling Hospitals; Fellow of the American College of Surgeons; Fellow of the New York Academy of Medicine; Member of the American Medical Association. Sixth Revised Edition, with 369 Illustrations, Including Full-Page Color and Halftone. Price $8. Philadelphia: F. A. Davis Company, 1921.

FOR many years McGrath's book has enjoyed wide popularity as a guide in the teaching of operative surgery; and it must have deserved this popularity, for otherwise it could not have survived in these days when an inordinate profusion of elaborate illustrations and numerous more or less valuable colored plates seem to be the fashion. Most of the illustrations in this book are in plain black and white, and there are few, if any, of the useless variety. Because of the author's long experience in the teaching of operative surgery and his natural ability for clear, concise statement, there is much less need for the artist than in the average book on this subject; yet there are occasional instances where additional illustrations would be a great help to the student.

As in the previous edition, the book is divided into ten parts under the following captions: General Considerations; Head and Face; Neck and Tongue; Thorax; Abdomen and Back; Rectum; Hernia; Spermatic Cord, Testis, etc.; Urinary System; Upper Extremity; Lower Extremity. In the chapter on General Considerations the author discusses the various types of anesthesia and the methods of their employment; but the technique of local anesthesia in individual operations is not discussed. Among other subjects discussed in this section are anoci-association, hemorrhage, intravenous infusion and transfusion by various methods, including both the older methods of arteriovenous anastomosis and the newer syringe-cannula methods.

Before taking up operative technique in each section of the body there is a concise résumé of the surgical anatomy of the part, usually covering the ground sufficiently so that reference to a book on anatomy is not necessary. The usual operations on the head, neck, and face are clearly described and usually sufficiently illustrated; but there are none in connection with operations on the tongue where, in our opinion, good illustrations would greatly help the student. But one radical operation for the removal of the cancerous breast and lymphatic glands is described, and in this the incision is neither exactly so placed nor so extensive as is commonly considered best to-day; while there are several other well-known incisions that should also be described. In operations upon the heart, pericardium, and pleura many will take exception to the author's advice regarding drains in at least some of the cases where there are no positive evidences of infection. The conventional methods of operating on intraabdominal organs common to both sexes are well described. We note, however, that the author still recommends anchoring the fundus of the gall bladder to the parietal peritoneum as a final step in cholecystostomy, although that practice has been well-nigh entirely abandoned in recent years. In the chapter on hernia the genesis and operative technique in the treatment of sliding herniæ should be thoroughly covered; for these are difficult and dangerous operations for the uninitiated and are seldom covered in books on operative surgery. The principal operations on the kidneys, ureters, bladder, prostate, and male sexual organs are well covered, and the same may be said of operations on the extremities.

ELEMENTS OF SURGICAL DIAGNOSIS. By Sir ALFRED PEARCE GOULD, K.C.V.O., M.S. Lond., F.R.C.S. Eng.; and ERIC PEARCE GOULD, M.D., M.Ch. Oxon., F.R.C.S. Eng. Fifth Edition, Revised, with 16 Radiographic Plates. Price $4. New York: Paul B. Hoeber, 1920.

FOR over thirty years this has been a favorite book with successive generations of students. The latest edition is very little larger than the first edition, but it is better printed and is on thinner paper and contains illustrations. The present revision contains new matter on such topics as gas gangrene and causalgia; and many of the chapters show necessary changes. Occasionally some of the older methods of diagnosis are omitted. The book treats of general methods in surgical diagnosis, and then gives the application of these principles to the diseases and injuries occurring in the various regions of the body. Throughout the work the diagnosis of injuries is separated from that of diseases; this makes for simplicity and clearness, and in no way interferes with the usefulness of the book. From its first appearance the book has been recognized as a safe guide for the student; and readers in search of a valuable work on surgical diagnosis will do well to examine the present volume.

NUTRITION AND CLINICAL DIETETICS. By HERBERT S. CARTER, M.A., M.D.; Assistant Professor of Medicine, Columbia University; Associate Attending Physician to the Presbyterian Hospital; Consulting Physician to the Lincoln Hospital, New York. PAUL E. HOWE, M.A., Ph.D.; Associate in Animal Pathology, Rockefeller Institute for Medical Research; Formerly Assistant Professor of Biological Chemistry, Columbia University, New York; Nutrition Officer, Camp Kearny, California; Officer in Charge of Laboratory of Nutrition, Army Medical School, Washington, D. C. HOWARD H. MASON, A.B., M.D.; Instructor in Diseases of Children, Columbia University, New York; Associate Attending Physician to the Presbyterian Hospital; Attending Physician to the Ruptured and Crippled Hospital, New York. Second Edition. Thoroughly Revised. Price $7.50. Philadelphia and New York: Lea & Febiger, 1921.

IT is one of the encouraging signs of the times that books on dietetics are multiplying, indicating as it does that we are beginning to appreciate the fact that the way to prevent disease is to fortify the body first and then, if that does not suffice, to supplement the natural forces by drugs. This is one of the most complete and satisfactory of the recent books on foods, and it is even better in the second edition than it was in the first. It contains a vast amount of information regarding the content in protein, fat, and carbohydrates of foods of all kinds, but it leaves unanswered a number of questions that are often asked of the physician. For instance, Why is whole wheat bread forbidden to the gouty? What is the acid in tomatoes and why is it so harmful as to cause tomatoes to be forbidden in many cases in spite of their large and varied vitamine content? Do the acids of fruits and vegetables increase or diminish the alkalinity of the body fluids, and why? Is grapefruit a beneficial fruit or the reverse? Has it the vitamines of the lemon or orange? Does lime juice contain the antiscorbutic vitamine? Is the fat-soluble a protective only against xerophthalmia? These and many other questions that naturally come into the mind of one seeking information regarding the proper food of man are left without answer so far as a diligent search with the aid of the index enables the reviewer to determine. This is the principal fault we have to find with this really most valuable and instructive book, and we call attention to it only because it is disappointing to find information on these points lacking when it is given so abundantly on so many other points. The most practical section of the book is that dealing with feeding in disease. Here the dietary prescriptions are very direct and simple. In spite of the omission noted and of a number of typographical errors, the work is of great value and should be studied by all who wish to be fully armed in the combat with disease.

MEDICAL NOTES. By Sir THOMAS HORDER, M.D. (Lond.), F.R.C.P. (Lond.), Physician with Charge of Out-Patients to St. Bartholomew's Hospital. New York: Oxford University Press, American Branch, 1921.

THIS is a slender volume of one hundred pages, containing notes or remarks made by the author in the course of clinical teaching. In general style the book reminds one of the "Clinical Aphorisms" of Samuel Gee; and readers of this latter work will probably view the present book as a kind of continuation of Gee's well-known book. It is eminently readable, and, while there is little in it that is new, most of the material is presented in a striking way; the occasional dogmatism is due to the author's constant aim at conciseness and his apparent abhorrence of verbiage.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held October 24, 1921.

THE PRESIDENT, DR. GEORGE GRAY WARD, JR., IN THE CHAIR.

Establishment of Official Organ.—Dr. DANIEL S. DOUGHERTY presented a recommendation from the Comitia Minora providing for the establishing of an official news organ of the Society, which was unanimously adopted.

Action on Amendment to the Volstead Act Deferred.—The Reference Committee to which the resolution offered at the stated meeting of the Society on April 25, 1921, that the Society petition Congress to defer action on the amendment to the Volstead Act, and referred back to the Comitia Minora at the stated meeting of May 21, handed in a report stating that the Comitia Minora, sitting as a reference committee recommended that, in view of the fact that the American Medical Association at its meeting in Boston referred this question to the Council on Scientific Assembly for consideration and report, no further action be taken by this Society.

Dr. JOHN P. DAVIN moved as a substitute that the matter be again considered in its original content and that the Society petition Congress not to limit the prescription of alcoholic liquors by duly licensed practitioners. He contended that this Society was quite as competent as the American Medical Association to pass upon this question, since it followed the lights of eminent medical authorities who were members of this Society. He moved that the report of the Comitia Minora be not received and that the Medical Society of the County of New York respectfully petition Congress not to incorporate in its legislation any restrictions on the prescription of alcohol by duly licensed practitioners of medicine.

Dr. HENRY S. STARK recalled that at the April meeting when this report was read he saw that as a matter of law the resolutions would not hold water and had therefore moved that they be referred back to the Comitia Minora. Two weeks later the matter was commented on editorially in the MEDICAL RECORD, and if it had not been for him the Society would have gone on record as almost asinine in its action. Strange as it might seem, so far as these resolutions went he agreed with Dr. Davin as to the inadvisability of waiting to see what action the American Medical Association was going to take. If they were going to have all their resolutions viséd and censored by the American Medical Association, the Medical Society of the County of New York might as well go out of existence. If they could not rely upon the five or six thousand members of this Society to settle the question they should go out of business as a society. The medical profession had come out plainly in favor of the Prohibition Amendment. There might be some therapeutic efficiency in alcohol, but when one took into consideration the vast amount of poverty, destitution, and crime that was laid at the door of alcoholic abuse, the question of the therapeutic value of alcohol was a negative quantity. The object of his speaking, he said was to urge that this resolution be not passed as it would hold the medical profession before the bar of judgment as it had never been held before.

The motion to adopt the report of the Comitia Minora, that the Society take no further action on these resolutions, was adopted. Dr. Davin's resolutions were referred to the Comitia Minora for consideration.

The Present Status of Operative Obstetrics Referring to the Abuse of Cesarean Section.—Dr. JOHN O. POLAK presented this communication, in which he deplored the operative furor which had invaded obstetrics, when even the physiological processes of normal labor were disturbed, and a normal sized child, in normal position, passing by a normal mechanism through an ample pelvis, with dilatable soft parts was interfered with; the head disengaged, a version done and delivery accomplished by breach extraction on the plea that the woman was saved an hour or two of second-stage pains. Other enthusiasts either for their own convenience, or to save the woman an hour or so of suffering, were routinely applying forceps when the head had reached the ischial spines, and the cervix was fully dilated; still others had so widened the indications for cesarean section that this operation was being employed daily on patients who presented no real obstetric indications for it, simply because it was the most convenient way to get the baby out. This paper had for its purpose to show that there was a difference between surgical obstetrics and obstetric surgery done for justifiable indications and that routine operative intervention even in the hands of the expert was not free from danger to both mother and child, and, finally, that while cesarean section was the easiest and quickest method of delivery, that there was a higher *morbidity* and *mortality* following abdominal hysterectomy, than follows abdominal section generally in properly selected cases. A study was presented of the operative incidents in a series of a thousand consecutive cases, which had had intelligent and painstaking prenatal study, where each labor was conducted with a full knowledge of existing conditions, on the principle of aseptic intelligent expectancy, and where intervention was done, not withheld, on proper indications solely in the interest of the mother and child. Comparison was made with 1,113 cases delivered by one man, an acknowledged expert, who had deliberately interfered with the normal processes of labor as a routine procedure. In this series of 1,000 cases there were 106 patients with actual contraction of the pelvis, an incidence of 10.6 per cent; 344 in which the occiput was posterior at the beginning of labor, and 42 in which the presentation was abnormal. Yet in this series the incidence of operative intervention showed forceps deliveries in 2.2 per cent; version in 0.5 per cent. and an incidence of cesarean section of 0.8 per cent. The number of stillbirths in this series was 19, or 1.9 per cent., including all infants dying during the first week after delivery, six more deaths should be added, making a total infant mortality of 2.5 per cent. In the series of 1,113 women personally delivered by one of the most skilful surgical obstetricians in America, he performed 920 versions, 39 forceps operations, and 80 cesarean sections, approximately one cesarean section to every fourteen cases. In his series 10 women were so far advanced in labor that they could not be prevented from delivering spontaneously, and 12 babies were born before the attendant reached them. In this series 41 were still-born, and 34 died before the mother was discharged from the hospital a fetal mortality of 6.7 per cent, or nearly three times the mortality of the infants in the previous series. Such facts left no room for argument, they clearly demonstrated the contention that routine operative intervention in the hands of the expert was not free from danger to both mother and child. Operative obstetrics no longer recognized the induction of premature labor in contracted pelves, for it was admitted that induction was not free from danger to both mother and child. *Present day obstetric teaching recognized the propriety of giving each case an aseptic* test of labor when the pelvic deformity fell within the relative class, for over 80 per cent. of these cases spontaneously delivered. High forceps was an operation of history. On the other hand, low forceps applied with the head at or below the spines, was an operation which when indicated was purely life saving. Many children lost their lives as the result of too conservative delay during the perineal stage. Low forceps applied under surgical anesthesia, with the patient in proper posture, did little or no damage to the pelvic soft parts (in the hands of a competent man). Version according to the technique perfected and so ably described by Potter, had a wider field than had generally been given it, *but not as an elective routine procedure in normal cases.* Version had its widest indication as an emergency procedure in complex presentations—brow, face, and the accidents such as prolapsed cord, placenta prævia, abrupto placenta where rapid delivery was demanded in the interest of the child. In present day obstetrics embryotomy had but a limited field, and was now practically never done on the living child except

in the presence of an infected mother and even here, the Perro operation might come into competition. On the other hand, perforation, cleidotomy, and evisceration should have a more general use in terminating the delivery of the dead fetus. In discussing the abuses of cesarean section, Dr. Polak said there was a fallacious impression in the minds of both the general medical and the lay public that cesarean section was a perfectly safe and simple operation which could always be guaranteed to give perfect results under all circumstances. The fact was that abdominal surgery *always carried with it a certain risk to the life of the patient*, even in the most competent hands and under the best conditions. Notwithstanding this general impression, his study of 2,200 operations of which 200 were from his own clinic showed that cesarean section had a *greater morbidity and a greater mortality than ordinary abdominal operation* done for other pelvic conditions. Study of the end results showed that those obtained by cesarean section performed at the time of election, that was before labor began or early in the course of labor were much better than the results of the late or secondary operation. This, therefore, *implied the necessity of very careful prenatal study, the proper estimation of the relative size of the child to the particular pelvis and the aseptic conduct of labor*, so that if the operation was indicated it might be performed when the best results might be expected for both patients. Cesarean section was indicated in the patient in whom some definite pelvic obstruction existed either as the result of actual contraction or by the presence of tumors blocking the pelvis, which rendered delivery of even a dead or mutilated fetus impossible or dangerous. A contracted pelvis with true conjugate of 6 or 6½ cm. or an immense child would give the absolute indication. Any operator who performed cesarean section for other reasons must be sure that the benefits which were to be expected from the operation to both mother and child were sufficient to warrant the increased risk to the mother. Further admitted indications might be stated as follows: Labors in multiparæ who had had previous obstetric disasters; placenta prævia when the patient was at or near term, in good condition, had not been subjected to vaginal invasion, with a live child and a central or nearly total implantation of the placenta; abruptio placenta was a proper though rare indication, and then only when the birth passages are totally unprepared. In addition to these there were a few other indications in which cesarean section was admissible, as breech presentation with large fetus in elderly primiparæ; prolapsed cord with ruptured membranes; large child and unprepared soft parts; the delivery of the physically unfit; in cardiacs to lessen the strain of labor; in women after previous cesareans because of danger of rupture of the hysterotomy scar; dystocias resulting from previous suspension operations which had become uterine fixations, and in deliveries after the cervix had been amputated and the pelvic structures repaired by extensive plastic operations.

Advances in the Study of Metabolism in Normal and Pathological Pregnancies.—Dr. HAROLD BAILEY made this presentation in which he summarized the results of various investigations as follows:

"(1) In pregnancy there is an increased metabolism of 4 per cent. This may represent an effort to keep stationary the hydrogen-ion concentration of the blood. (2) There is nitrogen retention throughout pregnancy and in the latter months there is also a slight tendency to an acidosis.

(3) The disturbances of protein metabolism in pernicious vomiting, acute yellow atrophy and eclampsia are expressed by a lower urea output with an increase of the ammonia and undetermined nitrogen, and probably indicate a failure of deamination of some high aminobody and a retarded urea synthesis. The evidence suggests that this is due to a degeneration of the liver cells and is secondary to the true etiological agent. (4) Blood chemistry shows that eclampsia is accompanied by an acidosis and that there is a low $\frac{\text{urea}}{\text{n.p.n.}}$ coefficient in most cases. When this coefficient rises it indicates a secondary degeneration of the kidney and consequent lowering of the functional activity. Blood analyses support the evidence furnished by the nitrogen partitions of the urine. Prognosis and even treatment may be based on the report of the blood findings."

Improved Maternity Care as a Public Health Question—Can We Provide for the Same by Legislative Enactments?—Dr. GEORGE W. KOSMAK presented this paper, in which he stated that the increasing attention given to questions of public health was conclusively demonstrated by the rapid strides during the past few decades in this domain and had also found expression in the widespread agitation and propaganda now so generally prevalent in both lay and professional circles. The campaigns against tuberculosis, the contagious diseases of children, typhoid, malaria, and other illnesses had now been succeeded, it seemed, by an almost worldwide propaganda for better maternity care and infant welfare. Tracing the development of this latter movement, Dr. Kosmak said that interests which were scattered through communities both large and small, because of their sentimental appeal, had gradually developed to such an extent that they had submerged in a country wide agitation and propaganda for national legislative support. The interest which the public, both as individuals and in organizations, had shown in this matter, behooved us as physicians to recognize these sentiments and to lend our constructive advice and technical knowledge in guiding the same along proper channels. It was necessary to bear in mind that the question of improved maternity care was largely a medical one and that while the economic and social factors were important, they should not lead one astray in any concerted attempt to remedy the situation. There was no field in which false sentiment could lead to such fatal errors. Childbirth and the preparation for the event aroused in the mind of everyone a feeling of sympathy or even pity and it was well known how dangerous an overabundance of these sentiments might become in the furnishing of practical relief. We all realized how important the childbearing life of a woman was to the community and to the state—the whole welfare of the nation was linked with healthy motherhood, the ability to bear and to rear children. As physicians a great deal of the burden and responsibility for securing the same rested upon their shoulders. The propaganda in this country in favor of national recognition of the maternal mortality depending on childbirth was to some extent based on a study made by Dr. Grace L. Meigs of the Children's Bureau of the U. S. Department of Labor, published in 1917. This report was an admirable study. Dr. Meigs claimed that in 1913 in this country 15,000 women died from conditions caused by childbirth, of which 7,000 were cases of puerperal fever. It was also pointed out that the death rate per 100,000 population was only a little lower than that from typhoid fever and that this rate would be almost quadrupled if only the group of the population that could be affected, namely, women of childbearing age, was considered. In the group of fifteen foreign countries only two were shown to have a higher death rate from this cause than the United States. Dr. Meigs claimed that the death rates showed no appreciable falling off during the period 1900-1913, although this same lapse of years had been marked by a revolution in the control of certain other preventable diseases such as typhoid fever, diphtheria, and tuberculosis. The author of the report believed the standards of obstetrical care in this country were low and that this resulted chiefly from two causes: (1) General ignorance of the dangers connected with childbirth and the need of proper hygiene and care to prevent them; (2) difficulty in the provision of adequate care due to special problems characteristic of this country. She concluded that improvement would only come through a general realization of the necessity for better care in childbirth, and that if women demanded better care physicians would provide it, medical colleges would furnish better training in obstetrics, and communities would realize the vital importance of community measures to insure good care for all classes of women. Dr. Kosmak called attention to the fact that this report contained no recommendations along the lines suggested at a later date by the Sheppard-Towner bill. So far as infant mortality was concerned, later statistics were at hand and very satisfactory reductions in infant mortality had been noted. From a survey of these statis-

ties, it might be claimed that whatever factors should be credited with the reduction in infant mortality, they had at least accomplished their purpose. A less satisfactory condition prevailed, however, in regard to the mortality from childbearing, for septicemia and eclampsia, among other conditions, still claimed an undue number of victims. The mortality from septicemia had remained practically the same for the past twenty years and the mortality from childbirth in general was second only to that from tuberculosis in women of reproductive age. The death rate from eclampsia seemed to have been equally high. Of course, we must expect that in the carrying out of the processes of gestation a large number of complicating factors entered and many of these were out of our control. On the other hand, it had been amply proved that with appropriate prenatal care and skilled attention during labor, the maternal morbidity and mortality could be much reduced. The assertion had frequently been made that only the rich and the very poor obtained adequate obstetrical care. This was secured for the former by their ability to pay for skilled attention, and by the latter through the provisions made by charitable agencies. If the foregoing facts were pondered it was natural that a propaganda should arise in which an attempt would be made to provide women unable to obtain it otherwise with such necessary care through public agencies. The development of this idea would readily lead to extreme measures. Progress to be satisfactory must be slow and thorough coordination between the medical and the contributory factors must be developed. We could not accomplish by radical legislation the solution of a problem which was purely personal, by methods which savored of the dictatorial, and which offended the sense of liberty of action as we understood it in this country. While within recent years direct legislation had been introduced, and people had begun to realize that for the benefit of the community they as individuals had to submit to certain definite regulations even if they were disagreeable, nevertheless there must necessarily be limits to which such methods could be applied. Dr. Kosmak traced the development of the health centers as a result of the fostering of community spirit and the expansion of public health activities. He asserted that there was no doubt that the institution of a public health center exerted a wide educational influence, and a knowledge of personal health and hygiene must be spread. If such an ideal condition could be brought about, and the giving of advice divorced from treatment, perhaps less opposition would be generated, but it was a difficult matter to separate the two. It would mean the gradual recognition of a system of State medicine which in this age at least we were not prepared to accept in the United States. Maternal and infant welfare being of greater popular interest than any other topic in the field of medicine, more concerted and serious attempts had been made to bring it under the control of central government supervision and authority, but admitting, as we had done, that the situation was in need of improvement, could we hope to accomplish this end by such widely heralded measures as the recently proposed Sheppard-Towner bill? The bill might be summarized as the most radical type of legislation which had ever been proposed in this or any other country, for it sought to establish through the medium of a minor government bureau a system of close supervision and direct federal financial support of certain essential functions of the individual States. The mere appropriation by the Federal Government of funds on a fifty-fifty basis, the expenditure to be supervised through the head of the Children's Bureau of the Department of Labor without control and the carrying out of the act largely through visiting nurses, constituted a measure that would effectually bar rather than further the progress of medicine along these lines for many years. It would take out of medical auspices the carrying on of a strictly medical work, and, judging by its accomplishments in the past, the work of this lay bureau would be largely of a sociological character and constitute an entering wedge for paternalistic and socialistic schemes with which this country was not in sympathy. Admitting that septicemia and the toxemias of pregnancy constituted the largest element in the mortality of childbirth, how much could these factors be reduced by advances in obstetric methods? Radical interference with the course of labor had been accused as one of the factors in an increased mortality. But could we say that this was true—could we say that more sepsis had resulted since these radical methods had come into vogue, and were they being done in sufficiently large numbers to influence the result as a whole? They certainly had nothing to do with the reported increase in the toxemias of pregnancy. In this connection it was of interest that in Germany during the war, when the nutrition of the nation was reduced to a low ebb, eclampsia became almost unknown. German observers attributed this to the compulsory change in diet when fats and proteids were reduced to far below the amounts usually consumed. Might not the unfavorable statistics as regarded eclampsia and the toxemias of pregnancy be due to the more abundant and richer food supply which our people had become accustomed to in recent years. Dr. Kosmak showed that the reduction in infant mortality had been brought about largely by the awakening of community spirit and the development of local interests in this problem. Further improvement, he claimed, would result from the continued development of local interests in this important problem, and what had been accomplished thus far should be a matter of greater pride in the particular localities, for the accomplishment of the end had been attained without the help either through financial assistance or supervisory restrictions, of the national government. He felt safe in claiming that further improvement would result if this method was extended, for it was a method particularly applicable to this country. If the wider aspects of the question demanded that the national government recognize the possible shortcomings in our plans for the welfare of women and children, then let this recognition take the form which it had in other great departments of the government. A great deal more dignity and credit would redound to a central government if it exercised its functions in a purely advisory capacity, stepping in where need be to help along by good advice, suggestion or precept, and carefully avoiding direct control or direct financial support. Our people were not constituted to tolerate this, and governmental interference in other ways had so often proved a dismal failure that it should not be repeated in this instance. If all the medical interests of the National Government were concentrated or coordinated in a department of national welfare or in a national department of health, this problem could readily enough be made a part of the general scheme. The Public Health Service was at the present time fully capable of taking up the National Government side of this important matter, and whatever was done could be done in a dignified way from the medical point of view and free from the socialistic and paternalistic aspect with which so much of the work of the U. S. Department of Labor had been characterized. It was his belief that improvement in obstetrics would result more rapidly and more directly by a recognition of the fact by the medical profession, by an improvement in teaching facilities in obstetrics, by an acknowledgment that this was one of the major branches of medicine, and by a full realization of the fact that improved maternity and infant care was a medical problem pure and simple with certain underlying economic factors, but a problem that must be kept free from all schemes for the endowment of motherhood, compulsory health insurance, or the subtle influences of the feminist movement.

Dr. JOHN A. KILLIAN stated that Dr. Bailey's paper on normal and abnormal metabolism in pregnancy had covered such an extensive field that it was impossible to discuss even the salient points. However, there were a few points that would stand a great deal more emphasis from the practical standpoint than Dr. Bailey had given them. It had been his experience in dealing with obstetricians that they clung to the idea that nitrogen partition of the urine was of some value during pregnancy or in eclampsia, whereas it had been demonstrated that the chemical analysis of the blood was infinitely more accurate and reliable in detecting the metabolic status of the patient than the results of urinalysis. Normal pregnancy was characterized by a retention of nitrogen, which indicated that there was an excessive demand on the maternal organism for this substance. Of the total amount of nitrogen, non-pro-

tein nitrogen and urea formed the largest factor, about 50 per cent.; 46 per cent. was in the form of little known nitrogenous compounds. This was spoken of as the "rest nitrogen." In eclampsia the ratio of urea nitrogen to non-protein nitrogen was decreased. The increase in the "rest nitrogen" ran parallel with the degree of toxemia, so that it would seem that some factor causing the toxemia was one of these nitrogen compounds. If one dialyzed blood taken from a case of toxemia of pregnancy and injected it into animals it produced convulsions, showing that the condition was really one of toxemia. There was also a drop in the carbon dioxide combining power of the blood in the toxemia of pregnancy, and under such condition of acidosis the risks of surgical operation requiring general anesthesia was evident. As the toxemia was relieved the carbon dioxide in the blood rapidly returned to normal. The toxemia of pregnancy was characterized by a rise in the uric acid, both in nephritis and eclampsia. In the analysis of the blood in pregnancy one should take into consideration the non-protein nitrogen and the urea nitrogen, laying emphasis on the ratio of the urea nitrogen to the non-protein nitrogen, and in calculating this ratio it was important to know the hydrogen-ion concentration of the blood.

Mr. MICHAEL M. DAVIS said that Dr. Kosmak appeared to refer to the Sheppard-Towner bill when he questioned the extent to which legislative enactment could promote matters of public health. An act of the Federal Government must not be judged from the local standpoint of New York City, but from the standpoint of all parts of the country. Two years ago he had been in Montana, where one might ride twenty-five miles and see only two ranches. The people there were not suffering from poverty, but owing to the great distances the problem of getting care in time of sickness was very difficult. The Federal Government must consider these sparsely settled regions; it must likewise consider the small poor communities in the South, and the comfortable middle-class regions whose people were on fertile farms and not in towns. A recent journal from the Middle West stated that the women of that section were setting up a new slogan. They were saying that whenever a farmer bought a new tractor to lighten his work on the farm his wife should be bought a new washing machine to lighten her work in the home. A public health department took up that suggestion and said that every time the farmer put in a petition for legislation for an agricultural school for the training of efficient farmers, the women should ask for public health nurses to help bring up better babies to provide material from which these more efficient farmers were to be made. It was not right to judge Federal legislation from anything else than its effect upon the whole country. The proposition of using the wealth of one section for other sections not so well provided for had been applied in other departments, as in education, and was applicable to this problem. As to people resenting the visit of a public health nurse, the public health nurse was usually a very popular person, and particularly among the women. The public sentiment developing among the women of this country for better maternity care was absolutely certain to find some definite means of getting results. Personally, Dr. Davis said he did not believe in educating people by hitting them on the head. He believed that education should be something attractive to those who were to be educated. One was justified in using compulsory methods in dealing with contagious diseases, but he thought maternity welfare work must be educational and attractive and not compulsory. It must be brought about by all agencies interested, including the medical profession and the medical schools, as well as lay groups. It was a work that was not solely medical and not solely lay. It was important that the lay group should not attempt the work alone, and on the other hand the medical group could not carry the work out successfully without the lay group, which must provide the sinews of war. As to how far legislative enactment could promote maternity care, he thought Dr. Kosmak had shown what it had done in New York City when he mentioned the improvement of the milk supply, the education of mothers, the work of the visiting nurses, and the baby health stations, as among the chief measures that had diminished infant mortality in this city. Analogous measures were applicable to mothers, and it was reasonable to expect that if legislative enactment had aided the work in one instance it could do so in the other. To bring about the desired results legislative enactment was necessary and it was also necessary that those engaged in this work should have constant prodding from such a medical body as this. He felt that in carrying out maternity welfare work there was needed the cooperative effort of the medical profession and lay groups working together for public education and for the enactment of proper legislation in order to achieve results.

Dr. KOSMAK, in closing the discussion, said that much of Mr. Davis' discussion bore out his contentions, though they seemed to be on opposite sides of the fence in the matter of the Sheppard-Towner bill. His contention was not that the Federal Government should not take part in maternity welfare work; his objection to it was the manner in which it sought to exercise this function. As he had said in his paper this was the most radical type of legislation of its kind. Mr. Davis had brought out the factors which had been effective in the reduction of infant mortality in this city and these measures had been duplicated all over the United States. This work was done by the community, without the assistance of the State. It was local community work developed by people who knew and were interested in what was going on around them. According to Mr. Davis one should not judge results by what was going on around one, but had to take into consideration what was going on all over the country. The Sheppard-Towner bill depended upon a fifty-fifty basis. The Federal Government would pay as much as the individual State paid. If one took great States like New York, Pennsylvania or Illinois, States appropriating $100,000 a year for the work, they could call on the Federal Government for another $100,000. But if one took certain States with a poor treasury that could make only a small appropriation, they would get a correspondingly small appropriation from the Federal Government, and consequently there would be insufficient funds to carry on the work just where it was most needed. The plan would therefore fall short in granting the desired relief.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held October 18, 1921.

DR. SAMUEL BRADBURY IN THE CHAIR.

THE subject of the evening was "The Pay Clinic."

Why the Public Needs Pay Clinics.—M. M. DAVIS, JR., Ph.D., spoke on this subject. He stated that his understanding of a pay clinic was a clinic which charged fees covering the cost of service for the patients and a clinic which paid salaries to physicians who did the work. He did not believe one should go on without the other. The public needed clinics because there was a large number of persons in the community who could afford to pay something for medical care and were not objects of charity, but who could not pay the usual kind of fees. There were three factors to be taken into account in determining whether an individual or a family "could pay:" (1) The income of the man or family. (2) The margin which the family or individual had over the minimum daily needs, such as shelter, clothing, food, etc. (3) The approximate cost of adequate treatment, depending upon the nature of the illness. This cost varied widely from a small amount in very minor ailments to the high cost of major surgery or the diagnostic procedures that called for expensive investigation. When these three factors were known one was in a position to know whether the patient could pay the usual private rates. Taking up these things separately we had, first, the cost of living. This had been a sore point with all of us. By the cost of living was meant the estimate of the cost of living on the basis of minimum requirements of health and decency. Such estimates had been made by many organizations. Perhaps the most reliable figures were those of the United States Department of Labor and of the New York Bureau of Municipal Research. These were probably as reliable as could be obtained. The minimum health and decency standard of the New York Bureau

for a single man per year was $1,093 and for a single woman $1,118; for a family of five, which was taken as the "average" family, the minimum "health and decency" standard required $2,263 per year. All these figures had been very accurately estimated, and they included a certain allowance for medical care. In the single man's budget of $1,093 an allowance of $32 was made for care of health. In the single woman's budget of $1,118, $43 was allowed for the care of health. In the family of five an allowance of $80 was made for the care of health. These figures were not made by doctors but by the Federal and local bureau who took the sums actually paid for health care or considered as practicable for people receiving these incomes. What would $80 do in providing medical care for a family of five? It must be borne in mind that $80 was the amount included in the minimum figures. Anything in excess of $80 must be taken not from luxuries but from the necessities of life. Obviously dental care and the allowance for medicines would easily eat up one-half of $80, and often much more, so that $80 could by no means be allowed for physicians' fees. The allowance for health care of a single man was $32 and of a single woman $43. No very expensive treatment could be obtained for that amount. If the services of a specialist were needed the situation would be still more difficult. If the child needed the services of an oculist and the usual office fee of $5 or $10 was paid and then from $5 to $15 for glasses, $10 to $25 for the examination and glasses, it made a big hole at once in the $80 allowed for medical care. Secondly, Dr. Davis said they had been collecting estimates from physicians, chiefly specialists, for the treatment of more or less typical ailments. These figures it was hardly necessary to read before a medical audience. The cost of the usual fees by a specialist for a baby with rickets during the course of a year's service was $195. At the hands of a pediatrist a child eight years of age with malnutrition for eight months' treatment was charged $55.50, to which must be added a certain amount for medicines. A case of syphilis cost for the first year $225 for treatment; a carbuncle cost $40; a corneal ulcer $49; a glaucoma running six months $157. A case of nephritis during the first period, when the case started with diagnosis and initial treatment, cost something like $100. It was obvious that these figures would be impossible of payment by a family of five with the income above named, or by a single man or woman with an allowance of $32 or $43 per year for health care. The conclusion was that people supporting themselves on earnings of $1,200 to $1,500 a year for single persons and $2,000 to $3,000 for families had a very small margin to expend for health over and above the necessities of life. The question then arose as to whether these figures applied to large groups in the community. The statistics in regard to income were not as reliable as one would like to have them. There were certain figures of income in New York City, compiled by the National Bureau of Economics which showed that in normal times, in a population of over 6,000,000, two and one-half million were employed. About 14 per cent. were estimated to have incomes of $3,000 or over; 86 per cent. had less than $3,000. As one went down the scale, 61 per cent. had incomes less than $2,000, 22½ per cent. less than $1,200. Approximately one-half of the two and a half million had incomes less than $1,700. A further analysis of these figures showed that a considerable proportion of those with incomes of $1,200 or less were single men and women or young persons living with their parents. The great bulk of those with incomes of $2,000 to $3,000 were heads of families. Approximately 240,000 families in New York had incomes between $2,000 and $3,000, meaning that there were over a million persons with that scale of income, and that was about the *minimum* scale of income to support the average family in health and decency. If we added an estimate of the number of single individuals with incomes of from $1,050 to $1,650, we might judge that there were about one and a half million persons in New York with incomes which just about extended to the minimum budget estimated as necessary to provide the necessities of life. There was also a large group habitually below this margin of self-support who were unable to pay anything for medical care. These constituted those who filled most of the free beds in hospitals and the free clinics. Over one million people were now annually receiving care in charitable clinics in New York City, and that corresponded with the figures quoted. There were, however, quite a number who were attending the charitable clinics yet who were willing and able to pay a small fee. In the studies made by the Public Health Committee of the Academy of Medicine it was found that three-fourths of all who went to the dispensaries went for care by specialists. The group of one and a half million were not able to afford specialist care at the rates usually charged by specialists and consultants. This large group fell between those who could pay the rates of the expensive specialist and those who were legitimate attendants at the free dispensary. Obviously it was impossible to generalize as to the fee for medical care, but there were one and a half million people who fell between the charity class and the well-to-do. Since the city together with the immediate suburbs had a population of 8,000,000, probably 2,000,000 of these fell between the well-to-do and the charity group. This 2,000,000 might be called the "pay clinic class." The pay clinic was not a new thing. It had been established on a small scale in New Yorn; in Boston, Cleveland and Chicago on a larger scale. It had been successful enough to prove that it met a definite need, but relatively little such work had been done in comparison with the large amount needed. Such a clinic ought to be a substantial help to the medical profession, for through it the family physician could get the help of better diagnosis. The pay clinic also brought to physicians a considerable sum of money which now did not go to the medical profession at all. Many patients now either paid nothing because the charitable clinics charged nothing or received no treatment because they did not wish to accept charity. If these persons paid a fee within their means a considerable amount of money would go to the medical profession. Approximately one-half the expenditures of the Boston Dispensary Pay Clinics were for salaries to physicians. Now the amount which the patients of those clinics paid for treatment plus medicines, etc., at cost just about equalled the cost of the medicines or appliances alone at commercial rates. If pay clinics were general, instead of all the patient could afford being paid to commercial enterprises, a considerable part of it would be turned over to physicians. But, of course, the essential result of the pay clinic was not financial benefit to the profession, desirable as that was, but larger service of the public. With the age-long tradition of the medical profession, service to the public had always ranked first.

Pay Clinics for Venereal Disease.—Dr. ALEC N. THOMSON read this paper, in which he stated that the pay clinic was established for the accommodation of those venereal-disease patients who were too poor to afford treatment by a well-qualified practitioner, and yet were economically above those who were admitted to dispensary service. At present, even though they were entitled to dispensary service, they did not want to avail themselves of what they termed "mere charity." The theory upon which the pay clinic was based was better specialized medical service within the reach of the average individual. The need for low cost and high grade service was especial in the case of the venereal diseases. With proper personnel, ethical publicity, social viewpoint, public-health ideas, and modern professional procedure, a clinic could be maintained to treat those individuals who could receive treatment in neither the dispensary clinic nor from the private specialist. The pay clinic was by no means a competitor of the private physician. Not over two per cent. of the patients could afford private treatment. Private treatment cost from $300 to $400 per year, whereas the pay clinic affords equivalent treatment for $100 to $125. This rate, which, on the one hand, was a considerable saving for the patient, on the other hand afforded the physician a reasonable compensation for his services. He got for his clinical work, $5 an hour, working six hours a day, six and one-half days a week. This amounted to $10 000 full time schedule, a net income greater than the average medical man's grand total with uncollectible bills included. He could afford to devote some hours a week upon a purely selfish basis. From the inception of the

pay clinic, it had developed along various lines in various places. Some had been affiliated with hospitals or dispensaries, such as the Boston and Brooklyn dispensaries. Others were separate entirely. It was the latter type which was growing more popular. Group medicine frequently resolved itself, in the final analysis, into the private pay clinic. Hitherto nothing better had been offered. It could administer salvarsan for $5 and compensate the administrator. This could not be accomplished by the private physician. The business principle of reducing cost as the volume of production increased applied, with certain modifications, to medical practice.

Boston Dispensary Health Clinic: Its Object, Mode of Operation, and Accomplishments; a Review of the First Four Hundred Cases.—Dr. LESLEY H. SPOONER of Boston read this paper. (See page 1028.)

Dr. THOMAS KIRBY DAVIS said he had had the experience of working in a neurological clinic which was a pay clinic. There were two things that might be considered as disagreeable factors. One was that there was a certain amount of abuse of the privilege, but a small amount, and another that inasmuch as it was a neurological clinic there were neurotic and functional cases which were rather difficult to deal with. In connection with the treatment there was a busy and well handled therapeutic department and there was a certain abuse of that aspect of the work, as many cases not needing hospital attention found that they could get this desirable treatment and cluttered up the clinic, but this was perhaps not altogether an objection because it did give them some benefit.

Dr. MAURICE FISHBERG said he was very glad to have heard this discussion on pay clinics and had learned a great deal from the three papers presented. Group diagnosis was like writing poetry by a group of would-be poets. Three or four of such could not produce a work as good as a poem by, say, Byron. A brilliant diagnosis was not usually made by a group; in the last analysis it must be made by an individual. Our great institutions were not made famous by groups, but by individuals who were leaders. After hearing the details of the Boston Dispensary Dr. Fishberg said he was surprised that only 50 per cent. of the patients were referred by city practitioners and he wondered how many kept on sending cases. The statistics given by the first speaker about the cost of living showed that a single man should allow $32 for health care and a family of five $80. Medical men would be happy to undertake at $30 a year to supply medical care and would find it a very good proposition. Fraternal orders had been supplied with medical care for $3, $5 and $6 per family per year. If this $30 to $80 would really go into the pockets of the profession it could be done on a wholesale scale, and enrich the profession. They had been told by one of the speakers that the doctors in the pay clinics were being paid at the rate of $10,000 a year, which he said was new to him. Work in the pay clinic probably covered three hours a week at $5 an hour. The physicians in the pay clinics were not working six or eight hours a day at five dollars an hour. Dr. Fishberg said he would like to know of a doctor in a pay clinic getting $10,000 a year. He pointed out that one of the speakers agreed that they were paid by prestige and experience, but the money remained with the social workers. He knew whereof he spoke because he had worked with the social workers. Of late they thought that medical fees were going up and had the idea that the doctors were getting too much, and when they made up statistics they put down that inasmuch as doctors were paid at $5 an hour it is clear that they were getting $10,000 a year. He suspected, however, that the doctor was working in a pay clinic only a few hours a week at the rate of $5 an hour. Group diagnosis at its best could be seen in the Life Extension Institute. They were advertising widely in newspapers and magazines, which would not be ethical for a group of physicians, and which they would not want to do. He had seen some very monstrous diagnoses made by the Life Extension. As soon as there was a group there was likely to be advertising, as witness the Chicago clinic which advertised in the daily papers. The publicity agent who does the advertising for them was usually one who had failed to do the publicity work for industrial enterprise, because there the department inquired at the end of the year how much increase in business the publicity manager had to show. As a matter of fact there was no need for pay clinics. Everywhere doctors were treating patients unable to pay their fees for one-fifth to one-tenth of their regular fees and on down to nothing, and the patient got proper attention such as he could not get in the pay clinic. However, the pay clinic might be of some use educationally.

Dr. STAFFORD MCLEAN stated they had started one of these pay clinics about a year ago at the Babies' Hospital. For many years patients had been refused there because their husbands were earning more than the law allowed to the person seeking admission to a charitable clinic. These people were willing to pay and wanted to receive the type of examination and treatment that the clinic at the Babies' Hospital could give them. They had made an arrangement to meet this special need. They charged patients $3 for the first visit and $1 for subsequent visits. An additional dollar was charged when a Wassermann test, a blood count, or a uranalysis was necessary. The idea of the three dollars for the first visit was because many came solely for an opinion, perhaps to check up their own doctor, or perhaps for advice they could not get in their own locality. For those cases that came only once they charged more than for patients who came frequently, such as feeding cases and leutic cases. The conditions in the pay clinic were no different than those in the free clinic, except there was less congestion in the former and the patients were not forced to wait for long periods. There was the same objective in both clinics but in the free clinic one traveled in the day coach while in the pay clinic one traveled in the parlor car.

Dr. WARD C. CRAMPTON expressed the opinion that the pay clinic simply pointed the way in which medicine was moving. The pay clinic was a phase of medical progress whether one liked it or not. The pay clinic was a movement in the direction of pay relative to the service rendered and the ability to pay. A feature that had particularly interested him in Dr. Spooner's paper was the prominence that was given in the Boston clinic to the habits of the individual. Physicians were primarily, fortunately or unfortunately, pathologists, concerning themselves with disease rather than health. It was natural that this should be so, since disease was an emergency, dramatic, important, and immediate. But there was a field where the charlatan had crept in and this was the field in which the Life Extension was working, whether we liked it or not, and this was the field of construction. It was for the medical profession to enter this field and develop it as a part of the medical profession. They should not permit the masseur, the osteopath, the chiropractor, the bonesetter, and the milk curist to foist their methods for the extension of life upon the public rather than those of the physician who had the knowledge to properly develop this field. The Boston clinic had shown in a definite, conservative, formative way that the physician could enter this field and work as effectively as in the field of pathology.

Dr. LOUIS FAUGÈRES BISHOP said he was interested in this question of pay clinics. Three or four years ago by force of circumstances he found himself president of a dispensary that was treating 6,000 patients a year and trying to collect ten cents from each patient. This was the Good Samaritan Dispensary at Essex and Broome streets. At this time the institution was running behind in its expenses, had had no improvements for a number of years and was in a distressing situation. He conceived the idea of converting this old institution into a pay clinic. The Board of Managers thought it could not be done. They said the people in this locality would not pay, that the dispensary had been running too many years in the old way and that nothing could be done. He took a man out of a drug store near the hospital, put him in charge of the clinic, and got his cooperation, explaining to him that his idea was to have these people pay as much as they could. The admission fee was raised from ten to twenty-five cents. A fee of five dollars was charged for a tonsillectomy, etc. At the end of the first year they had collected $3,000 more than their expenses, but they had not made many improvements. He went before the Board of Managers, showed that they had this balance

in their favor and that everybody liked the new plan better than the old one. The second year they showed a balance of $6,000 in favor of the dispensary. They established a model heart clinic, with electrocardiograph and *x*-ray apparatus, and charged $37.50 for complete examination and observation for a period of one month. This was done as a social experiment. When people came with heart conditions the complete diagnostic work was explained to them and they were told that if they did not care for it they could be treated in the dispensary in the old way. It was surprising the number of people who were willing to pay the cost for good service. This year the Board of Trustees were so elated with the evidence that the institution was self-supporting that they had voted $26,000 for improvements, and the whole institution had been practically rebuilt and renovated. His idea was that the physicians in a pay clinic should be paid according to their ability and that we should do away with the idea of paying them indirectly by experience, prestige, etc. The question of pay clinics was a part of the evolution of medicine and we could not get away from it. Public service was the only excuse for the existence of any philanthropy. He believed in raising the standard of practice and teaching the people the value of good medical service even when they were getting it at cost. No one was refused treatment because he had no money, but every medical philanthropy should teach the value of medical service. If every medical philanthropy in New York would hand to every patient a receipted bill showing the actual cost of the service rendered to him it would be an admirable educational movement for raising the respect of the public for medical service, assisting physicians to collect their proper fees, and in making people appreciate the service they received.

Dr. M. M. Davis, in closing the discussion, said he realized that anyone who was rash enough to quote figures of income laid himself open to criticism. He could recall the statement that there were three kinds of liars and that of these the statisticians were credited with being in the lowest grade. However, he believed the figures quoted were not based upon imagination but upon careful work and were as accurate as it had been possible to make them. It was quite true that if one took 10,000 people who had $30 each to spend on medical care and organized them into an insurance group one could probably build up an excellent scheme of health care but he would not care to undertake to do it because he believed it could not be done at the present time. Under such a scheme two things would be found, first, the sickly people would come in first so that there would not be a fair average of healthy and sick persons. In the second place objection would be raised to it as a form of contract practice which is generally regarded as a subversion of the current ideals of the medical profession. At the present time the pay clinic seemed to offer the best solution, though some time there might be a genius who would work out a system of taking this excess of $20 or $30 and building up a great system of group health insurance. But the pay clinic would be easier to get under way and would serve both the public and the medical profession.

Dr. Thomson asserted that syphilis clinics were today handling cases of tertiary syphilis that not only were not recognized but when recognized were not properly treated in the dispensaries. Dr. Fishberg evidently had not understood what he had said about the remuneration in the clinic. He said there was at the present time one full-time worker who was receiving approximately $10,000. In the Brooklyn dispensary the doctors were averaging $30 and $40 a week for a few hours' work. That was more than most doctors in New York were making net. Many specialists neglected to make examinations in other lines than their own. For example, in the tuberculosis clinics the examining physician frequently did not even ask the patient whether he had had syphilis, yet it was known that syphilis was 15 to 25 per cent. prevalent in tuberculosis individuals. Then there was the question of letting the patient understand what he should expect for the money invested. In one clinic dealing with venereal disease, a cash register had been installed and on the back of every receipt given to the patient was printed "Do not fail to come when the doctor tells you to return," and the doctor wrote on the case receipt the date of return.

Dr. Spooner, in closing the discussion, expressed the opinion that the objections used against group diagnosis were inadequate. There was no reason for assuming that the group was made up of inferior specialists. As to the fact that 50 per cent. of the patients were referred to the clinic by physicians, he had regarded it as a compliment to have outside physicians send their patients for diagnosis. He did not feel that the scope of the clinic was anything against its efficiency, and the fact that 50 per cent. of the clientele came from beyond the city limits was a healthy sign. The Life Extension Institute was quite a different affair. He felt that there were certain disadvantages to the Life Extension Institute. The examinations throughout the country were conducted by one man, who was probably a perfectly reliable physician, but by no means always an experienced practitioner. The reports of all examiners went to a central office and the diagnosis was made from this evidence. If the individual in question was overweight, he was sent a little book on obesity; if he was a little below weight he was sent a book on malnutrition; if his blood pressure was slightly elevated he received a book on hypertension. Diagnosis under these conditions lacked the common sense of the individual who saw the patient and sized up the whole situation first hand. In the Boston Clinic the final diagnosis was made by an internist whose judgment was not overbalanced by having his attention fixed on one field. He was not guided entirely by the finding of a diviated septum or hypertrophied tonsils, though it was important to have a record of these defects. Dr. Spooner said he was glad someone was impressed by the emphasis placed on habits and general hygiene; that had been a strong point with him and he was glad to have it appreciated.

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Rôle de la Radiologie dans le Pronostic des Affections Cardio-Vasculaires. By Dr. Andre Sorel. 90 pages with 59 illustrations. Price, 15 francs. Published by A. Davy et Fils Ainé, Paris.

State of Connecticut—Report of the State Tuberculosis Commission for October 1, 1918, to June 30, 1920; 81 pages with illustrations. Published by the State, Hartford.

Statistical Review of the Insane in the State Hospitals and Private Licensed Institutions, for year ending June 30, 1920. Prepared by H. M. Pollock. 368 pages, with tables. Published at Albany.

Anales de la Direccion de Sanidad Nacional. Director, Dr. L. G. Chacin Itriago. 296 pages with tables. Published in Caracas, Venezuela, by F. J. Camejo & Co.

The Block Supply to the Heart—in its Anatomical and Clinical Aspects. By Louis Gross, M.D., C.M. 171 pages with 29 full page plates and 6 text illustrations. Price, $5.00. Published by Paul B. Hoeber, New York.

Le Reflexe Pilomoteur. By Dr. André Thomas. 242 pages with 74 illustrations in black and colors. Price, 25 fr. net. Published by Masson & Cie., Paris.

La Dégénérescence Hepato-Lenticulaire (Maladie de Wilson—Pseudo-Sclerose). By Dr H. C. Hall. 361 pages with illustrations. Price, 20 fr. net. Published by Masson & Cie., Paris.

Atlas for Electro-Diagnosis and Therapeutics. By F. M. de Laroquette, M.D. 180 pages with 52 plates. Price, $4.50. Published by Paul B. Hoeber, New York.

Massage and Medical Gymnastics. By Dr. Emil A. G. Kleen and various contributors. 564 pages with 182 illustrations. Price, $7.00 net. Published by Wm. Wood & Company, New York.

Medical History.

WILLIAM WINWOOD READE, 1838-1875.

A NEGLECTED PROPHET AND DPSPISED REFORMER.

By BAYARD HOLMES, M.D.,

CHICAGO, ILL.

In his "Outline of History," H. G. Wells refers to the "Martyrdom of Man" as an early attempt to write the history of the human race. It was a book that I had never seen, and when it came into my hand my interest was aroused in the remarkable perspective and horizon with which the subject was presented, and my admiration excited in the erudition of the author at a time when scientific studies and philosophic interpretation were in a state of primeval chaos. This fascinating book was published in 1872 and at a time when the conflict between biology and the church was most acute. The style was popular and unconventional, but vivid and dramatic. The great literary critics passed it by with supercilious mention of its defects, the historians without a word or with a finger of scorn for some obvious historical mistake. The religious press and even the pulpit condemned it as irreligious and blasphemous. In spite of all, the untimely volume has gone through twenty-two editions in fifty years and its sales are increasing rather than diminishing. It is a book that any physician would read with profit, and many physicians with a great enthusiasm. I recommend it as a valuable and permanent addition to any library.

But it is to the author of this book that I would call attention, as it is in the author that my interest centers. He is a type of man of which modern society furnishes too few examples. He was almost contemporary with Samuel Butler, whose life affords a number of parallels. They were equally influenced by Charles Darwin, but Butler was educated for the ministry, while the author of the "Martyrdom of Man" would be a physician. They were both prospectively rich men, but they could neither of them wait the disbursements of time and death. Butler went to Australasia and was a sheep rancher in a plateau of New Zealand, and there in his lonely cabin, with the mountains and the literature of the world about him, he conceived his "Erehwon," a great metaphysical and prophetic document. The author of the "Martyrdom of Man" was hundreds of miles from any white man, camped on the headwaters of the Niger, reading his Herodotus, when he conceived his outlines of the history of man, a popular exposition of the evolution of human society.

William Winwood Reade was the nephew of Charles Reade, the novelist, and was born in 1838 at Ipsden House, Oxfordshire. In 1856 he matriculated at Magdalen Hall, Oxford. He took no degree at Oxford, and does not seem to have distinguished himself as a scholar. However, he had a good time and wrote a three-volume novel which seems to have been suggested by his college experiences. It was said to have been rough and youthful and never attained popularity. It is now extremely rare, and is not to be found in any public library in Chicago. It might be interesting to compare this record of life at Oxford in 1860 with that of our own universities half a century later.

Legge seems to think that Reade described himself in "Liberty Hall, Oxon.," as the drunken man, but in his African Sketch Book he attributes his long freedom from fever to his abstemious habits.

When he was made a Mason he immediately ransacked the literature of secret societies, and especially that found in the classics on the Druids, and wrote the "Veil of Isis." This book is also rare, and it is not to be found in any of the libraries to which the writer has access. One cannot depend much on the reviews of the time, because Reade's mind was distinctly an anachronism, as his subsequent work fully demonstrated.

By the study of Charles Darwin's "Origin of Species" Reade became converted to the philosophy of the unity of nature and the uniformity and consistency of natural phenomena, including human life. This idea was fixed by the discussion of Du Chaillu's gorilla skins with the surgeon of an African coasting steamer, and after this conversation Reade determined to go forthwith to the Gabbon and observe the habits of the gorilla for himself. His egotism soon made for himself the prospective reputation of an African explorer, and he set his stunt to be the discovery of the source of the Niger.

All of these undertakings were unprecedented among the young fellows that made up the membership of the Conservative Club in London. Reade was not a highbrow, and he had no sympathy with the smug Victorian proprieties. He had begun to understand the origins of ecclesiasticism in his study of the Druids. Now he learned about missionaries in his preparations for African exploration. His preparations for sailing to the Gold Coast were hurried and incomplete. He embarked in December, 1862, in the S.S. *Armenian*, and after much suffering and hardship he returned to England within a year, the victim of African fever.

This experience decided him to study medicine at St. Mary's Hospital, Paddington, and when cholera broke out, as it did over the whole world in 1866, he served in the cholera hospital at Southampton. Evidently he learned little of malaria from the books and his teachers, though the publication of his "Savage Africa" and an anonymous romance, "See-Saw," under the *nom-de-plume* Francesco Abati, shows he was anything but idle. In "Savage Africa" there is a chapter on malaria which gives a perfect picture, hard for the modern medical man to conceive, of the lay and professional psychosis of the disease in the 1870's. It is well worth reading.

European knowledge of Africa in 1866 was meager, but there was a great awakening of interest in exploration. Livingston was opening up the southern plateau. The Burton and Speke exploration was a conspicuous symptom of the psychosis of the time of the *Zeitgeist*, as the Germans say. Now, the effect of exploration and of colonization on the mind is sometimes much the same as the effect of transplanting on the tree. There develops at the root of the tree an inhibiting toxic substance comparable to the state of mind

which we recognize in the provincial. A similar condition existed in the mind in England during the Victorian period. Butler broke loose from the fetters of this psychosis in the wilds of New Zealand. Reade became partially emancipated through his solitary journeys in Angola, his stay in Fernando Po and his repeated search for the source of the Niger.

What Reade did for geography and trade in the "Savage Africa" and "The African Sketch Book" is trifling compared with what contact with the Africans did for him in inspiring his "Martyrdom of Man." That the book was not well received and the author died thinking himself a failure and a mediocre mind was inherent in the novelty of his vision. "Erehwon" and the "Martyrdom of Man" needed a public opinion, a psychosis, a Zeitgeist which smug England and smugger America did not yet possess. The American Civil War was over. The blacks were free. Lincoln was assassinated. Public opinion and public spirit in the States had sunk to the lowest level of groveling economics. In England conditions were much the same. The preachers and the priests were in the saddle. The conflict between science and religion, as it was incorrectly called, was raging. Reason and perspective were lost sight of. There was no social enzyme in religious fervor or historical philosophy. The law of the survival of the fittest was interpreted to mean the survival of the strongest. "Whatever is is right" was the byword of manufacture, of commerce, and of politics. There was unmitigated child labor and unrestrained labor importation. Great, soulless corporations exploited everything that could have social influence from newspapers and theological seminaries to school books and Sunday School leaflets. The occasional appearance of a mind unfettered by the accepted "principles" and restrictions of the time and place is the only hope of human progress. Only such a mind can lead to those adaptations on which the prolonged tenancy of the earth by our species depends.

Italian Physicians and Aortic Aneurysm.—*La Riforma Medica* some time ago published one of its characteristic illustrated symposia dealing with the achievements of the native specialists in a given field of medical practice. It was in Italy that the Belgian Vesalius published the first account of the autopsy finds of an aneurysm of the descending thoracic aorta. This was in 1557. In 1804 Scarpa wrote a monograph on aneurysm in which he showed that it differed throughout from a mere dilatation, although the latter might and often did coexist. In his textbook on diseases of the heart and aorta, Huchard awards to Scarpa the credit for inaugurating our modern conceptions of neurysm, for his finds put an end to a long period of controversy. This does not take away from Morgagni the credit for the description of aneurysm in his "De sedibus et causis morborum," and Testa and Lancisi, two of Morgagni's scholars, also made contributions to the subject; the latter, in fact, in 1740, anticipated Scarpa in distinguishing between dilatation and aneurysm. But as stated, Scarpa brought harmony to the subject which for years had been the occasion of much polemic.

The next to be mentioned chronologically is Cardarelli, who began to write on aortic aneurysm in 1868. It was in 1878 that he described the sign which goes by his name for the recognition of the condition—laryngotracheal pulsation. In the same year Oliver described a similar phenomenon. In 1889 Cardarelli described the percussion signs of aneurysm and two years later Grocco and Lussati the auscultatory signs along the laryngotracheal tube. Cardarelli has also described other laryngeal symptoms of this affection, as have further Villanova, Baccelli, and the Irishman Stokes (aphonia and cough). As far back as 1868 Cardarelli had described the sensory symptoms—neuralgiform pains, etc.—and in 1873 he followed with the vasomotor phenomena, of aortic aneurysm. Massei and Pansini, old pupils of Cardarelli, considered the same affection, the former from the angle of the laryngologist and the latter from that of the Internist. The presence of aortic aneurysm causes a number of endolaryngeal and other symptoms affecting the air-passages, due in part to recurrent compression. Pansini added to the general symptomatology, which is very extensive, in part running parallel to that of angina pectoris. He added also to the symptomatology of the systolic laryngotracheal pulsation. D'Amato, another old pupil of Cardarelli, made further contributions along the same lines. At a somewhat earlier period other Italian clinicians, including Rummo, Cantani, Ferrannini, and Bozzolo, studied the influence of the breathing on the circulation in the subjects of aneurysm (1887).

In 1894 Castellino noted that laryngotracheal pulsations were sometimes noticeable in mediastinal tumors. Pansini afterward corroborated this discovery. Slightly in advance of Cardarelli, Baccelli and Fedeli, in their work on diseases of the heart and aorta (1864) had laid stress on the importance of pain in the symptomatology which pointed to the aorta as its source. Cardarelli followed with an analysis of the topographical relations and landmarks of the various structures in physical diagnosis, and another early writer on the same subject was Concato (1881). Baccelli laid down a series of rules for the diagnosis of aneurysm of the descending aorta. The writer notes that Fernelius, who indeed was a Frenchman, stated in 1554 that syphilis could cause aneurysms. In 1724 Severino, an Italian, wrote of "Gallic aneurysm."

Medical Record

INTELLIGENCE, SO-CALLED.

BY MAXIMILIAN P. E. GROSZMANN, PH.D.,

NEW YORK.

A SENSATIONAL notice has been printed recently in a number of papers. One of the "twenty-five best minds in America" has been discovered. It is not stated who the other twenty-four "best minds" are. But we shall pass that over. The gentleman in question is forty-two years old. So far, he does not seem to have distinguished himself in public or private service, to be ranked among the twenty-five pinnacles of intelligence in a low-land of over 100,000,000 inferior minds. He is neither a leading statesman, nor a scientist, nor a philosopher, nor a poet, nor a captain of industry—nor a psychologist. But he has made a perfect record in the U. S. Navy Intelligence Test, scored 211 points out of a possible 212 in the Army Alpha Test, and 166 out of a possible 180 in the test given by the University of the State of Washington, said to be "far more difficult than either Army or Navy test, and so abstruse that even the directions are not comprehensible to the average intellect." Think of it! And think of the genius of psychologists who are capable of giving tests, and directions for doing them, which are incomprehensible to the average intellect! We may look forward to this man getting ready to unhinge the universe, or at least to unravel all the mysteries of nature and to solve the problem of our present world cataclysm.

May we, really?

By way of contrast with this "evidence" of superior intelligence let us quote what Mr. Simon S. Patten thinks he has found regarding the intelligence of the great mass of the American people. In an article printed in *The Survey* some time ago, he expressed deductions which were based in a great measure upon statements made by those psychologists who developed and applied the Army Mental Tests in which the first-mentioned gentleman excelled. From a summary of conclusions in a book by Dr. Henry H. Goddard he draws these figures:

> About 20 per cent. of the drafted men were unfit for military service and, of those accepted, half had obvious (physical) defects. This would indicate that at least three-fifths of the male population lack some of the qualities essential to manhood. Were women included in this schedule the percentage would run much higher. It is probable, therefore, that three-fourths of the adult population suffers from some handicap which prevents a full expression of inherent traits. The psychologic tests of intelligence levels are more valuable because they measure the mental depression which these (physical) defects create. *Seventy per cent. of the recruits showed an intelligence below that of the normal 15-year old boy.* It is plain that the mass of the recruits are still infantile in thought and disposition.

One consoling element in this statement is that Mr. Patten seems to find the cause of the mental depression in remediable bodily defects. If that is so, the present great interest and activity in public health measures may be expected to improve not only physical health but also mental efficiency. Psychologists in general are dwelling more particularly on the great lack of "intelligence," without pointing to physical troubles as possible causes. Many ascribe, without much qualification, intellectual growth to hereditary factors and assume that the social stratification of society corresponds to, and is correlated with, a stratification of intellectual capacity. Professor William McDougall, who makes this assertion, indeed also considers moral elements; but he maintains that even these, particularly the degrees of will power, fall into the same category of hereditary qualities, coordinated in part, at least, with intellectual capacity. He distinguishes between ruling and docile races, the first type represented by the English, the second by the French and Germans. His deductions would establish an inevitable division of types of intelligence, independent of the factor of health which Patten adduces as an explanation of mutable intelligence levels.

If the efficiency valuation of the great mass of the American people as stated by Patten is correct, and if McDougall's contentions prevail, the country is in a bad way as an exponent of democratic institutions. In my book, "The Exceptional Child" (Scribner's), I have discussed the problem of different "civilization levels" in modern society quite fully. In fact, I was among the first to state this problem concisely when I read a paper on this subject before the American Academy of Medicine on May 31, 1912, more than nine years ago. In the book mentioned, the relation of mentality to health is also fully discussed. But it is quite another matter to relegate a vast majority of our population to the backyards of civilization and to pronounce it infantile in thought and disposition. There must be an error somewhere.

The error must be found in the method of mental testing, and in the evaluation of the results of such tests.

As the Army Mental Tests have become so widely considered as a standard of intellectual measurement, it may not be amiss to discuss some of its features which exhibit some of the errors leading to a wrong valuation of the mental capacity of our citizenry.

The growing interest in mental testing and its supposed value in quick differentiation of mental

types led to a desire to assist the army command in making a rapid survey of drafted men for the purpose of classification in service. A Committee for Psychology was organized by the National Research Council; within the Medical Department of the Army a Division of Psychology was organized. A committee of seven "experts in practical mental measurements" was formed in the summer of 1917 and called together for the preparation or selection of suitable methods of testing enlisted men and commissioned officers. After various trials and revisions the tests elaborated by them were officially introduced for the purpose of (*a*) aiding in segregating the mentally incompetent; (*b*) classifying men according to their mental capacity; and (*c*) assisting in selecting competent men for responsible positions.

We see that the first purpose is one biased by the present trend of looking for mental defect. Those who look for trouble generally find it.

In the trial tests, to arrive at what the psychologists considered a safe basis of standardization, many different groups were tested, and it can be cheerfully admitted that the experimenters labored faithfully along the lines of their accustomed methods. For instance, ten selected tests were given to approximately 5000 men in the Regular Army and National Guard, and, in addition, to a variety of subjects outside of the Army, like inmates of institutions for the feeble-minded, members of officers' training schools, and students in universities and colleges, even school children, most of whom had been previously examined and graded by "established" methods of testing. Other measures of intelligence, such as officers' ratings, teachers' estimates of intelligence, and college and school grades, were used for comparison. In this way, it was thought, a fair degree of accuracy of valuation was obtained. There proved to be, to the satisfaction of the experimenters, a regular gradation of score distributions from the graduate students through the officers' training school men, regular and National Guard privates, down to the inmates of institutions for the feeble-minded; and although speed was a prominent element, it is claimed, as set forth by the leaders of the work, Professors Clarence S. Yoakum and Robert M. Yerkes, that the tests approximated a measure of actual ability.

Before entering into a discussion of the merits of the system, I will briefly describe it, on the basis of the book compiled by Drs. Yoakum and Yerkes, and published by Henry Holt & Co. of New York, in which the entire process is set forth.

There are four main groups of tests. The first group, the much-talked-about Alpha Test, is intended for literates. These were examined in groups of 100 to 200 men each. To those who failed in this examination, and to illiterates, Group Examination Beta was given, to groups of men up to 60 each. The term "illiterate" was applied to those enlisted men who could not master English sufficiently well, even though they were proficient in other languages, comprising, therefore, many "foreigners," so called.

Men failing in Beta, or having been especially referred for some reason, were given individual examinations. In these, either the Yerkes Point Scale, or the Stanford Revision of the Binet Scale, or a "Performance Scale," was employed. A Mechanical Skill examination was supplementary.

The time allowed for Alpha examination was 40-50 minutes; for Beta, 50-60 minutes; for Individual, 15-60 minutes (!), and for Mechanical Skill, 15-30 minutes. The examinations were given with a sort of military precision.

For each one of the eight tests of which the Alpha series consists, alternatives were presented, so that different groups had different questions.

As the Alpha Tests are those which have served the examiners, and their followers, to arrive at their main conclusions, I will confine myself here to a discussion of the problems presented by them.

The first test of the Alpha series is a sort of performance test, requiring the drawing of lines around circles, marking squares, etc. The second presents arithmetical problems; the third is intended to test practical judgment; the fourth introduces synonyms and antonyms; the fifth, disarranged sentences; the sixth, number series completion; the seventh, analogies; the eighth is an information test.

The eight tests are rated quite differently, from 12 to 40 points respectively. The maximum score is 212 points. The examiners expressed the individual ratings as follows:

Score Made	Rating	Meaning
135—212	A	Very superior intelligence.
105—134	B	Superior intelligence.
75—104	C +	High average intelligence.
45— 74	C	Average intelligence.
25— 44	C —	Low average intelligence.
15— 24	D	Inferior intelligence.
0— 14	D —	Very inferior intelligence.

All ratings above D— were entered and reported at once. Men whose scores were below D were recalled for examination Beta.

Inasmuch as the "Mental Age" idea governs the ultimate findings, especially in connection with the individual examinations, it is well to give here the corresponding "mental age" as computed by the examiners.

A	corresponds to a mental age of	18.	—19.5 years
B	corresponds to a mental age of	16.5	—17.9 years
C +	corresponds to a mental age of	15.	—16.4 years
C	corresponds to a mental age of	13.	—14.9 years
C —	corresponds to a mental age of	11.	—12.9 years
D	corresponds to a mental age of	9.5	—10.9 years
D —	corresponds to a mental age of	below	9.5 years

It is stated that 1,726,966 men were examined, certainly a colossal undertaking, hardly equalled in any other country—yet also indicating the possibility of speeded-up and superficial work. Of the total, 45,653, or less than 3 per cent., were judged to be under ten years "mental age," comprising many "illiterates" and "foreigners." Statements given a few pages later seem to differ from this calculation; for a tabulation of percentages on pp. 22 and 23 would give the following picture:

A	4— 5	per cent. of total
B	8—10	per cent. of total
C +	15—18	per cent. of total
C	25	per cent. of total
C—	20	per cent. of total
D	15	per cent. of total

This means a total of from 87 to 93 per cent. (it is not quite clear from where the difference of 6 per cent. is calculated), leaving a residue of from 7 to 13 per cent. of lower grade. This percentage

includes all those who, as D—, represent, according to the schedule quoted before, a "mental age" below nine and one-half years, and an E grade which is here suddenly introduced.

It is claimed that men of "A" intelligence have the ability to make a superior record in college or university, while "D—" men are of such inferior mentality that they are rarely able to go beyond the third or fourth grade of the elementary school no matter how long they may attend. In fact, many "D—" and "E" men are of the moron grade of feeble-mindedness, we are told. On the other hand, it is claimed that the score is little influenced by schooling so that some of the highest records have been made by men who had not completed the eighth grade. Only one-half of one per cent. seems to have been rated as clearly feeble-minded, whatever that meant to the examiners.

It is distinctly and repeatedly emphasized in the book that these tests were prepared for army use, not for civilian use, and are applicable to other uses only within certain limits. Nevertheless, the outspoken tendency of the book is to show that the tests are actually a measure of native ability, that the rating a man earned furnished a fairly reliable index of his ability to learn, to think quickly and accurately, to analyze a situation, to maintain a state of mental alertness, and to comprehend and follow instructions. If this be the case, it would seem unnecessary to issue a warning against the use of these tests for civilian purposes. As a matter of fact, the results were actually applied by the examiners to parallel an occupational gradation.

Another warning is expressed by the authors of the book, to the effect that the tests should be given only by "experts." I quote: "The ease with which the army group test can be given and scored makes it a dangerous method in the hands of the inexpert." It is not explained why. Truly, there is no difficulty in giving and scoring these tests, as they are presented in a purely mechanical manner and scored by a simple mathematical method. There is no need of an *interpretation* of results. They are all tabulated. Of course, if the tests were of a kind which must be given with caution and in an expert way, as the psychiatrist approaches his patient, it would be a different matter; the problem would then be the proper interpretation of responses and reactions. The psychologists who conducted these tests do not seem to have had need of interpretations of this kind. But they may have had a lurking suspicion that after all these tests were not the last word in judging a man. Or was the warning issued to give the impression that the professional psychologist has a sacred inspiration of his own? Certainly, the clinical psychologist, as he is called, has had his ascendency lately, and tests like these have become the by-word of modern efficiency measurements—with more or less reliability.

That the examiners admit other elements to enter into a true measurement of human efficiency, is apparent from other places in the book. The mental tests are, in their estimation, tests of "intelligence," whatever this term may really mean. In one place they put it: "Intelligence or mental alertness." This juxtaposition is to a certain extent a giveaway, for the two terms are by no means identical. But it is plain that mental alertness is really the thing they wish to ascertain. Yet they say: "A man's value to the service should not be judged by his intelligence alone, but that instead temperamental characteristics, reliability, ability to lead and to 'carry on' under varied conditions should be taken into account. . . . The company commander should be cautioned not to neglect the importance of other qualities, such as personal appearance, energy, military experience, leadership, initiative, tact, etc. . . . The fact must not be overlooked that there are individuals of high intelligence who are not properly fitted to command. . . ." That the reverse is also true is not mentioned. It is also admitted in various places in the book that race characteristics, emotional states, volitional elements, and a number of other elements are not considered in these tests. Yet, the statement is made that the comparison of negro with white recruits revealed markedly lower mental ratings for the negroes, especially the Southern negroes.

But the examiners endeavor to wipe out the objection that intelligence tests have no value without tests of the other kind, by claiming that there is a fairly high correlation between general intelligence and other desirable traits, like discipline, character, leadership, etc., and an equally high correlation between the results of these tests and success in studies and occupations. In other words, the examiners claim for these tests the same effectiveness which has been claimed for the Binet and similar scales, namely that they furnish a fair index of general efficiency, and can therefore be used as a sort of short-cut for ranking the personnel of the army—and, for that matter, any other kind of personnel. This in spite of the fact that the tables of results given for students of various colleges who were tested in this manner show most astounding differences.

Some further results of the army testing must here be recorded to give the proper perspective. Militaristically speaking, the authors claim that officers' training school candidates and graduate students made as a rule A and B scores. Clerical assistants and men in the Regular Army who could handle the paper work, usually made grades in upper C or B. The average private scored C. Men who reported themselves as laborers fell in Grade D, and privates who were relatively ineffective in the Army, or men who were inmates of institutions for the feeble-minded made scores in low D or E. It is not quite clear where the inmates of the institutions came from in this inquiry which, it would appear, merely embraced the personnel of enlisted men. Be that as it may, this grading is obviously based upon the previous history of the men. A fuller list is given on pp. 198 and 199 where occupational intelligence standards, so called, are tabulated, based on data for 18,423 men, taken from soldiers' qualification cards. Indeed, in each group, practically all grades of scoring are represented by certain individuals. The variations themselves give food for thought. By taking the median in each group, the general ranking is as follows:

The greatest percentage of "A" scores was made by the Engineer officers who headed the list. A "B" median was reached by the Medical officers, civil engineers, accountants, mechanical draftsmen, and dental officers, in the descending order indicated in

the enumeration. A median C+ included, in descending order, the following occupations: Bookkeeper, army nurse, general clerk, filing clerk, railroad clerk, telegrapher, photographer, stockkeeper, concrete construction foreman. "C" is represented by telephone operator, ship carpenter, auto assembler, auto engine mechanic, general auto repairman, general mechanic, gunsmith, tool and gage maker, plumber, general pipe-fitter, telegraph and telephone linemen, hand riveter, general machinist, butcher, general carpenter, general blacksmith, painter, baker, cook, bricklayer, horseshoer. A "C—" median is reached by barbers, teamsters, miners; and at the bottom of the list stands the common, or unskilled, laborer with about 33 per cent. of "D" and "D—" scores.

The examiners themselves seem puzzled by some of their results. They say: "There is no obvious reason for assuming that the military duties (!) of the engineer demand higher intelligence or more mental alertness (!) than do those of the medical officer." Their answer to this puzzle is: "Since it is improbable that any arm of the service possesses more intelligence than can be used to advantage, the necessary inference is that certain arms would benefit by the elimination of low-grade men and the substitution of officers with better intellectual ability." Very clear, indeed! Another puzzle was presented to the examiners by the higher averages reached by "conscientious objectors." Their explanation (p. 196) must be read in toto to be fully appreciated; it would lose by an abbreviated quotation.

We must bear in mind that the authors are constantly reiterating the statement that the tests refer to "military" qualifications only. What experience did they have to establish a reliable gage of "military" qualifications? It is hardly evident why the tests presented have any particular bearing upon "military duties" any more than upon any other kind of responsible duties. It will be noted that the inferences are altogether too often confused as to military or other vocational activities.

That this schedule cannot represent the actual scale of intelligence of the workers as enumerated seems so evident that it would hardly need an argument. There is something wrong about the classification.

It is noteworthy that the authors quote on p. 176 from an article by Lieut.-Col. W. V. Bingham as follows: "Can mental tests be of any assistance whatever in specific vocational guidance? At some far-distant date psychological methods are going to be a help even in this difficult task of guidance. They cannot help today. I mean that there exist now no adequate psychological tests of specialized vocational talent." If this is the case, of what value are these tabulations? They apparently do not justly represent the mental efficiency level characteristic of the vocations as listed.

Incidentally it may be remarked why lawyers, teachers, ministers, merchants, bankers, farmers, and, last but not least, psychologists, etc., do not appear in this list. Were there none among the drafted men, or were they mercifully left out from this schedule?

If we would accept this kind of gradation; if we could consider these tests as a new discovery in "mental engineering"; if the relation of intelligence to occupation were as it here appears; if it were true that there is a diminishing degree of intelligence in occupational groups from the professions down to the trades, and to skilled and unskilled labor; if, perchance, as some maintain, this is largely a hereditary condition, we might wonder why there should be any excitement or worry about economic and social reforms. Then the world were wonderfully organized as it is, and every attempt of the underdog to rise to a higher level would be futile. Everything is as it is because it is foreordained by the intellectual endowments of the various classes of men.

The "ruling" classes would be perfectly justified in keeping a restraining hand upon reform movements and in denouncing every opposition to the existing order as wicked and destructively revolutionary.

Even if the schedule as presented by these psychologists were to be considered merely as a classification of performance levels while it would leave open the question whether or not the rising generation might not be educated out of this sinister intellectual predicament, it would spell condemnation of the hopes of the present generation. Of course, many may greet this classification as a full vindication of their distrust in popular government, of their fear of the masses, of the mob spirit; an explanation of the prejudices, superstitions, narrownesses, and general ignorance of the public. This would, incidentally, imply a gigantic impeachment of our current methods of education.

While there are, undoubtedly, different civilization levels in human society (cf. my book, "The Exceptional Child," quoted before), these are certainly not identical with occupational or economic levels.

This is felt by the authors of the book to some extent; they admit that temperament is as important as intelligence for industrial placement and vocational guidance. But they leave us there. What will loom up in the mind of the average reader is the alleged importance of these intelligence tests. As a matter of fact they have already been taken up by manufacturers, merchants and others to test applicants for positions in their plants; by colleges to be used in connection with, or in lieu of, entrance examinations, and in several other ways. We have seen, in the beginning of this study, that they have been applied as a proof of the unusual intelligence of one of the "twenty-five best minds" in the country.

But let us consider what these tests really test. Is it general intelligence? What is meant by this term? Innate mental capacity? The hidden powers of the mind which do not otherwise come to the surface?

Quite apart from the subconscious promptings, repressions and motives; from the emotional states, temperamental and racial characteristics, strength of will—and equally apart from the physical and biological factors and the environmental elements which enter into the mental and emotional make-up of the individual: can these tests do justice to the thought life of the examined? To his power of judgment and discretion, his mental leadership, his capacity for growth and expansion, of subtle dis-

crimination and critical discernment, of wise counsel and philosophic reflection, of poetic imagery and creative thinking?

To my mind, they cannot. They measure surface appearances, momentary abilities, a mechanical quickness, speed of adaptation, placid readiness of response—all on a relatively low level. They are a sort of expanded and glorified Binet scale, with all its shortcomings. They do not measure intelligence so much as a certain type of mental response and activity, and the measure of training the mind has received, in one way or another. A small amount of real intelligence, well trained in traditional lines, aided by a good memory, may show off well when there is smiling, smooth alertness, the ready shrewdness of the commercial mind—while a deliberate, or neurotic person, although he be a deep thinker of creative thoughts, and of extraordinary intelligence, might not measure up immediately in ready response.

That this is true may be deduced from the amazing difference in points demanded of the different groups. This difference was determined by purely empiric methods, not on the basis of a deep study of psychological principles. The *average* man, scoring C, was supposed to make 45 to 74 points out of a possible 212! That is to say, not more than 22 per cent. to 35 per cent. of the total, with a range limit of only 30 points! Only 44 points were left to those who were marked as being below the average—or about 21 per cent. of the total. Sixty-five per cent. were reserved for those above the "average," three times as much as for those below. The C+ group had a range limit of 29 points, practically as many as the C group; the same number (30) for the B group, and 78 points, or nearly 37 per cent. of the total number of possible points, were reserved for the A group. The whole arrangement presents a most curious perspective. Little wonder that there was such a high correlation with other criteria. For these criteria, as far as they implied success in scholarship, in teachers' evaluations, and similar factors, represented precisely the same type of mental gage as these tests. They were tests for the discovery of specialized students' work, of capacity for the learned professions, so-called, of a particular type of mind. But there are other types of mind, equally, or more valuable, in human efficiency, if properly recognized and trained.

It will be interesting to apply eventually the test of real life success, of humanitarian worth, of true greatness to the students of colleges and other institutions, even to "engineering officers" and others who scored so highly in the army tests. Will they make good?

We may also point to another element in the appreciation of the value of these tests. All deductions are based on averages, or medians. But there is no group which shows an even grade. In every one there are representatives of practically all scores. There are C— scores among the medical officers, and A and B scores among the laborers. Would the authors' deduction be, as suggested by their remark in behalf of the medical officers which I quoted, that all A's and B's should be put into the officers' class, or the university grade, and that the representatives of lower scores should be distributed among the other occupations in descending scale? What are we to expect of the D— men among the electricians, and of the A— men among the barbers?

Another element is introduced when we learn that there was a high correlation between officers' judgments of military value and the intelligence rating. Here we may remember that the authors claim these tests to have been elaborated exclusively for army purposes. In other words, for war purposes. War, however, while historically considered an element of the civilizing process, implies a suspension of ordinary rules of human conduct. Every war is a reversion to the primitive type. War efficiency is of a very particular kind. It is not altogether ratable in terms of human service, as constructive efficiency. We cannot, therefore, immediately apply the results of war efficiency tests, even if they were altogether reliable,* to the rating of peace time human efficiency. It might, by the way, be interesting to look into the war record of those who stood high in these tests, to see whether they actually justified the high hopes which their scores may have aroused.

Considering the army tests as tests of military efficiency, we may perhaps appreciate the occupational rating quoted before: it may be a perfectly normal schedule as long as our economic conditions represent a state of war, war between different classes of society, between capital and labor, between employers and employees. Cunning and unscrupulously ruthless tactics often win out when real intelligence fails, on either side. In economic and commercial competition a type of mind may triumph which represents a relatively low level of human intelligence in spite of its mathematical perfection and economic leadership.

Again, life—as it is—has often been compared to a game, a big game, to be sure, but nevertheless a game. Let us be good sports, is the injunction. Be a good loser. Too bad that in life's game the loser sacrifices his own and his family's happiness and existence, just as the gambler does. Bluff and warlike "strategy" decide many a time when the mere scientific game will invite defeat. He who is defeated in life's game becomes the underdog, the proletarian, condemned to live from hand to mouth. The winning of this game, indeed, presupposes "mental alertness" of a kind which is not necessarily coupled with conscience.

Our present economic conditions represent, as the famous English writer, John Galsworthy, put it in an article in the *Atlantic Monthly*, a bankrupt ideal. Mental measurements based on them must lead to wrong conclusions. They often stunt and paralyze mental ability, even in the age of childhood. We need a psychological valuation which will help us to detect true human values, for the building up of a new humanity. As it is, as Galsworthy says, "we are all borne along in the car of industry, driven by that blind driver, our own competitive mood."

Three other factors must be briefly discussed to understand the nature of these tests. One is the factor of speed. To make the total of 212 points, 212 answers must be given within the specified time of about three-quarters of an hour. Although the giving of these answers is facilitated by various

*It is reported that an eminent general in command of one of our armies was set down as a ten-year old in intelligence.

devices, the thought work required is not inconsiderable, especialy in the more complicated questions. It is not everybody's way to think fast, and not a few of the questions refer to matters which may not at all be present in the minds of many at the time of the examination. The more deliberate and conscientious thinker may lose out in a race requiring speed. The sprinter will win in a running race; he will lose in the lifting of heavy weights, and vice versa.

To meet questions of the kind proposed by these tests with quickness and alertness, may be considered to require concentration. In this sense, it may be claimed for them that they give a valuation of a person's power of concentration, of will power. In a measure, this is correct. There is concentrated effort needed to meet the demands, and a man who can give concentrated effort is surer to succeed than one who is not so capable.

But again, there is a limitation. There are different types of mind. Some will float lightly along, skimming over surfaces, solving problems with lightning speed and little concentration. They may be helped by a good memory, or by a mechanical endowment similar to that possessed by the "idiots-savants," like the lightning calculators. There may be no depth at all. The deliberate person, or the person fighting against distracting temptations, may need much more power of concentration than these "brilliant," yet oft so superficial minds.

Besides, the difference in type will fit different tasks. The engineer, building a railroad, or a tunnel, or a viaduct, in treacherous mountain country, must be ready to face emergencies on the spur of the moment. So must the operating surgeon, or the army officer leading his squadron to attack. Speed of decision and execution is here an indispensable requisite. The scientist, on the other hand, the inventor and research worker, the astronomer, the diagnosing physician who arrives at his conclusion by careful elimination, and many other thinkers and workers of the deliberative and plodding kind, must scorn speed. What they need is time, patience, endurance, long-extended application, the ability to meet disappointments and failures with equanimity, never "saying fail."

Thus, the factors of speed and concentration demand individualized discrimination before we can judge a person's "intelligence" and ability rightly.

The third factor to be finally considered is that of distribution of answers. It will be remembered that in counting the points and grading the men only the totals were marked. A man was put down as being of average intelligence if he made from 45 to 74 points. To do this, he would really not need to answer questions in every one of the eight groups of the Alpha test. The number of points varies in the different groups, with as many as 40 in groups Four (synonyms and antonyms), Seven (analogies), and Eight (information test), and as few as 12 in Group One (drawing lines, etc.), and 16 in Group Three (practical judgment). It is plain that very different types of mind, even people of very limited endowments and information, might make 45 points quite easily from selected groups only. Even higher scores can be attained by very one-sided success. Such kind of evaluation must naturally obscure the meaning of the results.

These comments are applicable not only to the Army Mental Tests, but to others as well. While they are critical, they are not intended to be destructive or inimical. Quite the contrary. I do not underrate them. All these tests are serious attempts to reach out to a desirable goal; to find some ways and means to diagnose mental equipment. They represent big steps toward discovering methods of mental evaluation, along certain specific lines. It is merely the extravagant claims which have been made for them, the idea that they actually measure human intelligence and can classify human strata, that I have endeavored to comment upon.

Apart from the Alpha test of the Army series: the Beta test, and the Performance and Mechanical Skill scales which I have not described in these lines, have their own particular significance. They point hopefully towards the discovery of some of the mainsprings of human capacity. They have a distinct vocational value. A decade or so past, the great Münsterberg and others made a notable beginning in the development of vocational tests in the psychological laboratory. We have not gone very far since. The tests used by the authors of the Army tests and by their associates will contribute their share to the development of satisfactory measurements of vocational ability. Such measurements, however, are not necessarily measurement of mental gradation.

If we can also elaborate suitable methods to determine racial and temperamental attitudes, character differences, emotional states, and perhaps even those subconscious elements which are so powerful in the conditioning of human conduct, we may begin to understand something about human values and social efficiency. But at best we may have to admit that the human psyche contains so many "imponderabilia" that we shall forever fall short of reducing it to a simple psychological, or mathematical, formula. "Mental engineering" may remain a dream, after all, when all is said and done.

The true measure of human personality is human service.

276 WEST NINETY-FOURTH STREET.

MEDICAL IMPRESSIONS OF SOUTH AMERICA.

BY WILLIAM SHARPE, M.D.,

NEW YORK.

A TRIP of four months to the principal cities of South America during our summer (their winter) forms not only a most delightful vacation but a period of much educational value, especially to the medical profession of North America. We here know very little of South America and particularly of its medical profession and institutions, and possibly we have been inclined to overlook the medical development of this wonderful continent as not being a factor of very great importance. Naturally, the difficulty of language is a real obstacle in the more intimate association of the medical professions of the two continents and yet it was very surprising to find that most of the doctors in their medical schools could understand English when spoken clearly and slowly, and many of them were able to express their ideas in intelligible English.

On the other hand, a working knowledge of Spanish is not difficult to acquire, especially after our usual training of several years in Latin, and this elementary acquisition opens a field of the most interesting literature—not only of writers of the Spanish peninsula, but also of an increasing group of South Americans. To be sure, in Rio de Janeiro the language is Portuguese, but Spanish is well understood there, so that even in Brazil a smattering of Spanish will suffice the visitor when there is any difficulty with English. Vigorous study and practice of Spanish upon shipboard en route to South America will prove of much value.

A visit to the principal cities of the southern portion of South America such as I have just completed with Mrs. Sharpe, may be down the east coast first in one of the palatial steamships of the American Munson Line to Rio de Janeiro, Montevideo and Buenos Aires, then over the mountains of the Andes by the Transandine railroad to Santiago, and from Valparaiso up the west coast on the Grace Line of American steamships to the Panama Canal and then home; naturally, the trip may be made in just the opposite manner, visiting the west coast of South America first, over the Andes, and home by the east coast.

In speaking of the four principal medical centers of South America visited by me in Brazil, Uruguay, Argentine, and Chile, I must at the very beginning express my profound admiration of the excellent surgical work being carried on in their hospitals. Although many of the hospitals are old—in fact, some of them have been constructed almost two hundred years ago—yet the wards are clean and the patients are as well cared for as is possible, without the assistance of trained nurses (as we here understand that term); this lack of skilled female nurses is a real one in South America—not only in the ward treatment of the patients but also in that of the operating room itself; rarely did I see a trained nurse assisting the surgeon during the operation. In spite of this definite handicap in the operative technique, I was very much impressed by the operative ability of the individual surgeon, who, assisted by only one young doctor, would perform most skillfully and rapidly major operations of extreme complexity. The surgery of North America has little to offer these brilliant surgeons in a technical way, although the services of an assistant nurse to take care of the instruments, needles, sponges, et cetera, would be a great asset in their work.

There is one feature, however, in the surgical work of South America that is much more advanced than in North America and this is the skilful use of local anesthesia. It was the exception to see ether or chloroform used as a general anesthetic—in fact, after witnessing eight consecutive major operations in Buenos Aires performed under local anesthesia and operations of the character of total laryngectomy, carcinoma of the lower lip with bilateral resection of the cervical glands, thyroidectomy, double inguinal hernia, posterior gastroenterostomy for extensive pyloric cancer, etc., I felt obliged to apologize for the use of a general anesthetic when I operated in the clinic of Dr. David Prando at the Rawson Hospital to sever the posterior root of the Gasserian ganglion for chronic trifacial neuralgia. Not only is novocaine used extensively as a local anesthetic, but also as a means of spinal anesthesia in abdominal and pelvic operations; in the clinic of Professor José Arce at the Hospital de Medicina Clínica, an accurate record of over five thousand patients does not show one serious complication, either of a local or permanent general character. Rectal anesthesia is also being successfully used in selected patients; in fact, it was in Buenos Aires that I extirpated a Gasserian ganglion for the first time with rectal anesthesia. The clinic is not delayed by this extensive use of local anesthesia in that the assistants and even advanced medical students are instructed in the practical technique and in this manner, there is no long interval between operations. It was indeed a revelation to me to watch Dr. Adrián Bengolea, a surgeon of forty years of age, at the Rivadavia Hospital, perform a vaginal hysterectomy under local anesthesia only, and within one hour; such skillful technique with only one male assistant and no nurse, is not surpassed anywhere. In this connection I should like to mention the superb technique used by Dr. Segura in Buenos Aires and by Dr. Vidal in Santiago in performing the operation of

Pupils in the Training School for Nurses of the Hospital Parmenio Piñero, Buenos Aires.

sellar decompression for pituitary lesion by the intranasal transphenoidal route, and with local anesthesia—in many respects a simple and an ideal method.

The problem of the trained nurse is a most difficult one in South America. Until the recent war, her social status was that of a servant, and naturally only girls of the servant class—usually ignorant Indians—entered the hospitals to serve in the care of patients; their training was a meager one—more that of a maid. A marked advance in the training of nurses—not as servants but as real assistants and as competent aids to the doctor not only in the care of the patients in the ward but also in the operating room—has recently been made. At the Hospital Parmenio Piñero, Buenos Aires, Dr. Delfor del Valle has organized a most efficient training school for nurses, twenty girls now being enrolled in a three years' course which would compare favorably with the best schools in North America (vide photograph); it is an excellent beginning, and Doctor del Valle is the progressive type of physician to make it a success. In Santiago, as the result of the well-directed efforts of Doctor Manuel Torres Boonen and of Señora Eastman Huneus, the Red Cross Society has established an out-patient clinic

in which the nurses are all girls of the best education and social position, and by their excellent work the status of the hospital nurse has been greatly raised, so that now in Chile the profession of nursing is becoming a well-recognized one, and naturally a better type of girl is being attracted to it as a life work. Trained nurses are not servants or maids, but assistants to physicians, and they must be treated and respected as such.

Rio de Janeiro.—Under the able leadership of Doctor Aloysio de Castro, the medical school of Rio de Janeiro, a city having the most beautiful and picturesque scenery and especially its environs of a majestic grandeur unsurpassed anywhere in the world, has completed the central portion of its school building in white marble, and the construction of a similar building upon each side for additional laboratories and especially animal research laboratories for physiology and surgery, is planned for the near future. With the brilliant and efficient service rendered by the Oswaldo Cruz Institute under Doctors Chagas and Crowell, the medical profession of Brazil realizes the importance of well-equipped laboratories in making possible and stimulating the research work of postgraduate students, so that the younger group of doctors, such as Oscar Clark, Dionysio Cerquiera, and others, is making use of these modern advantages. The surgical work of Doctor Mendonça is indeed an inspiration to the medical profession. The Hospital for Mental Diseases, with Doctor Juliano Moreira as Director, is situated beside the medical school and is affording excellent treatment to the patients as well as most modern instruction to the students; the library is unusually large.

Montevideo.—Leaving the tropical climate of Rio where ocean bathing is a winter sport and straw hats are in fashion throughout the year, we find a more temperate climate in Uruguay—rarely snow, however, and similar to the winters in the eastern part of North Carolina. As an item of interest to all travelers, the Parque Hotel may be mentioned as the most luxuriously appointed one in South America and what is most important of all, its service and food are the equal of any hotel in the world.

As in all of the South American countries, the medical school of Uruguay is a government institution, not being supported financially by private subscriptions and endowments, as are the majority of the schools in North America. The Asistencia Pública, in which department the large municipal hospitals are managed, maintains a very active ambulance service. As dean of the medical school, Doctor Manuel Quintela has established an enviable reputation as an organizer in that the heads of the various departments are men of the highest professional standing and ability, such as Doctors Navarro, Garcia Lagos, Lorenzo Mérola, and others; the medical buildings are well equipped for instruction with excellent hospital facilities for the more advanced students. The military hospital under Doctor Acevedo Blanco (who had five years' experience in France during the war), and the Italian Hospital, with Doctor Mérola as one of the chief surgeons, are excellent examples of modern medicine. The British Hospital directed by Doctor Garcia Lagos is distinguished by its excellent corps of English nurses—well trained for the operating room as in the after-care of patients.

Buenos Aires.—In this most modern of the cities of South America, there is almost as varied a population as in New York—Spanish and Italian predominating. Argentine is essentially an agricultural country, and from the standpoint of its medical institutions, Buenos Aires is Argentine.

Besides a number of private hospitals and sanatoria, there are seventeen large hospitals under the control of the Asistencia Pública, with Doctor Delfor del Valle at its head; such excellent hospitals of the older type as Rawson (800 beds—Drs. David Prando and Enrique Finochietto), and of the newer type as Parmenio Piñero (600 beds—Drs. Herrera Vegas, R. Spurr, and del Valle), Duran (500 beds—Drs. Palma and Kenny), and Alvear (1500 beds—Drs. Solé, Valdés and Capello), form a group which will compare favorably with any of the hospitals in North America. A ladies organization, Sociedad de Beneficencia, well endowed, controls two of the most efficient hospitals in Buenos Aires—the Rivadavia (500 beds—Drs. Caballero, Zabala, Belaustegui, Bengolea, and del Pino), and the Children's Hospital (600 beds); the latter is a most attractive hospital with its open clean wards, numerous patios and orange trees; it is here that Drs. Castro, Viñas, Capello, and Rivarola are doing such excellent work.

Opposite the medical school of which Dr. Alfredo Lanari is the dean, is the Hospital de Medicina Clínica, under the control of the school, and intimately associated in the teaching of clinical medicine and surgery to the students; the brilliant surgery of Doctor José Arce at this clinic is an inspiration to all.

The Bacteriological Institute has proven of great value to Argentine—not only in the preparation of vaccines, but in research work of diseases common to the entire country; the Director, Dr. R. Krause, has made a number of important contributions in addition to developing a small group of able assistants to carry on this work. When one considers this large group of well-equipped buildings devoted to bacteriology and then realizes the need in South America of experimental animal laboratories in physiological medicine and in surgery, it cannot be denied that within a few years this great advance in scientific medicine and surgery will also be made here. The younger group of men are ready and anxious for this work—they need only the facilities of buildings and equipment to make it possible.

The system of instruction in the medical school is a most practical one—a six years' course, the last two years being spent in hospitals and under the teachers selected by the student; this elective method stimulates the teachers to do their best in order that a larger number of students may choose their courses, and so it happens that teachers may have excellent appointments and the best of clinical facilities and yet their number of students may be very small, because their teaching ability is inferior to that of others having less favorable hospital appointments. This elective system was finally adopted only in 1920 after over fifteen years of agitation on the part of the students in favor of it—in fact, in 1906 the students went "on strike" to demand it,

and after various compromises it was eventually adopted last year. The influence of the French school of medicine throughout South America is largely explained by the fact that practically all of the medical textbooks are in French and not in Spanish, so that in the very first year the study of anatomy begins with a French textbook of anatomy and so on throughout the medical course. A Spanish medical literature and especially the fundamental textbooks will be a marked advance in the progress of Spanish and South American medicine.

One is greatly impressed in Buenos Aires by the surgical ability and skill of the younger men. It is rare in North America, under our present hospital system, for a surgeon to develop much operative ability under forty years of age—due chiefly to the fact that he has not the control of the patients of a ward, but remains an assistant to the older surgeon until a vacancy occurs, possibly when he is over forty-five years of age. This method does not develop surgical ability and originality to the extent that the system used in the Argentine and Chile does—where the older surgeons permit their various assistants each to control a ward of forty to eighty patients for whom the assistant is responsible; this method has permitted the younger group of surgeons to develop a surgical technique far superior to that to be observed in a similar group of surgeons in North America; I must express my profound admiration of the surgical ability of this younger group of surgeons in Buenos Aires—Drs. Pasman, R. Finochietto, Jorge, Bosch Arana, Bengolea, P. Chutro, del Pino, Ceballos, Zorraquin, del Valle, Pirovano, Kenny, and many others.

One of the most attractive of the smaller hospitals is the British Hospital where Dr. Roberto Hallahan is doing such excellent work. A group of well-trained English nurses under their competent matron, is of great value in the treatment of the patients both in the operating room and in their after-care—and the condition of the patients in the wards reflects their assistance and their presence.

Santiago.—It is difficult to conceive of a medical atmosphere more conducive to good-fellowship and scientific endeavor than in the capital of Chile. Situated upon a high plateau with the snow-capped Andes on the east and the Cordilleras on the west, this most Spanish of the cities of South America makes a profound impression upon the visitor. To me the word Chilean means, among many other things, courtesy of the most sincere type.

At the head of the medical organization in Santiago is Doctor Amunátegui, the dean. Many of the more recent developments in the various branches of medicine are due to his tireless energy, and with the able support of the younger men, such as Drs. Torres Boonen, Vargas Salcedo, Charlin, Vidal, and others, the medical situation is not only favorable to the most modern instruction in the medical school but also to the encouragement and stimulation of research work among the graduates. There is need here, however, of an animal research laboratory with modern facilities, and fortunately the plans are already being made for the creation of such a department.

The hospitals are most attractive, and no matter how old some of the buildings may be, yet the wards are most clean and the patients well treated. The hospital San Juan de Dios (500 beds) is two hundred years old and in the center of the city, and yet it would be most difficult to find a more attractive hospital—with its numerous wards radiating from a central chapel, large gardens and patios filled with orange trees heavy with the luscious yellow fruit and on all sides the many sun pavillions and promenades for the ambulatory patients.

Another hospital of the highest standing and efficiency is the San Salvador (500 beds). A large central patio with beautiful trees of all kinds and many walks make it one of the most attractive hospitals in South America. For fear of possible earthquakes, the buildings are not over one story in height, but with their overhanging roofs shading the pavements below, the comfort afforded the patients is very great indeed and especially in summer.

The Children's Hospital under the able direction of Dr. Commentz is one of the most modern of the hospitals in South America. Besides the excellent feeding facilities for both in- and out-patients, there are the stables at the farther end of the hospital grounds where the best of milch cows are kept under sanitary conditions, and in this way the milk for the patients may be considered as being the purest obtainable in Santiago. The isolation wards for infectious diseases are admirable.

Much to my regret only one morning was spent in Valparaiso, but during these few hours, Doctor E. P. Reed made it possible for me to witness the skillful major surgery of Doctor Guillermo Münnich at the German Hospital and also to observe the excellent clinical facilities of the Hospital San Juan de Dios and especially to take note of its luxurious private pavilion.

Upon my return trip up the west coast I was unfortunate in not being able to remain more than one day with Doctor Soldan in that most historic city of South America—Lima. It is my hope, however, that during another summer's vacation I shall have the pleasure of visiting the capitals of Peru, Ecuador, Colombia and Venezuela, and of observing the progress of medicine and of surgery in their respective medical schools and hospitals. The Panama Canal has made these countries easily accessible to us in North America and the thrill of passing from the Pacific to the Atlantic Ocean in one day over this beautiful highway of modern engineering genius, is one never to be forgotten. In closing, I wish to express our appreciation of the many courtesies extended by the members of the diplomatic corps and especially of our cordial reception by Ambassador Morgan in Brazil. As a field of recreation during our summer season, South America cannot be excelled, and to the medical profession it offers an opportunity of learning much.

20 WEST FIFTIETH STREET.

Stiller's Asthenic Constitution.—Stiller has recently summed up the habitus which has long been known by his name as one of general relaxation and atony. The face is small, facial bones delicate, neck long, thorax of the paralytic type with the Stiller rib (tenth ribs mobile). Other changes suggest hypoplasia and infantilism affecting a considerable number of the organs and structures of the body. These subjects, although predisposed to a large number of diseases, are relatively immune to the degenerative and metabolic affections of advancing years.—*Schweizerische medizinische Wochenschrift.*

THE TREATMENT OF MENTAL ABERRATIONS AND UNDESIRABLE HABIT-FORMATIONS BY PSYCHOTHERAPEUTIC METHODS.

By CARL SCHEFFEL, Ph.B., M.D.,

BROOKLINE, MASS.

PROFESSOR OF PSYCHOPATHOLOGY, UNIVERSITY OF MASSACHUSETTS.

In the domain of psychopathology, as in many other special branches of medicine, much more time and study seem to be devoted and considerable more space seems to be given to the publicity of diagnostic measures than has been accorded the therapeutic possibilities and the results capable of being produced in many of these conditions. But what is still worse, inasmuch as a large number of the sufferers from these psychopathic conditions sooner or later become medicolegal problems, the neglect of the medical profession to intelligently coöperate with the legal profession in considering the medicolegal aspect of these conditions is resulting in the sending of many unfortunate sufferers of some mental aberration, some abnormal impulse, or from some uncontrollable habit-formation to the various reformatories as criminals, whereas they should be sent to proper psychopathic institutions or schools to be treated as patients afflicted with curable forms of mental disease.

As matters now stand, the majority of the medical profession, and practically the entire legal profession, associate abnormal mental conditions with medicolegal practice only when considering insanity and feeblemindedness. The large number of cases, especially those coming to the attention of our juvenile courts, which have psychopathic conditions as the underlying causative factors that result in various antisocial acts, is practically being ignored by both professions. Furthermore, the great bulk of undesirable habit-formations and uncontrollable impulses which come to the attention of the physician only are being sadly neglected by the profession from the standpoint of rational therapeutics.

Many cases of the socalled stubborn child, the sexual or moral pervert, the drug addict, and a host of others who habitually practise antisocial acts which may bring them into conflict with our laws if they are detected, are nothing less than psychopathic cases which should be accorded scientific treatment rather than legal punishment, and proper psychotherapeutic measures persistently and intelligently applied certainly bring about a cure in many of these cases of abnormal mental activity precisely as medicinal therapeutics can bring about a socalled cure in many physical ailments. From a legal point of view it is curious to note that in capital crimes the legal profession is very often quick to utilize medical science for the purpose of attempting to show that their client was non-compos at the time of the homicide; but in the more common minor cases having a much easier diagnosable psychopathic condition as their underlying cause which very often makes their defendant non-compos, and which may be perhaps successfully treated by proper psychotherapeutic measures, they are slow to avail themselves of the services of the physician with special training along these lines.

There are any number of conditions which manifest themselves in various abnormal mental activities which certainly do not involve insanity or even come within the meaning of the socalled border line cases, but which nevertheless leave in grave doubt the controllability of these manifestations or the responsibility of those suffering from them. In the past many of these conditions have come under the jurisdiction of the psychiatrist who is very apt to view them from the point of view of psychiatry rather than from the point of view of the psychopathologist who does not deal with the actually insane. It seems to me that the field of the psychiatrist should be confined to the study, diagnosis, and treatment of actual insanity and to those abnormal mental cases coming within the range of socalled borderline cases—while the psychopathologist should confine his activities to the study, diagnosis and treatment of those mental aberrations which do not involve actual insanity or even so-called borderline cases—and there is ample work to be done in both fields without overlapping activities.

It is true, the line of demarcation between sanity and insanity has not yet been determined with precision by either the legal or medical professions, and admittedly a person is only then possessed of a normal healthy state of mind when there exists complete mental equilibrium to the extent that the personality easily adjusts itself to those accepted actions which have been deemed good and proper standards set by the majority of the community in which he resides. Every disturbance of this normal mental equilibrium may be considered as a psychopathological manifestation, but many and I dare say most of these disturbances which come to our notice could hardly be termed manifestations of insanity. The moral or sexual pervert, the masturbator and the sodomist, the petty thief, the habitual drunkard, the drug addict, and to a certain extent all psychasthenics are examples of psychopathological manifestations, but who would care to place the unfortunate sufferers of these manifestations in the category of the insane? At the same time the moral or sexual pervert, the habitual drunkard, the drug addict, and the petty thief may be suffering from uncontrollable impulses or habit-formations that make their actions as involuntary and almost as irresponsible as are the acts of the insane.

In a great many of the cases of juvenile delinquency the neglect of proper training during the developmental period may have resulted in that mental retardation which yields the symptoms of a poorly balanced mentality, or possibly created vicious habits which have become firmly established so that they seriously disturb the mental equilibrium to the extent that oftentimes antisocial acts are committed as the result. Emotional conflicts, moral lethargy, morbid sexual ideas and imaginations, as well as a host of other psychasthenic manifestations have very often potent impulsive attributes which culminate in antisocial activities if left untreated, and the moral or sexual pervert as well as the drug addict or petty thief are no less immune to the good effects of prolonged and proper psychotherapeutic treatment than are those unfortunates suffering from emotional conflicts or

other similar psychopathic conditions in which psychotherapy is the only rational and effective remedy.

Of course, in dealing with such mental aberrations and undesirable habit-formations, proper diagnostic methods are as important as in all other diseases of body or mind. It is no more scientific or even logical to attempt to treat a patient who comes to us as being unable to control her sexual impulse as a mere prostitute, or the unfortunate addict to morphine as a mere drug addict, than it would be to treat socalled rheumatism or plumbism without seeking to determine all that is possible to unearth as to the source and extent of these intoxications. In the proper diagnosis of undesirable habit-formations and other mental aberrations a thorough examination of such attributes of conscious activity as attention, reasoning, judgment, moral appreciation, volition, emotion, and associational activities should be made before actual treatment can be intelligently attempted, for in an astonishing number of cases the causes that have led to these psychopathic conditions may be unearthed in this manner, and not a few may be removed.

The diagnostic results of a large number of cases of this nature demonstrate that present-day education and training, both in the home and in the schools, leads to the cultivation of superficiality, to ill-developed powers of attention, to lack of self-control, and lack of character development. In our younger population these laxities in our educational system bring with them severe mental reactions which lead to lowered standards of moral appreciation that make the incurrence of anti-social and illegal practices more prevalent than ever before. A sound, well-balanced mentality is one in which an idea, an impulse, and to some extent an emotion are able to inhibit opposite mental activities; and trained powers of attention, self-control, and mental discipline enable us to do this without fear of defeat through the intrusion of chance impulses from within our own consciousness or suggestion from others. On the other hand, he who has never learned obedience and self-control can never become his own master.

From a therapeutic point of view it therefore becomes apparent that in not a few of these cases re-education and retraining of the several attributes of consciousness which make up the abnormal mental activities becomes necessary. In practically all cases either this or that abnormal impulse needs to be overcome, this or that uncontrollable habit-formation requires to be broken up, this or that emotional conflict needs to be straightened out, and new channels of discharge need to be established for this or that mental activity, and this or that attribute of conscious activity which forms the weak link in the chain of mental events needs to be strengthened by an artificially created mental bulwark.

In all this work the very first requisite necessary for laying a successful foundation upon which to base psychotherapeutic treatment is the establishment of rapport between physician and patient. How to get en rapport with the patient for psychotherapeutic purposes cannot be outlined in any routine way, everything depending upon the nature of the case and the personality of the patient. However, a happy combination of dignified sympathy plus the display of genuine friendliness in act as well as in word will aid in bringing about the desired mental setting in many of these unfortunate cases. In dealing with moral or sexual perverts or with those addicted to uncontrollable habits, we should always take into consideration the fact that most of them are seriously misunderstood and often mistreated by those with whom they come into contact. The relatives of many of these unfortunates treat them with disdain; their associates shun them as soon as they become aware of their weaknesses; and if they happen to be so unfortunate as to come under the jurisdiction of the law, they are treated as criminals. Under these conditions the experienced psychotherapist should have little difficulty in getting en rapport with the majority of these unfortunates.

In the cases of uncontrollable and undesirable habit-formations, whether the term is used to designate warped mental activity followed by abnormal physical activity, or whether it is confined to include only wrong ideational or associational reasoning, thought, or other purely mental activities, the first necessary psychotherapeutic step consists in the attempted destruction of these abnormal mental activities by closing the existing channels of mental discharge, by side-tracking pent up mental energies into new and harmless channels of discharge and by cultivating entirely new associational paths over which the mental activities connected with the habits may travel. While admittedly such therapeutic procedures require skill, patience, and much time, they result in much good if well established psychological laws are closely adhered to in their application.

Once an acquired habit-formation has been broken up by proper psychotherapeutic methods, then, and then only, have we the right to employ constructive therapy in the form of suggestion in either the hypnoid or waking state. At this juncture I would point out that the customary short-cut psychotherapy of relying upon constructive suggestive therapeutics at the outset in many of these cases has been the direct cause of many failures, and the indirect cause of the unjust condemnation of the value of suggestive therapeutics as a remedy in these conditions. Unfortunately many who have attempted to utilize this therapeutic measure in the past have limited themselves to its direct application without first endeavoring to ascertain the suggestibility of their patients, or the heightening of the suggestibility by appropriate methods if undue resistance existed—and there is nothing so fatal to successful suggestive therapeutics as the undesirable reaction which accompanies unaccepted suggestions.

Subsequent to the scientific determination of the degree of suggestibility of a patient, and heightened suggestibility brought about through appropriate methods in cases where the original resistance was too high, suggestive therapy is a most valuable means of aiding in the restoration of normal equilibrium. It forms a powerful factor in assisting the individual in overcoming the uncontrollability of many mental activities; it enables the unfortunate more easily to get a foothold in

overcoming abnormal impulses and unpleasant emotive reactions. It is by no means a panacea and is admittedly a dangerous weapon in unscrupulous hands, but no more so than strychnine or certain gynecological instruments in similar hands.

In cases where the underlying causative factor seems to be repressed emotions or certain types of mental conflict, and in cases involving certain abnormal associational activities, in addition to suggestion, the various socalled cathartic psychoanalytical methods may be the means of aiding in the readjustment of the mental functions so as better to fit them to withstand the shocks that are bound to come to us all in every-day life, and which succeed in breaking the weak link in the chain of mental resistance in just this class of cases. It is the aim of psychotherapy to repair and reinforce these weak links in their mental make-up so that the future strain of mental stresses shall make no, or very little impression on them.

Proper psychotherapeutic methods diligently and persistently applied certainly will overcome many socalled uncontrollable impulses and undesirable habit-formations. This field of therapeutic endeavor has not received the proper study and attention that its deserves for the best interests of the community. The present tendency among professional men seems to be antagonistic to the employment of time-consuming and often unremunerative therapeutic measures. But freeing the mentality of an unfortunate of some uncontrollable impulse, of some undesirable habit-formation, or of some emotional conflict or other mental aberration is fully as important in the prophylaxis of insanity as are other measures in preventing chronic and incurable physical ailments. From an economic point of view there can be no question that the proper treatment of many forms of mental aberrations surely would tend to stem the rising tide against our ever-increasing cases of actual insanity. In most lines of medical endeavor there seems to be widespread appreciation of prophylactic therapy, but in dealing with the manifold manifestations which in many cases are the direct forerunners of actual insanity if not checked in time, and which very often culminate in the perpetration of illegal acts, both the medical and legal professions are hopelessly unprogressive.

To-day, as never before, the sexual or moral pervert is apt to be treated as a law-breaker only, instead of being considered a distinct type of pyschopath. The unfortunate addict to the uncontrollable use of morphine, alcohol, or other narcotic is being dealt with most unscientifically by both law and medicine. The sufferer from abnormal impulses whose manifestations creep out in the nature of antisocial acts is also dealt with as a criminal instead of being treated as a patient with a strong possibility of being cured by proper psychotherapeutic treatment. If the punishment now handed out to these unfortunates were at all effective, its unfairness and crudeness could be overlooked; but the facts are that both legal and unscientific medical measures do not produce even transient favorable effects. Nowadays the moral or sexual pervert may be given probation, may be sent to some socalled reform school where he is capable of infecting others with his pernicious habits, or may be thrown into the house of correction which has not corrected his mental aberration at the expiration of sentence. To-day the socalled drug addict is temporarily locked up either in some institution or in jail where he is deprived of his drug and sometimes given some routine medicinal treatment, but almost invariably is sent out into the world again still uncured of an uncontrollable and long-standing habit-formation. What is the result to the community of these illogical and unscientific methods of disposing of this class of cases? The country is experiencing a distinct increase in juvenile delinquency, certain types of adult crime, and a large increase in insanity. What could be done to improve existing conditions by appropriate methods? If those mental aberrations which very often manifest themselves during youth and which in not a few instances are the direct causes of juvenile delinquency, later crime, and forerunners of insanity itself, were appropriately treated as pathological conditions instead of being dealt with as legal and social problems only, the results would make themselves apparent in a very few years. If the subjects of those undesirable and often uncontrollable habit-formations which display themselves in both youths and grown-ups, which are apt to make their unfortunate victims the perpetrators of illegal acts that cause them to be treated as criminals, were treated as distinct psychopaths suffering from curable conditions, not only would much be gained from a social and economic point of view, but from a eugenic point of view the benefit would be marked to the coming generation.

The modus operandi of bringing about this much desired change in dealing with this unfortunate class of mental defectives is primarily one of education. Both the medical and the legal professions need to be educated along these lines before intelligent co-operation can be anticipated. The medical profession needs to adopt rational therapeutic measures that show real results, and these cannot be produced by therapeutic shortcuts or haphazard methods. The legal profession and the public need to be awakened to the much neglected fact that far more cases coming within the jurisdiction of the law have important psychopathological aspects which have a direct bearing upon their antisocial behavior than is now generally appreciated. It is very important to the individual as well as to the entire community that the legally trained mind with judicial powers should learn to appreciate that many more and varied conditions besides feeblemindedness and actual insanity are to be taken into consideration in determining whether an alleged offender is capable of controlling his act or is responsible for committing it.

Once the professions have become alive to the possibilities of real applied scientific diagnostic and therapeutic methods in dealing with this class of offenders, then it will not be long before the intelligent public will demand the services of a psychopathologically trained physician connected with every court much the same as they now utilize the services of district attorneys. Then, too, the day will arrive when socalled reform schools, socalled houses of correction, and even jails and

prisons will be presided over by properly trained physicians who will transform many of these penal institutions into psychopathic institutions and real training schools where physicians may work unhampered in their endeavors to treat the mentally ill and retrain and re-educate their warped mentalities with some reasonable outlook of restoring their unfortunate charges to become useful members of society again. It is being done successfully on a small scale among those who have not yet come within the jurisdiction of the law, and it is possible, feasible, and entirely desirable to take this work up on a large scale and produce excellent results.

Nowadays the services of psychopathologists in our courts are taken as a novelty and often work out as a farce. Resident physicians for our socalled correctional institutions are very often underlings with no executive power and usually with no special training. This is an extremely sad state of affairs, and the indirect cause of much unnecessary expense and suffering. Reform schools, reformatories, and even houses of correction should harbor those whose psychopathological examinations have demonstrated the existence of some mental aberration or undesirable habit-formation which may be cured by prolonged and proper treatment and re-education, and these institutions should be presided over by physicians especially trained in this line of work and not by political underlings as is now too often the case. Furthermore, if juvenile delinquents, addicts to undesirable habit-formations, and even some classes of petty criminals are to be cured so that the possibilities of their becoming later inmates of our prisons, jails, or insane asylums become greatly diminished, the present system of sentences of fixed duration must be eliminated, for then they will be treated as sick individuals who require proper treatment until the physician considers them cured, whether that implies institutional treatment for six months or six years.

I do not mean to imply that prisons and jails are superfluous and of no value; but I do mean to state the fact that the time will come when those suffering from some curable mental aberrations or undesirable and uncontrollable impulses or habit-formations whose manifestations may have brought them into conflict with the law, will be rationally and scientifically classed as patients and treated with the view of really curing their weaknesses; while those with normal mental make-up who knowingly and deliberately commit crime will be classed as criminals to be dealt with much more severely than is now the case. In the meantime the few physicians who handle cases of mental aberration that are entirely curable by appropriate methods must continue to endeavor to perfect existing methods of psychotherapy and attempt to demonstrate to their professional brethren of the medical and legal professions the vast importance of this therapeutic measure as a means of curing many of these psychopathic conditions when properly applied. Mental hygiene is no less important than physical hygiene; and in actual practice both law and medicine must unite before either may apply effective means of safeguarding the future physical and mental health of the American people. If we had to-day as many hospitals harboring contagious diseases such as smallpox, yellow fever, typhoid, etc., as we now have insane hospitals, socalled reform schools, reformatories, houses of correction, and even jails harboring the unfortunate victims of mental aberrations who are unjustly classified as criminals, I believe the profession would wake up to the seriousness of the situation and get busy; but curious enough the preponderance of the latter institutions seems to be taken as a matter of fact as being necessary, while the truth is that many of them would become superfluous if their unfortunate inmates were rationally treated as patients rather than as criminals.

It is high time that the sufferer from mental aberration or undesirable habit-formation who has violated our laws be separated from the deliberate criminal with sound mentality and be given the proper treatment that will cause him to become again a useful member of society. It is not enough that the psychopathologist classify juvenile or adult delinquents into various gradations of mental defectiveness, although that is a step in the right direction; it is equally, if not more important that these unfortunates be given the proper treatment which will cure many of them—and psychotherapeutics, expertly, rationally, and persistently applied will result in success in a great many cases and is certainly worthy of a fair trial in all of them. I for one hope to see the day when law and medicine shall so co-operate that the poor may receive the beneficial effects of modern psychotherapeutics in our correctional institutions that the well-to-do suffering from certain mental aberrations, undesirable habit-formations, uncontrollable impulses, and other curable mental abnormalities now find available in private institutions under the care of specially trained physicians.

1680 BEACON STREET.

SOME GENERAL ASPECTS OF DIGESTIVE DISTURBANCES.*

BY ELLIOTT C. PRENTISS, M.S., M.D.,

EL PASO, TEXAS.

THERE are some general features of digestive disturbances that are not only of interest but also of great importance, many of which are not receiving the attention from the medical profession that they deserve. This becomes clearly evident to us when we study carefully many of our cases, particularly some of the serious ones of long or fairly long standing. Abdominal conditions requiring operation are frequently the logical result of factors leading up to them. Many of these factors are easily discoverable and easily preventable. The importance of slight symptoms and errors of living in youth and early adult life is not fully realized by medical men. Many serious cases would not have become so if early mild symptoms had received the proper attention and been relieved. These points are easily brought out by the taking of careful detailed histories in long-standing cases. This will frequently give valuable suggestions for the medical treatment,

*Read before the El Paso County Medical Society on May 17, 1921.

or the after-treatment when an operation has been performed.

Faulty habits of living and some other unfavorable factors are at the bottom of many digestive conditions that become later so serious as to require operation. In many individuals these are unavoidable, but in general this is not so, and they are of such a nature as to be easily avoided or overcome. I will detail briefly a few of these:

The value of the regular toilet habit, whether there be a desire to defecate or not, can hardly be overestimated. Constipation is too often the beginning of serious conditions, such as gastrointestinal catarrh, subinfection, adhesions, appendicitis, gastric and duodenal ulcer, and gall-bladder infection. The use of a cold toilet will occasionally lead to constipation with its resulting conditions. The toilets in office buildings, stores, and other places of business are occasionally not only cold but dark and dirty, and very disagreeable to use. Consequently there is an unconscious tendency to put off using them as long as possible. Also the cold in such cases will frequently lead to piles and acute attacks of diarrhea.

The drinking of too little water is frequently a factor in causing constipation and faulty elimination, especially in women.

Poor care of the teeth, caries, pyorrhea, and loss of teeth, and then inability to chew the food properly, are common. Too many people have teeth pulled that should be filled and saved. The swallowing of pus from pyorrhea may cause digestive troubles, and may seriously influence the cure of a condition that may otherwise yield readily to treatment.

The lack of exercise is a factor of great importance. This leads to constipation along with such other conditions as muscular flabbiness, the putting on of useless fat, overweight, and poor elimination. This is due to carelessness, as a man, no matter how busy he may be, can put aside sufficient time to take a reasonable amount of exercise. Irregular hours of eating and improper food are usually under one's control but not always, although, even when conditions are unfavorable, the most injurious factors may be avoided if an effort be made to do so. Frequently there is no effort made to cut out the satisfying of appetites that are known to be harmful.

Late night hours with too little sleep and insufficient recuperation from the previous day's work affect the general health, and also the digestive apparatus secondarily.

To-day the excessive use of alcohol has nearly stopped in this country, but a few individuals are still getting it on this side of the border, and many are imbibing across the river. We are still dealing with the effects of it in people who have been habitual users for years. We shall see less and less of this as time passes.

The use of tobacco is now more prevalent among the men of our country than alcohol ever was. It probably causes some digestive disturbances, but its principal harmful effects on digestion are in aggravating existing disturbances, or in preventing their cure. I believe that this is particularly true in gastric and duodenal ulcer, and gastrointestinal catarrh from whatever cause.

The continual rush of modern business leads not only to the development of bad and faulty habits, but to the prevention of, rather than the inability properly to take care of slight troubles that arise. Consequently these conditions are allowed to continue until they seriously interfere with comfort or work, and are in many instances then of a surgical nature. Some of these cases result fatally or develop semi-invalidism. A little time and care at the beginning would easily have been preventive.

In many instances a person will be very much given to worry over large or small troubles, whether unnecessarily or with good reasons. This seriously affects the health in many cases by reducing appetite, diminishing the secretory and motor functions of the digestive apparatus, diminishing sleep and thereby interfering with recuperation from the daily duties, and in other ways.

Occasionally business or other trips to a distance become necessary and too frequently during them not sufficient care is given to the mode of living, such as rest, food, late hours, use of alcohol, excessive smoking, and other factors. Such trips frequently will originate a digestive disturbance, cause a lighting up of an inactive process, or prevent the cure of a chronic condition.

With regard to food, idiosyncrasy may be mentioned. In such cases some individuals will persistently try to eat articles of food against which they know that they have an idiosyncrasy. This condition, when suspected, should be proved or disproved by the physician and if it exists that particular food should be stopped or the idiosyncrasy corrected.

Several other possible causative factors may be mentioned; one is the condition of the tonsils. Bacteria from discharging tonsils being swallowed with the food, no doubt at times cause disturbance of the digestion, and certainly in many cases may be the cause of failure to relieve or cure the patient. I have seen several cases of gastric and duodenal ulcer that would not heal until bad tonsils had been removed.

Another factor is pregnancy. It seems to me remarkable that pregnancy does not cause more digestive disturbances than it does. It is no doubt responsible for many cases of ptosis and gall-bladder inflammation.

Most individuals suffering from chronic digestive disturbances do not possess vitality that is up to the normal. As a rule they are more susceptible to minor acute ailments, and show more frequent and more serious complications and sequelæ and also a higher mortality from serious intercurrent affections.

I wish now to take up a few of the results of factors previously mentioned. Constipation is certainly the most important one. Retention of material in the intestines for a longer period than normal always sooner or later leads to increased bacterial decomposition of the food, with the formation and absorption of toxins. As time passes, laxatives cause more or less catarrh, general symptoms due to the toxins occur, and local inflammatory conditions, such as acute or chronic appendicitis, gall-bladder inflammation, gastric

and duodenal ulcer, and adhesions, are apt to occur. Frequently in such cases the patient has lassitude and gets tired very easily; this leads to diminished exercise, and thereby a vicious circle is created.

The following is a combination that I have noticed in a number of long-standing cases: Stasis, marked decomposition of food in the intestines with evidences of autointoxication, and passage of large amount of pale urine giving a very intense reaction for indican, low specific gravity, a trace of albumin, and a few hyaline casts. Upon treatment as the condition improves the indican in many cases will disappear, the amount of urine gets to normal, the specific gravity rises, and the albumin and casts disappear. Some of these cases will show a low blood pressure without sclerosis due to diminished general strength. Some others have reached the stage of atheroma, high blood pressure, enlarged heart, and other symptoms which go with them.

With women, disturbed menstruation is not at all rare as a result of the toxemia of intestinal origin. This will usually return to normal when the intestinal condition is corrected, but not always, as it may have had time to have produced a permanent pathological condition. Also in women, and occasionally in men, the threshold of symptoms will be passed, owing to the toxemia, and hysteria, periodical headaches, or other symptoms may develop that otherwise would not have occurred.

I will now cite a few case histories. They are composite, but are easily recognized, if one will take careful, detailed histories.

CASE I.—The patient was a successful merchant. As a boy he worked hard around stores, did a good deal of lifting, and had considerable exercise; he had plenty of food, but it was of indifferent quality and not well prepared, and as his parents were not well educated, the regular toilet habit was not established, and he was slightly constipated. However, he was well and his digestion was good. At about the age of 15 he began smoking a great many cigarettes, chewed tobacco a little, and occasionally used alcohol to excess. Owing to the fact that he was earning more money he occasionally had large indigestible meals away from home. He became a little wild, less attention was paid to his habits, constipation was more marked, and he began having a little gas formation in the intestines. At 23 he was earning enough money to get married, had better food and owing to a very good appetite, ate more than formerly. He had a horse and buggy and rode back and forth from the store, and ordered his clerk to do the physical work. This resulted in a marked increase in weight, aggravation of the constipation and gas formation, and beginning twinges of pain in the region of the appendix. At 30 he was making more money, eating rich food and more of it, and the other factors became more marked, with the result that one day he had a very severe pain in the region of the appendix. His physician was called, acute appendicitis was diagnosed, and after time spent on consultation with a surgeon and counting the leucocytes, operation was performed twelve hours after the beginning of symptoms. The appendix was found to be gangrenous and general peritonitis had begun. Owing to his poor general condition he gradually grew worse and died on the third day after the operation.

This fatal outcome could easily have been prevented if the family and their attending physician, if they had one, had given the proper attention to the boy's habits and constipation at the time symptoms began.

CASE II.—Physician, 45 years of age. As a boy he went through the grades and high school and was in perfect health, as he had good exercise, good food, and good training. He went to a neighboring city to study medicine and while there lived in a boarding house, had very ordinary food, took but little exercise, and worked very hard, studying usually until late at night. This led to slight constipation, occasional insomnia, and slight headaches. In the summer following his second year he developed typhoid fever, from which he promptly recovered. He used tobacco excessively, drank more or less beer all the time, was occasionally led into sprees by his friends, and drank a great deal of coffee. After he graduated he made his calls either afoot or riding a bicycle, and his physical condition was good. He played outdoor games, had plenty of exercise and his bowels were regular. At the end of 5 years he was making more money, made his calls with the horse and buggy, was too busy to take exercise, and when evening came, either spent it with his friends or went to bed to rest up for the next day. His constipation became worse, headaches were more frequent and severe, he had a little rheumatism, and began to notice frequent eructation of gas after meals. He had been eating more, had gained considerably in weight, his muscles were flabby, and his abdomen was getting a little prominent. Five years later all of these factors had become more pronounced. He had eructation of gas off and on all day with more after meals, twinges of pain in the right hypochondriac region, with occasional attacks of pain of moderate severity lasting an hour or two. At the age of 45 he woke up in the middle of one night with a typical severe attack of gallstone colic. Jaundice set in in due time. After waiting the proper length of time operation was performed and he made a good recovery.

If this man had used what he knew about medicine he could easily have corrected the factors leading to his ill health, except perhaps that of the cholecystitis, which was probably due to the typhoid bacillus, although this infection may not have occurred in the absence of predisposing causes.

CASE III.—Housewife, 40 years old. As a child she was not strong, being of a moderately asthenic type. She would catch cold easily, the throat frequently getting sore. The tonsils were slightly enlarged. She was fond of reading and sewing and had poor energy, consequently did not take much exercise. She did not have a regular toilet habit, did not drink much water, and was quite constipated. Frequent headaches developed, and she became very nervous. At 15 menstruation began, which was irregular, painful, and as a rule scant. She developed occasional spells of hysteria, which gradually became more pronounced. She was above the average height and much below normal weight. At 21 she married and bore five children, 18 months apart. This, together with increased worries and confinement in the house very much aggravated her previous condition. Upon careful examination the following symptoms and conditions were found: Patient very much underweight, complexion sallow, marked pyorrhea, some teeth out and the rest in bad condition; marked chronic tonsillitis, a great deal of eructation of gas after meals, feeling of weight and fullness in the stomach, occasional nausea and vomiting; a great deal of borborygmus with occasional cramps; marked constipation; hemorrhoids; insomnia, lassitude, frequent headaches; poor strength; occasional fever to 99° or 100°; occasional edema of the feet; marked nervousness and irritability; frequent spells of hysteria; dyspnea on exertion; spells of palpitation and tachycardia; frequent passage of light colored urine, and irregular painful menstruation. Physical examination shows a flabby abdomen, prominent below the umbilicus; ptosis of the stomach, intestines, liver, and right kidney; slight tenderness over the appendix, gall-bladder, and epigastric regions. Blood— hemoglobin 80 per cent., urine—low specific gravity; trace of albumin; intense reaction for indican and indigo red; and a few hyaline casts. Blood pressure low and arteries soft.

It is not necessary to mention the proper treat-

ment of a case of this kind, as all of you know what it is, but suffice it to say that if she had received the proper treatment as a child and later this end result would not have occurred. The fault for such a result frequently lies with the family or patient for not getting the proper advice and carrying it out, or using patent medicines and doing what any old granny tells them to do. But this is not always the case; often the physician does not go into sufficient detail, either in examination or in outlining the treatment, on account of rush of work, to get the desired result.

Conclusions — 1. Slight digestive disturbances should receive very careful treatment. 2. Their importance is not fully realized by the general physician. 3. If they are relieved when they are readily amenable to treatment, many serious conditions can be prevented. 4. Faulty habits and unfavorable factors of living should be sought for and corrected when possible. 5. The history should be taken with sufficient care and detail to bring out these facts.

515 Roberts-Banner Building.

SIMPLE AND RELATIVELY SAFE THYROIDECTOMY.

By WELLER VAN HOOK, A.B., M.D.,

CHICAGO.

One of the most serious difficulties associated with the treatment of goiter lies in the determination of the amount of tissue to be removed. The writer, in common with many other surgeons, formerly removed the larger of the two lateral lobes, and with this mass he often excised part of the isthmus and occasionally smaller masses of the smaller lobe.

But this routine practice occasionally led to disappointment. For in the case of exophthalmic and toxic goiters, and even in the simpler forms of the disease where one operates on account of mass, the complaint of the patient is only temporarily stilled, in the one case on account of the persistence or the return of the toxic symptoms and in the other case on account of the growth of the masses remaining.

For this reason the writer more recently has been removing almost all of both lobes as well as the isthmus of the organ. But who knows how much of the masses must be left in order to prevent cachexia strumipriva and how much must be removed to do away with the toxic state? This difficulty is enhanced by the fact that, before the removal and sectioning of the tissues, no one can do more than guess at the proportion of normal to abnormal tissue in the parts not obviously to be excised. The old procedure of removing one lobe is inadequate; the dictum that one-fifth of the thyroid mass should be left is equally unsatisfactory.

The writer has recently left small masses at each of the horns of the organ and, in addition, a thin layer of thyroid tissue attached to the posterior, untouched part of the gland capsule. These tissue masses are left by choice because their volume can be rather accurately gauged and because they are well provided with blood vessels and lymphatics, allowing for hypertrophy if that need be brought about by demand of the organism.

A second, remoter danger encountered in these operations now generally recognized is that of injury to the parathyroid bodies either immediately or through damage done to their vessels and nerves. The writer agrees with the majority of operators in preserving a layer of gland and capsular tissue comparatively undisturbed at the back of the gland.

The recurrent laryngeal nerves are best managed by the same artifice, leaving the region which they traverse entirely untouched. The operation may be systematically considered:

The position of the patient upon the operating table is of prime importance both for the administration of the anesthetic and for the work of the operator. Not only must the conditions be satisfactory at the outset, but at all stages of the procedure it must be easily possible to alter the relations of the parts under manipulation.

For it is necessary for the anesthetist to be able at any time to lift the lower jaw from its angles in order to aid respiration. And he must have reasonably clean hands and must be screened away from the operation by sterilized linen.

Two cylindrical sandbags are needed, each four inches in diameter and about fifteen inches long. One is placed transversely under the back at the upper scapular level. The other is placed exactly under the occipital protuberance. It is not to be put under the neck. Now, if the head is to be extended upon the neck it is merely lifted a half inch, rotated backward about an imaginary point located in the upper cervical region, and then replaced upon the sandbag. If the neck is to be flexed the process is reversed. The novice will find that his difficulties in making and closing the wound and in manipulating the thyroid are pronouncedly minimized by this simple device. During the early part of the operation the anterior part of the neck is made prominent to facilitate the removal of the mass; during the latter part it is relaxed so that the muscular layers may be readily brought together.

Kocher's collar incision, which Doyen of Paris claims to have practised since 1887 (Traité de Thérapeutique Chirurgicale, Paris, 1910. Vol. III, p. 40), is made a finger's breadth or so above the sternum. The exact level of the incision above the sternum cannot be stated for all cases in inches. Some necks are short, wide, and thick, while those of the contrasting type are long, narrow, and meager. The incision should be made at such a level as will give the best access to the *horns of the gland*. The length of the incision must be such as will give the operator enough room for his work. The inexperienced operator should allow himself abundance of room before attacking the difficult, deep work. The prime ideal of the operation is the conserving of life, and the nicking of the inner borders of the sternomastoid muscles is of small disadvantage in comparison with the great value of abundance of room for dealing with the vessels of the gland. If these muscles are slightly incised, sutures can be placed when the wound is closed.

The platysma is next divided, and any blood vessels injured are clamped as they are cut. As a rule there is no hemorrhage from any of these vessels caught by the forceps, even when the

clamps are removed, provided the pressure has been maintained for five or ten minutes while one continues the work of exposing the gland. Yet, unless one has had large experience with thyroidectomy, it is best to ligate the large veins with very fine catgut the moment they are seized.

The platysma having been transected and the superficial veins clamped or tied off, the sternothyroid and sternohyoid muscles may be retracted after they have been separated by a longitudinal incision, or they may be transversely divided, as suits the skill and experience of the operator and the difficulty of the case. I have had opportunity to reopen a neck in which recurrence took place a year after I had removed one lobe of a thyroid with transection of these muscles, and I found the wound in the sternothyroid and sternohyoid muscles so smoothly united that one could not well have imagined any serious functional disturbance, as indeed the history substantiated. Operative elegance and smoothness of function are highly desirable and are much to be sought after, but the honest operator should transect or leave these muscles intact after deciding upon the method by which he can best conserve his patient's chance of recovery with general usefulness in his place in society.

Exploration gives certainty in reference to many of the important inquiries that the surgeon would make. He wants to know, especially, what is the size and shape of each lobe of the gland and what the relations of each lobe are to the other cervical structures. It is important to know whether the gland extends around the trachea to the œsophageal region or not and whether the lower lobes reach down into the mediastinum or thorax.

The half of the gland chosen as the first one to be attacked is lifted between the thumb and forefinger, a piece of gauze having been interposed if the mass is slippery. Sometimes the small Tuffier's (Allis's) forceps is used if the goiter tissue is firm enough to bear it without laceration and hemorrhage. The operator is fortunate if the lobe comes up easily. Inflammatory adhesions are rare; usually it is only the shortness of the connective tissue strands that prevents the gland from coming freely into the wound. It is, of course, easier to perform the necessary manipulation if the part of the thyroid involved can be drawn forward and isolated.

Firm and fairly deep retraction is now made by an assistant and the cornu of the gland is grasped by an ordinary forceps of the Kocher type. The forceps used should be carefully selected before the operation because so much depends on them. The thyroid having been brought into view, the finger is carefully passed around one lobe of the gland dividing the filmy connective tissue, at first laterally and then toward the upper and lower lobes successively. If resistance is encountered I am in the habit of overcoming it tentatively and, as it were, experimentally and coaxingly. By this I mean that pushing the finger along the gland surface and hugging the gland closely, the lighter and looser resistances of connective tissue are overcome at once, while the more heavily binding masses are left until later. In case this is necessary one passes to another part of the field, loosens the gland and then, returning to the earlier point of attack, frequently finds the conditions more readily understood and the separation easier.

The purposes of this manœuver are to explore, to separate the connective-tissue masses that bind, and especially to free the lobe so that it can be lifted somewhat from its bed in preparation for its excision.

The forceps should be applied in such a way that its jaws grasp no unidentified tissues behind the exposed horn. The thumb and finger passed around the gland act as guides. It is not requisite that the whole mass of the horn be grasped by the forceps and it is not necessary, though it is desirable, that but one forceps be used.

The purposes of the clamping are, first, to hold the horn, preventing its slipping out of reach when transection has been affected; second, and most important, to provide provisional hemostasis, and, third, to mark the amount of gland tissue to be left.

The lower lobe is clamped with especially great care, and I usually apply the forceps almost exclusively to the anterior two-thirds or three-fourths of the mass. The forceps immediately crushes the soft tissues and hemostasis is thereby simplified. One forceps grasping but part of the horn does not always wholly prevent hemorrhage, but two or three others, superficially applied, will almost certainly catch all the accessory vessels that may bleed when the gland is incised.

Supposing the forceps has been applied on one side, the operator may at once attack the opposite lobe in the same way, if he wishes, without, for the moment, doing anything more to the first lobe. The clamps are placed on the second lobe while the operator stands on the same side of the table as that on which he stood for the first lobe, or it may be done after he has moved around to the other side of the table, exchanging places with his assistants. Though this is a matter of convenience, it may be important, since position may facilitate the work for some operators.

The forceps having been placed, the operator takes the knife, severs one horn of the thyroid at a quarter or a third of an inch beyond the forceps holding it, and, pausing for a moment if necessary to apply an artery forceps to any small accessory bleeding vessel, he proceeds to sever the second horn on the same side and then to lift and to shave off the main mass of the gland from the posterior layer of the capsule, which, together with a little gland tissue, is left in the wound. This shaving off process is continued until the trachea and the isthmus are reached, where the direction of the curved plane of section is changed to run parallel with the tracheal wall, the isthmus being similarly treated. One carefully avoids cutting deep enough to injure the trachea. The median line having been passed, the opposite lobe of the gland is freed from the stumps of the horns and the posterior part of the capsule in the same way.

The wound in the thyroid is now large and usually has a number of artery forceps attached to it, especially about the lower horns, where the

inferior thyroid artery will sometimes have divided to send several branches through and over the gland. One does not ligate these small arteries as a rule; instead he uses a curved needle and light catgut and passes the thread around the cornu just above the artery forceps and makes the first hitch of a knot. He then has the forceps removed by the assistant. Thereupon the knot is drawn gently taut and the second hitch completes the ligation.

The ingenuity of the operator is now applied. He examines the thyroid tissues left and uses the remainder of the suture to bring together, if possible, the capsule of the gland in such a manner as to diminish the wound surface of the gland and simultaneously to close blood vessels. The other horn of the same lobe is similarly treated. Many ligations are thus avoided. Now, one of the great advantages of this method is to be observed in that *hemostasis and wound closure are combined*. The operation is shortened and simplified. One is careful not to draw the capsule into a puckered mass that may injure the recurrent, the parathyroids or their blood supply, the trachea, or the jugular vein. This necessity is easily complied with, since there are many alternative ways of closing this deeper wound that will present themselves to the attention of the surgeon.

Next, the muscles are sutured together with great accuracy in neat layers, and, lastly, the skin. I leave a tiny tape drain in the wound to permit fluids to escape. Accurate closure conduces to comfort in the finer neck movements later on and prevents undue deformity. Careful closure of the skin gives a nearly invisible scar. The drain is removed after twenty-four to thirty-six hours; the sutures are taken away after five or six days.

We have thus far considered the simplest and easiest cases. Let us now discuss some of the difficulties to be encountered.

Large goiters, symmetrically developed and not growing into the mediastinum or enveloping the trachea, demand but little variation from the simplest normal procedure. The wound must be large enough to give the operator enough space to suit his own skill, experience, and feeling of confidence. Then one must exercise great care that superficial veins coursing over the mass are not torn by rough manipulation or by rubbing. And the lifting out of the lobes of the goiter from their beds must be carefully effected. I use the forefinger as a sort of probe and instrument for lifting the gland. Kocher used a goiter "spoon," an instrument much like a dessert spoon, not very deep and quite strong. When the gland is somewhat free from its laterally associated structures it is well to use the thumb and finger with which to draw the lobe upward and outward. Grasping the smooth gland is aided by placing a layer or two of gauze next to the tissue. A danger to be dreaded in all goiter operations is—not hemorrhage in the visible operative field, but bleeding from points not at once in view. It is just at this stage in the operation that such a hemorrhage may occur. When the lobe has been lifted into view its bed becomes, as a rule, accessible. But when venous hemorrhage takes place deep in the wound, especially if it comes from a vessel behind a lobe still *in situ*, it may be the best policy to pack the wound for a few minutes until coagulation takes place. The time may be used in working elsewhere.

Recently I have sometimes used the Tuffier (so-called Allis) forceps with which to grasp the lobe and draw it out of its bed. If one follows this plan he must be ready to apply more than one forceps so as to make no more tension at one point of traction than is absolutely necessary. And he must observe with care the toughness of the capsule and the gland tissue as he subjects them to the traumatism that is necessary. Sometimes the tissue is too delicate to permit the forceps to be used. Then one must depend upon using the finger and thumb. Kocher's spoon may be used. A German surgeon uses a loop of gauze passed around the lobe with which to lift it. It is stated that mediastinal (retrosternal) masses are easily raised with a loop of tape. Thus far I have always succeeded with the simpler means above referred to.

When once the lobe is raised at one of its corners and clamped as suggested, one usually proceeds quite easily to the other cornu of the same lobe, managing in the same manner. When the clamps are thus placed the excision may be undertaken as heretofore described.

In all larger goiters there may be irregular arrangement of the arteries demanding the use of a few extra clamps.

If displacement of the lobe through irregular enlargement has brought about peculiarities of localization, the clamps are to be placed where they will carry out the central plan—that is, where they will serve the purpose of preliminary or provisional hemostasis, to be followed by definitive closure.

Cysts that are infected may be incised if one wishes, in order to diminish their mass before removing them.

31 North State Street.

SOME UNUSUAL FEATURES IN A LOCALIZED EPIDEMIC OF INFLUENZA.

By S. R. Blatteis, M.D.,
and
M. Brunner, M.D.,
Brooklyn, N. Y.

Following the pandemic of 1918-1919 the whole civilized world was in suspense about the question of recurrences. Authoritative sources differed widely on this question, and though the years 1920-1921 did show recurrences, yet they were not extensive and did not cause much alarm. However, when epidemics, no matter how localized, took place the entire community became greatly perturbed. Possibly were not medical men and health authorities as alert as they were, a different story of these outbreaks might have been told.

The epidemic reported here is to illustrate in a small way what can be done in limiting and, in fact, stamping out an infectious communicable disease that, without the proper measures, might have run like wildfire through the immediate community and might have been the focus of a much larger outbreak.

This is a narrative of an outbreak occurring at a girls' camp located in a summer mountain resort section of New York State. The camp was situated in a thickly wooded region bordering on a large lake, so that as a health resort conditions were ideal. At one of the public assemblies held weekly in this camp it was observed that one of the visitors (who afterward, it was learned, was convalescing from a double pneumonia) was a constant source of annoyance by her persistent hacking cough. A few days later four girls reported to the camp nurse, complaining of a slight dry cough, a feeling of general malaise, and slight fever. The temperatures then were of 102.°, 100.4°, 102°, and 102°. The girls were put to bed in the infirmary and kept under observation. Physical examination revealed a negative chest and negative abdomen. The fauces were slightly reddened and the tongue was coated. For the following four days the temperatures varied from 101°—104°, the pulses from 85—100, and respirations averaged 24.

The cases presented a picture clinically lending itself readily to a tentative diagnosis of typhoid fever. During the first five days no corroborative evidences were observed. Physical examination failed to reveal any positive chest or abdominal findings. The only subjective symptoms were slight dry cough, fever, and a feeling of general malaise; yet they felt so well that they repeatedly asked to be let out of bed.

The simultaneous occurrence of four cases of an indefinite illness in a camp previously remarkably free from any disease immediately led us to suspect the presence of one of the more common of the infectious diseases. The tentative diagnosis of typhoid fever made it obligatory to institute all the preventative measures possible. Strict isolation and thorough methods of disinfection were enforced. No contact in any manner whatsoever was permitted between the healthy members of this community and those who were sick. Of those instances where this rule was not strictly observed, specific mention will be subsequently made.

A complete and careful physical examination was made by both of us at least daily. It was only after the temperature had reached its fastigium and was beginning to drop that the first physical signs of pulmonary involvement were observed. This was true of all the cases. On the fifth day of the disease Case No. 1 presented numerous crepitant and subcrepitant râles over the right upper chest anteriorly and posteriorly without any evidence of consolidation. On the following day cases 2, 3, and 4 presented positive chest signs as follows:

Case 2.—Numerous diffusely scattered crepitant and subcrepitant râles over both bases posteriorly and several small areas of increased voice and breath sounds.

Case 3.—A distinct area of consolidation about the size of the palm of the hand in the base of the right lung posteriorly with a diffuse infiltration of the remainder of the right lung.

Case 4.—A definite area of consolidation about the size of a silver dollar in the left axillary region.

Those who came in contact with the patients were the doctors and nurses. Because of the absence of the parents, the camp directress was compelled to mingle with them. A daughter of the camp directress was also a camper. It was learned that in some way or other the mother and daughter met, greeting each other in the usual manner of kissing. For how long after the outbreak this had been going on is not known, but ten days after the onset of the first case of illness the daughter and her tent-mate reported to the nurse complaining of headache, slight fever, general malaise, and slight cough. Their temperatures were 104° and 102° respectively. These two patients were put to bed and kept under observation in the infirmary. The same precautions were followed out with these two patients as with the other four. Physical examination failed to reveal any positive chest or abdominal findings until the fifth day when signs of consolidation and infiltration of the upper lobe of the right lung were made out in the daughter of the camp directress. Five days later, when the temperature was nearly normal, pneumonic signs were found in the left upper lobe. Her tent-mate likewise presented signs of infiltration of the base of the left lung without any areas of consolidation, on the fourth day of her illness.

Sixteen days had elapsed since the outbreak of illness with the situation apparently under control. The convalescents were doing well. Then along came the camp directress with complaints of general malaise, slight cough, and fever. Her temperature registered 102°. The patients now numbered seven. Physical examination on admission was negative. On the following day the patient complained of sticking pains during respirations in the right lower posterior chest region. Examination of the chest revealed the presence of a diffuse infiltration of the base of the right lung with a slight pleuritic friction rub in the axillary region.

The eighth and last case occurred in the following manner: One of the counsellors learning the good news of the recovery of the first case, forgot for the moment the precautions which had been in vogue, and yielding to her impulse kissed the patient. Two days after this the counsellor experienced chilly sensations, slight cough, slight headache, and general malaise. Reporting at the infirmary later in the day, her temperature registered 101° and during that night rose to 103°. On the third day a small area of consolidation at the base of the right lung was recorded.

Laboratory aids in the diagnosis of the first cases were lacking, because the nearest laboratory was 45 miles distant. On the third day of the disease Widals were taken and reported negative. About ten days after the onset another Widal and differential leucocyte counts were submitted. Widals for typhoid and for paratyphoid A and B proved negative. The differential leucocyte counts were as follows:

Case	1	2	3	4	5	6
Polynuclears	60	68	64	66	53	45
Lymphocytes	36	30	32	33	47	44
Eosinophiles	4	2	4	1	..	1

From a review of this epidemic it seemed proper to have entertained the opinion of typhoid fever as

most plausible during the first few days of illness. There were the headache, general malaise, slight cough, very slight congestion of the throat, the modified step-ladder type of temperature, and the relatively slow pulse; a further sign was the simultaneous outbreak of four cases.

If not typhoid fever, then it was thought possible that some form of food poisoning producing a mild ptomaine effect might be the explanation. But the absence of gastrointestinal symptoms and no appearance of anaphylactic skin rashes made that diagnosis highly improbable.

It was only after the discovery of definite chest signs, not only in one but in all of the four first cases, that the diagnosis of influenza was justified. This was further confirmed by the presence of lung signs in every one of the eight cases, by the character of the temperature, by the definite relative lymphocytosis, and by the persistence of the lung signs for some time after the patients felt perfectly well.

Conclusions.—1. Four cases of an acute infectious disease appearing simultaneously in a summer camp, were tentatively diagnosed as typhoid fever and were placed at the very outset under the strictest isolation and disinfection.

2. The subsequent occurrence of four other cases resulted from contact definitely traced.

3. The definite diagnosis of influenza was made on the fifth day of the disease by the appearance of lung signs for the first time after the beginning of defervescence. This was true of all the cases and is noted as an unusual experience.

4. Prostration was never a feature of any of the cases.

5. The absence of expectoration during the entire period of the acute and convalescent stages is an unusual clinical observation.

6. The strictly limited nature of the outbreak under conditions most favorable for its wide and rapid dissemination is exceedingly rare, but can be accounted for by the early thorough and persistent use of isolation and disinfection.

We therefore conclude that the same methods employed in an outbreak of any suspicious infectious disease can, as here illustrated, be definitely and sharply circumscribed.

THREE LARGE BABIES FROM ONE MOTHER.

By G. B. Foscue, M.D.,
Waco, Tex.

The following case is so unusual, if not unique, that it seems worthy of record.

Mrs. H. W. A., primipara, white, aged 20. On the 27th of November, 1917, I delivered her of a male child which weighed at birth 14 lb. 6 oz.

On Feb. 27, 1920, she again came under my care and was delivered of a girl weighing at birth 13 lb. 2 oz.

On Sept. 4, 1921, I again delivered this young woman. This time is was a boy who weighed 13 lb. 8 oz.

These three children were born within a period of 45 months. Their combined weight was 41 lb.

The first labor was a high forceps delivery with a perineal laceration of the second degree. An immediate repair was made with only partial success. The other two births were normal. The three children are alive and healthy.

The mother is 5 ft. 6 in. in height and weighs about 130 lb. Her mother is a rather large woman who has given birth to six children, the largest of which weighed 10 lb. Her father also is a large man.

The father of these three children is 5 ft. 7 in. tall and weighs 137 lb.

1603 Amicable Building.

Medicolegal Notes.

Construction of Agreement by Seller of Practice Not to Establish Himself in Practice Within Certain Radius.—In an action to prohibit the enforcement of an injunction against the seller of a physician's practice, it is held that an undertaking in the contract of sale by the seller and his wife "not to establish themselves as a practising physician and surgeon" within a radius of five miles of the seller's home is not ambiguous, and needs no extrinsic evidence to show the intention of the parties as to its meaning. It was held that the parties thereby intended that the seller should not maintain an office for the practice of medicine or surgery within the prescribed district, and nothing more. In other words, it was intended by this portion of the contract to restrain the seller from opening an office as a practising physician or surgeon at any point within five miles of the home, which, under the agreement of sale, was sold. The court refused to read the language of the agreement as intending to mean that the seller was not at any time within five years to call upon or prescribe for any person living within a radius of five miles of his former home. A writ of prohibition was therefore made permanent prohibiting the enforcement of an injunction against the seller, except in so far as it enjoined him from opening or establishing an office for the practice of medicine or surgery within a radius of five miles of the premises sold.—State v. Calhoun (Mo. App.), 231 S. W., 647.

Expert Testimony as to Nature and Permanence of Injuries.—In a personal injury case exceptions were taken by the defendant to the admission of testimony by medical and surgical experts who had treated or examined the plaintiff, expressing the opinion that his injuries were permanent; that he would never regain the normal use of his injured foot and ankle; would always walk with a limp, and other matters of the same general nature. It was argued that this testimony offended against the rule that the expert witness may not be allowed to express an opinion in effect determining the ultimate question which the jury is impaneled to try. It was held that this rule had no application under the facts of the case. "The witnesses were not asked, and expressed no opinion, whether the defendant was negligent in respect to any of the matters alleged in the pleadings, or whether the plaintiff himself was negligent in any respect, or whether his injuries, if any, were caused by any act or omission of the defendant. In cases of this character, where damages are sought for personal injuries, it is always admissible to show by expert evidence the nature and extent of such injuries, whether permanent or otherwise, and the manner and extent to which his injured or crippled condition, if any, affects his ability to labor or to make use of his normal physical powers."—Bradley v. Interurban Ry. Co., Iowa Supreme Court, 183 N. W. 493.

X-Ray Photographs, Properly Authenticated, Admitted in Evidence.—In a personal injury case, *x*-ray photographs purporting to show the fractures of the bones in the plaintiff's injured foot and leg were held properly admitted, where the evidence showed that they were made by a skilled and practised operator of such machines, and that the machine was properly focused and so located to the injured limb and foot as to give a clear and correct view and impression of the fracture, and that the plates were faithfully reproduced by the photographs.—City of Covington v. Bowen, Kentucky Court of Appeals, 230 S. W. 532.

SERUM SICKNESS.

UNDER this term are understood those serological accidents which are fairly frequently observed during the week following injections derived from horse serum, more common in adults than in children and more common in subjects who have already had one or several injections of serum, and which are also more prone to occur after intravenous than after hypodermic administration and with large rather than with small doses. It would appear that these accidents are due to the precipitation of horse serum, considered as antigen in presence of antibodies called precipitins, which appear in the blood of those injected. The symptomatology assumes the form of a true syndrome, called the serological syndrome, and is essentially characterized by cutaneous and mucous eruptions, accompanied or not by a rise of temperature, arthralgia, tumefaction of the lymphnodes, etc. The exanthemata are usually of the simple kind, or polymorphous, particularly nettle-like, rarely scarlatiniform, or purpuric. They last for two to three days. The nettle-like form of rash is accompanied by severe pruritus and edema of the eyelids and prepuce. When the mucosæ become involved the exanthema provokes an edematous swelling, but glottic edema and bronchial or intestinal disturbances due to local rashes have rarely been met with. Tumefaction of the lymphnodes commences with the nodes tributary to the area in which the injection has been given. The arthralgia presents nothing special, while the fever is moderate and hardly ever lasts for more than one or two days. What usually takes place is a generalized urticaria with severe pruritus for one or two days, accompanied by a temperature of 101° to 103° F. with occasionally some arthralgia, myalgia, or lymphatic tumefaction. Between the mild serological reactions which remain localized at the site of the injection—and these are by far the most frequent—and the intense reactions of a dramatic character, which are rare and usually due to some technical error, there are all sorts of intermediary types. The serological accidents usually appear about one week after the injection and last for three or four days, recovery being the rule.

The diagnosis is usually easy, especially when it is known that the patient has been given a serum injection, but it may be somewhat embarrassing in certain cases in which the symptomatology assumes the appearance of an acute intercurrent disease, such as rubeola, during the course of a diphtheria, tetanus, or cerebrospinal meningitis which is receiving serum treatment. This is particularly the case when, after repeated intramedullary serum injections, the cerebrospinal meningitis seems to return. The coexistence of a cutaneous eruption will, however, remove all doubt.

The treatment consists of purging the patient, the exhibition of calcium chloride in a daily dose of three to four grams, powdering the parts involved by the exanthem with talcum to quiet the pruritus, strengthening the heart's action in the severe cases with the usual cardiac stimulants, especially camphorated oil hypodermically. The prophylaxis of serological accidents is confined to the exhibition of calcium chloride in the doses above mentioned at the expected time of the occurrence of the accidents, or to the employment of Besredka's so-called anti-anaphylactizing method. This consists, as is known, in giving one or several very small subcutaneous injections of serum several minutes or several hours before the regular serum injection.

THE PATHOGENESIS OF FORWARD DISLOCATION OF THE UPPER END OF THE RADIUS WITH FRACTURE OF THE ULNA.

THE mechanism of the production of this double lesion was first studied by Grenier, and afterwards by Dorfler, Helferich, and Schüller, but of all the experiments carried out, those of Dorfler are the most evident and convincing. Two different conditions must be first considered. In the first, the dislocation of the radius and the fracture are contemporaneous; it is an immediate dislocation. In the second, the dislocation of the radius occurs gradually after fracture of the ulna and requires several days or even weeks to take place. These are what Desprès called gradual dislocations. When the posterointernal portion of the forearm receives a trauma it is the ulna that first supports the intensity of the violence, because it is both superficial and on a lower plane in relation to the radius. Fixed at both ends, directly vulnerable to shock, it breaks under the influence of direct or indirect causes with the greatest ease, although indirect fracture is much less common as Brossard (Thesis, Lyons, 1883) long since showed by a large series of experiments. When a force acts vertically, the limb being in adduction, the ulnar inclination of the hand makes the ulna the agent of transmission of the pressure it receives to the carpus. But although fracture of the ulna is produced so readily, it is not the same with dislocation of the head of the radius. And in point of fact, this isolated dislocation of the radial head—which was for a long

time supposed to be impossible—is rare clinically. The anatomical reason resides in the fact of the intimate and solid union of the radius to the upper part of the ulna.

Although this dislocation alone is occasionally met with in children, it is because its cause is not a trauma acting directly on the posterointernal aspect of the forearm, but rather forced movements of pronation and supination, traction on the hand, or a fall upon it. Consequently when it is questioned which one of these two actions—dislocation of the radius or fracture of the ulna—occurred first, the answer seems easy. Dummreicher and Albert are the only ones who maintain that the fracture is the second in occurrence, but this opinion is at present completely abandoned since Dorfler published his experiments. Schüller has very properly affirmed that although it is difficult to produce dislocation of the radius when this bone is intimately united to the ulna, it becomes easy to produce it when a fracture of the ulna has dissolved the union between the two bones. The outcome of the discussion is that dislocation of the radius is always secondary to fracture of the ulna, which itself is nearly always the result of a direct traumatic force and is the primary lesion.

It was by starting from the assumption that fracture of the ulna in its upper or middle part has a direct traumatic action as its cause, that Dorfler and then Schüller carried out their experiments. It is unquestionably accepted that fracture of the ulna, by increasing the inability of the radius and by doing away with a certain amount of fixity in its relations to the humerus, greatly facilitates dislocation of this bone. But does the dislocation always result fram a traumatic action contemporaneous with the fracture and is the latter always the primary lesion?

Dorfler's experiments show, firstly, that if the forearm is injured by the passage over it of a heavy weight, a wagon wheel for example, the prolonged pressure of the wheel fractures the ulna and then, continuing to exercise its traumatic force, dislocates the head of the radius. The lesions are therefore almost simultaneous and clinical observation proves this. It is also important to remark that upon the direction of the traumatic force depends the type of dislocation and that although this is produced especially in front in most cases, it may also take place outwardly, sometimes even from behind.

EPILEPSY.

THE issue of the *Bulletin Médical* for September 21-24, 1921, xxxv, 39, is devoted to this disease, with a belated article in the succeeding issue. The articles are obviously intended for the general reader and are therefore presumably of practical significance. Dr. Roubinovitch of the Bicêtre discusses the nosological position of the epilepsies. During and since the late war the literature of these affections has been heavy. During the war, whether as the result of cranial wound or commotion, every possible clinical form was studied, and this fact confirms the author as to the unwisdom of trying to break up the conception of the disease into different basic types. Furthermore, attacks might come on directly after injury or only after a long period of latency, due in part to scar formation. Transitory does not differ radically from permanent epilepsy, nor Jacksonian from essential, nor convulsive from psychic. There appears to be an anatomical substratum—proliferation of the subcortical neuroglia, as was well shown in the military material. In addition to the exciting factors, predisposition counts, and neuropathic heredity is the chief among these. The taint not only favors the first appearance of the disease, but aids in making it chronic and of severe degree. A heavy consumer of meat or alcohol has a sort of acquired predisposition. The cranial trauma or commotion can light up a latent epilepsy. We now know and no longer have to surmise that the child of the alcoholic, epileptic, syphilitic, etc., has a brain which is far more vulnerable to epilepsy than that of the untainted child, a fact which sheds much light on child epilepsy.

In discussing treatment, Maillard of the Bicêtre begins with a full account of the drug phenylethylmalonylurea, called for short gardenal in France and luminal in this country. This includes the peculiar intoxication which follows its abuse, which suggests alcoholism. This drug possesses the great advantage over bromides that it exerts the same power over all clinical forms of epilepsy; while the fact that it is quite inert in the treatment of hysteria makes it of diagnostic value. Another tremendous advantage is the absence of any cachexia following its use, and the fact that aside from the absence of anything corresponding to bromism it actually antagonizes the mental failure, while producing in the undernourished a remarkable increase in weight and vigor. Although he has tested it on no more than 200 Bicêtre patients the author seems enthusiastic over his results. But certain patients do not tolerate it and in that case it must be given in small doses and with great care, and combined with some organic bromide. It is possible that boropotassic tartrate may come to replace bromine in these mixed cases, regarding which at present comparative tests are being carried out. Attempts to lay down rules for surgical intervention are as usual unsatisfactory.

BIOLOGICAL PROBLEMS OF CONTEMPORARY INTEREST.

THERE is at present so great a degree of activity in biological study that even a reading man may fail to keep in touch with all of the important developments of the day. Some of these, like anaphylaxis, have been before the public for many years, yet are as active as ever; others like colloidoclasis are relatively new, yet the latter is only a phase of the former. Glycosuria and glycemia are old yet

active problems, and protein-therapy is comparatively recent. The important subjects of vitamines and lipoids stand midway between the oldest and most recent developments. Yet it would, of course, be an easy matter to trace some of the more recent subjects back to remote beginnings.

In a general view of recent biological problems, Gautrelet, writing in *La Médecine* for September, 1921, ii, 12, traces the beginnings of protein-therapy to the use by Weill in 1905 of horse serum for hemophilia. He was followed by Nolff with the peptone treatment of paroxysmal hemoglobinuria and later this management was extended to infectious diseases. Both hemophilia and paroxysmal hemoglobinuria are, however, anaphylactic phenomena, while protein-therapy is closely related to the therapeutic employment of inorganic or metallic colloids. Both forms of treatment come under the head of antianaphylaxis, and protein-therapy is only a phase of the wider subject of colloidotherapy. Enthusiastic devotees are already predicting that the latter is destined to revolutionize drug therapeutics by driving out the crystalline drugs and synthetics of the day. But certain crystalline substances which are hardly regarded as drugs—like sodium chloride and carbonate—may be made to behave in the body like colloids and can exert an antianaphylactic activity. Sodium hyposulphite is also valuable in that it hinders that precipitation in the blood which is the essential part of anaphylaxis.

The subject of vitamines is far more complex than was once believed. In this it agrees with the subject of hormones. A mass of unwieldly and conflicting data has accumulated. It was once thought that rickets could be explained by hormones and again by vitamines, or both conjoined, but we are farther than ever from understanding rickets and perhaps the same may be said of pellagra. Not long ago the thyroid and later the adrenal were looked upon as "almost the whole of physiology." Quite recently, however, experiments seem to throw grave doubts on the importance of these small organs for the dynamics of the organism, and the larger viscera also are now thought to supply hormonic or endocrinic principles once believed to be the special products of the chromaffins. Experiments by L. Stern have succeeded in isolating vasoconstricting substances from the liver, kidneys, and spleen. These bodies belong under the proteogenic amines and are not even close kin of adrenalin. It has always seemed absurd to reflect that we know so little of the true biological importance of great viscera like the liver and spleen, while we have made a few small organs responsible for most of the growth, development, and dynamics of the organism.

Tuberculosis of the Kidney in the Aged.

This localization of tuberculosis is rare in those beyond the age of sixty or perhaps it would be more nearly correct to state that few are operated on in advanced life. Marion has operated on 273 patients, counting only his nephrectomies, and among this number 18 were more than 50 years of age. Figures limited to medical cases show a somewhat larger percentage of the elderly, as might be anticipated. In a recent Paris thesis (Lepidus, 1920) there are case histories of patients aged 61, 64 and 72 years. Apparently the physiological sclerosis of the kidneys of individuals over 70 tends to make the kidneys nearly immune to infection. Some of the findings of Lepidus are given by Plicque in the *Journal de médecine et de chirurgie pratiques* for October 25, 1921, xxcviii, 20. The symptoms at the onset are purely vesical and by reason of the age-factor cystitis is apt to be the diagnosis. One thinks of everything but tuberculous nephritis—of prostatic hypertrophy with secondary cystitis, of renal or vesical calculosis, and of cancer of the prostate, bladder, or kidney. Errors of diagnosis are commonly made. But the disease progresses rapidly albeit perhaps slow in comparison with early life. Sooner or later the picture of a nephritis looms up and it may take the form of a medical or surgical nephritis. It is of course not to be suggested that a competent urologist who examines all his cases systematically will be deceived in making his diagnosis, but the author is evidently writing for the benefit of the general practitioner. The hazard of nephrectomy with the other kidney intact is not much increased in the elderly, for Marion lost but one of his 18 patients from the intervention. The cystitis may subside spontaneously after nephrectomy, or it may persist and be aggravated, requiring extreme measures to control it—cystotomy, iodine vapor, fulguration, etc.

Erythema Nodosum.

This affection resembles a constitutional infectious disease of the exanthematous type, being preceded by the typical prodromic stage of these affections, having an epidemic and even at times contagious incidence, and relapsing occasionally. It must not be confounded with erythema induratum which is a tuberculous manifestation. Nevertheless patients with the nodose form, while but seldom tuberculous, often come of tuberculous stock. Röntgenography of these subjects shows as a rule no tracheobronchial adenopathy. It is true that old clinicians regarded nodose erythema as allied in some way to tuberculosis, and it is of course possible that there is a special form of this origin. Some of the subjects give a positive cutireaction, but this is no proof that the eruption is motivated by the bacillus. Recently a few writers have come out positively in favor of the view that the dermatosis tends to appear predominantly in a tuberculous soil. But we find no evidence of an association of the latter with clinical tuberculosis. In an endeavor to throw light on the etiology of erythema nodosum Professor Demiéville of Lausanne had an assistant investigate 300 cases which had been treated in the Polyclinic during a period of 22 years. (*Revue médicale de la Suisse romande*, October 10, 1921, xi, 10.) A survey of the tabulation which gives the antecedents and coexistent phenomena with, in some instances, the family history, seems to show plainly that the dermatosis, so far as Geneva is concerned, is an autonomous disease in which there is no more tuberculosis, rheumatism, etc.,

than there would be in an equal number of controls. All of the ordinary dispensary affections are properly represented, as anemia, adenoids, hysteria and neurasthenia, gastric disturbances, syphilis, cough and bronchitis, chlorosis, etc., but none was present to any striking extent.

News of the Week.

Typhus Spreads in Moscow.—A dispatch from Moscow, under date of December 2, reports that there are more than 2,000 cases of typhus fever in the hospitals of that city. Three thousand new beds have been prepared for the reception of typhus cases. Advices from Astrakhan state that typhus fever, smallpox, cholera and "black death" have appeared there.

Is There a Shortage of Physicians in Connecticut?—The *New Haven Register*, commenting on a recent report, stating that there are only 1,600 physicians in the State of Connecticut and that forty-six towns are without a resident doctor, says it would be well to do a little figuring before worrying. It appears that there has been in the past ten years an increase of 12 per cent. in the number of doctors, while during the same time the population of the State increased 24 per cent. This should not be alarming in view of the fact that deaths from tuberculosis are decreasing and likewise the mortality from preventable diseases, and at the same time among the physicians who are left there are some remarkably competent ones. It is pointed out that some of these forty-six towns never did support a physician, and when they had one they worked him to death. It costs more to outfit a practice now than formerly it did. The inevitable result is that these towns must depend on service from the nearest city or large town, but with the aid of the telephone and the swift automobile it is probable that the smaller proportion of physicians goes further now than the larger one used to do.

Workmen's Compensation Law Revised.—The tentative recodification and revision of the Workmen's Compensation Law in this State has just been completed by a joint legislative committee, and for the purpose of study and criticism copies of the changes are being distributed. Public hearings are to be held in New York, Albany, and other places during this and next month, and the full revision is to be presented to the legislature early in February. This is the physician's opportunity to see that he gets the "square deal" under the new law.

Lebanon Hospital Surgical Fellowship.—A Surgical Fellowship amounting to $600 has been established at the Lebanon Hospital, New York, by Dr. A. J. Rongy. Each year three house surgeons graduate, and this fellowship will be awarded annually to the one who, in the opinion of the Medical Board, has had the best record during his entire term as a member of the house staff.

Industrial Hospital Advocated for Philadelphia.—Dr. W. R. Taylor, chief of the medical department of the Bell Telephone Company of Pennsylvania, in an address before the Philadelphia Safety Council, charges that existing hospitals in Philadelphia do not give proper attention or service to industrial cases. He proposes a chain of clinics in industrial centers with a central free hospital devoted to industrial cases. His proposal has been indorsed by the Chamber of Commerce and the Philadelphia Association of Industrial Medicine. Several insurance companies have indicated their willingness to lend aid to the project.

A Public Health Reference Library.—The attention of the physicians of the city is invited to the facilities of the Public Health Division of the Municipal Reference Library, on the third floor of the department's headquarters at 505 Pearl Street. In this library physicians interested will find a very up-to-date collection of books and pamphlets on public health matters, including preventive medicine. The resources of the library are at the service of the profession every day, except Sundays and holidays, from 9 to 5; Saturdays, 9 to noon.

Insurance Records Show 1921 Healthiest Year.—According to the records of thirty-seven leading American insurance companies, the year 1921 has been the healthiest in the history of both the United States and Canada. Among the striking things shown by the figures, which cover 27,000,000 persons, are that influenza has almost disappeared from the United States and Canada, and that pneumonia has decreased 50 per cent. from 1920. On the other hand, mortalities due to automobile accidents show a 15 per cent. increase, with an indication of 10,000 deaths from this cause. Homicides and suicides also show large increases, being four times more frequent than in 1920. In the first ten months of 1920 deaths numbered 205,941, for the same period this year only 184,860 deaths have occurred. This shows a reduction of 21,081 in the actual number of their death losses this year. About 28 per cent. of deaths during this year have been caused by cerebral hemorrhage, organic diseases of the heart, and Bright's disease. The report states that in the main these are diseases of the more advanced years. Therefore, the hope of further reducing the death rate must be sought in other causes of death, constituting 72 per cent. of the total.

Large Families Show Increase in France.—From this report it would seem that the decrease in population in France is not as serious as the world has been taught to believe. The statistics are especially interesting, as no families with less than nine children are eligible. The distribution of ninety prizes to the parents of the largest families under the terms of a trust fund created by the Chauchard family showed that, whereas last year only 24,000 families sought awards, this year more than 42,000 entered the lists. Several parents of eighteen, sixteen, and fifteen children have entered, chiefly from the southern departments.

Hospital Notes.—The Board of Estimate of New York City has authorized the construction of a city hospital at Walton and Gerard avenues, between 168th and 169th streets, The Bronx.

The Boone County (Missouri) Hospital, erected through a $175,000 bond issue by the people of the county, was formally opened on December 10.

A movement has been started to raise $500,000 for a general hospital to be located in Daytona, Fla.

Five counties in southeastern Arkansas have united to further a campaign to raise $75,000 for the erection of a hospital in that part of the State.

The Oklahoma County (Okla.) Tuberculosis Hospital has been completed and is ready for occupancy.

Dr. Henry F. Vaughan, Health Commissioner of Detroit, announces that the new $500,000 children's hospital, which is in the process of construction, will be ready to receive patients by March 1, 1922.

The new temporary Bristol (Conn.) Hospital was formally opened on December 4.

The contract has been awarded for the construction of the East Texas Hospital for the Insane at Rusk. The new building is to be erected at a cost of $30,000.

Secretary Mellon has approved the expenditure of $1,400,000 to provide a permanent hospital for ex-soldiers suffering from nervous and mental diseases, to be located at Palo Alto, Cal. The Public Health Service is at present operating a hospital on this site with a capacity of 550 beds. The new hospital building will accommodate 1,000 patients.

The Treasury Department announces that the work of remodeling the Roman Catholic Orphan Asylum in New York, which was purchased by the Government at a cost of $2,750,000, will be begun about the middle of December. According to the announcement, one of the reasons for beginning work at this time is to aid in relieving the unemployment situation.

Dr. Robert Snedeker has removed his offices to the National Bank Building, Broadway and Columbus Circle, New York.

Sir Arthur Pearson, widely known because of his work for the blind and founder of St. Dunstan's Training College for Blind Soldiers, was accidentally drowned in his bathtub on December 9. A deep wound over his temple indicated that he had fallen and struck the water tap, which rendered him unconscious, though death was probably due to drowning. Since becoming blind in 1914, he had kept no valet because he believed that a personal servant would be a stumbling block in the path toward blind efficiency which he strove so energetically and enthusiastically to teach. Sir Arthur enjoyed a wide reputation as a successful journalist, having founded the *Daily Mail, Daily Express,* and *Pearson's Weekly.* He followed these with *Tit-Bits, Home Notes, Pearson's Magazine, Royal Magazine, Novel Magazine, Rapid Review* and others.

Dr. Arthur J. Schwenkenberg of Galveston, Tex., has been decorated by the Greek Government for the part he has played in the Near East Relief, and particularly for his aid in constructing and superintending a hospital in Salonica.

Dr. Sterling Newton Pierce has resigned his commission as past assistant surgeon in the Medical Corps of the United States Navy and will practise medicine in Los Angeles, Cal.

Dr. G. Alder Blumer has resigned his position as superintendent of the Butler Hospital, Providence, R. I. He will be succeeded on January 1, 1922, by Dr. Arthur H. Ruggles.

Dr. E. E. Hodgin has been appointed chairman of the Indianapolis Board of Health.

Dr. Henry Heiman has removed his office to 125 West Eighty-sixth Street, New York City.

Dr. John R. Ransom of Keene, Tex., has been awarded the Greek Medal for distinguished service as a member of the Salonica unit of the American Red Cross.

Gifts and Bequests.—Mt. Sinai Hospital, New York, is the recipient of a bequest of $5,000, and the Hebrew Orphan Asylum and Montefiore Home, each $2,500, under the will of Mrs. Caroline Bookman.

By the will of the late Anna C. Nice of Philadelphia the sum of $5,000 is bequeathed to Jefferson Hospital.

By the will of the late Amelia Rice of Philadelphia the sum of $5,000 is bequeathed to the Jewish Hospital.

Through the generosity of A. Barton Hepburn of New York the Hepburn Hospital, Ogdensburg, N. Y., has received an endowment fund of $500,000. This is the third liberal gift Mr. Hepburn has made to this institution which bears his name.

Vacancies in the United States Public Health Service.—Examinations of candidates for entrance into the Regular Corps of the U. S. Public Health Service will be held January 9, 1922, at Washington, D. C., and San Francisco, Cal. Candidates must be between 22 and 32 years of age, and graduates of a reputable medical school. They must pass satisfactorily oral, written, and clinical tests before a board of medical officers. Requests for information or permission to take this examination should be addressed to the Surgeon General, U. S. Public Health Service, Washington, D. C.

Medical College and Hospital for Colorado.—Under a plan approved by the agents of the University of Colorado, 200,000 persons will be asked to subscribe $200,000 to make up the balance of $600,000 pledged by the State toward the construction of a hospital. The last legislature appropriated $400,000 to the fund and, by agreement, the Rockefeller Foundation will contribute $600,000. The plans include a medical school which shall be a part of the University of Colorado.

Obituary Notes.—Dr. WILLIAM LLEWELLYN BANER of New York, for twenty years visiting physician to St. Vincent's Hospital, died from cerebral hemorrhage on Dec. 9, at the age of sixty years. He was graduated from the College of Physicians and Surgeons in 1885, and was a Fellow of the American Medical Association and of the New York Academy of Medicine.

Dr. CHARLES WESLEY GORDON of Fort Wayne, Ind., died from a complication of diseases on Nov. 21, at the age of sixty-nine years. He was graduated from the Medical College of Fort Wayne in 1877.

Dr. B. LAWRENCE TALIAFERRO of Lynchburg, Va., chief physician of the Catawba Sanatorium, died in Roanoke on Nov. 21, at the age of forty-five years. He was graduated from the Medical College of Virginia in 1898, was a member of the ad-

junct faculty of the Medical College of Virginia, and formerly was on the staff of the Trudeau Sanatorium at Saranac, N. Y.

Dr. HENRY W. TERRELL of La Grange, Ga., a graduate of Emory Medical College, Atlanta, Ga., in 1892, died suddenly on Nov. 24, at the age of fifty-three years. He was a member of the American Medical Association, first vice-president of the Georgia Medical Association, and a former president of the Troup County Medical Association. He was also a member of the State Board of Medical Examiners.

Dr. ALBERT D. YORKE of Jamaica Plains, Mass., a graduate of the University of Vermont College of Medicine in 1891, died suddenly on Nov. 22, at the age of fifty-seven years.

Dr. ELIJAH W. LAWRENCE of Newark, N. J., a graduate of the Philadelphia University of Medicine and Surgery in 1863, died on Nov. 26, at the age of seventy-eight years.

Dr. WILLIAM S. CARRION of St. Joseph, Mo., a graduate of the Meharry Medical College, Nashville, in 1898, died on Nov. 15. He was a charter member of the Pan-Medical Association of the State of Missouri.

Dr. WILLIAM C. WATERS, a graduate of the Columbus (Ohio) Medical College in 1882, and a Civil War veteran, died at his home in Zanesville, Ohio, on Nov. 22, at the age of seventy-four years.

Dr. DAVID G. CURTIS of Chattanooga, Tenn., a graduate of the Homeopathic Medical College of Missouri in 1860, died on Nov. 26, at the age of eighty-six years.

Dr. ELIZABETH LILLIAN RADOM of Bridgeport, Conn., a graduate of the Woman's Medical College of Pennsylvania, Philadelphia, in 1915, died suddenly Dec. 2, at the age of twenty-nine years.

Dr. BERNARD A. O'HARA, of Waterbury, Conn., died at his home on Nov. 25, at the age of sixty-two years. He was graduated from Bellevue Hospital Medical College in 1882.

Dr. EDWARD AUGUSTUS BOGUE, a graduate of the New York Dental Surgery College, Syracuse, and of the Castleton Medical College, Vt., in 1857, died of pneumonia on Nov. 22, at the age of eighty-three years. He was a member of the Orthodontological Society of Great Britain, the International Society of Orthodontics, the New York Academy of Medicine, the American Academy of Dental Science, the American Society of Orthodontics and the New York Dental Society.

Dr. LOUIS E. NEWMAN of St. Louis died on Nov. 19, after an illness of more than a year, at the age of sixty-one years. He was graduated from Jefferson Medical College, Philadelphia, in 1883. He was a member of the American Medical Association and a former president of the St. Louis Medical Society.

Dr. GARRETT K. W. SCHENCK of Far Rockaway, N. Y., a graduate of the College of Physicians and Surgeons in 1901, shot himself because of suffering from cancer of the stomach, on Dec. 6. He was visiting physician to the Bradford Street Hospital, Coney Island, and to the Kings County and Rockaway Beach hospitals.

Dr. WILLIAM REID PRIME of New York, a graduate of New York University Medical College in 1879, died of heart disease at his home on Dec. 6, at the age of sixty-four years.

Dr. THOMAS E. KRUM of Reading, Pa., died on Nov. 22 at the age of sixty-one years. He was graduated from the College of Physicians and Surgeons of Baltimore in 1886.

Dr. HARRY KEISER WEILER of Delanco, N. J., died of apoplexy on Nov. 24 at the age of sixty-seven years. He was graduated from Hahnemann Hospital and Medical College, Philadelphia, in 1883.

Dr. DANIEL WUNDERLICH NEAD of Reading, Pa., died at Chambersburg on Dec. 1, at the age of sixty-three years. He was a member of the Berks County Medical Society and the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association. He was for many years associated with the medical department of the Pennsylvania Railroad. He was graduated from the medical department of the University of Pennsylvania in 1881.

Dr. JOHN JOSEPH MCLAUGHLIN of Philadelphia died on Dec. 1, at the age of fifty-eight years. He was graduated from Jefferson Medical College in 1891. He was a member of the Philadelphia County Medical Society and of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. CHARLES W. SWAN, a retired physician of New Haven, Conn., died on Dec. 2, at the age of eighty-three years. He served as surgeon on a warship during the Civil War and was graduated from Harvard Medical School in 1864. For many years he was secretary of the Massachusetts Medical Society.

Dr. LEWIS C. NEWMAN, a graduate of Emory University School of Medicine, Atlanta, in 1895, died at his home in Atlanta, Ga., on Nov. 30, at the age of fifty-three years.

Dr. LAWRENCE C. CARR of Cincinnati, a graduate of the Ohio Medical College, Cincinnati, in 1878, died suddenly from heart disease on Dec. 4, at the age of sixty-six years. He was one of five physicians from the North who volunteered their services to the Government during the yellow fever epidemic in Jacksonville, Fla., in 1888, and was interested in eradicating this malady from Cuba.

Dr. JOHN MCGINNIS of Springfield, Ill., a graduate of Rush Medical College, Chicago, in 1869, died suddenly of cerebral hemorrhage on Dec. 1, at the age of seventy-nine years.

Dr. PEARL M. SATER, a graduate of the Medical College of Ohio, Cincinnati, in 1893, died suddenly at his home in Hamilton, Ohio, on Dec. 1, at the age of fifty-two years.

Dr. JOHN LUTHER MCMILLAN of Red Springs, N. C., died of heart disease after a long illness on Nov. 8, at the age of sixty-six years. He was graduated from the University of Maryland Medical College in 1881. He was a member of the Maryland Medical Association and of the Southern Medical Association, and a Fellow of the American Medical Association.

Dr. JOHN J. GOODWILL of Laurel Hill, N. J., a graduate of the University of Virginia Department of Medicine in 1908, died of pneumonia on Dec. 2, at the age of thirty-six years. He served eighteen months overseas during the recent war, being in charge of an ambulance company in the St. Mihiel and Meuse-Argonne battles and regimental surgeon of the 312th Infantry.

Dr. D. WALTER STRAUB of Bethlehem, Pa., died on Nov. 29, following an operation for cancer of the stomach, at the age of sixty-six years. He was graduated from the Hahnemann Medical College and Hospital, Philadelphia, in 1877, and was a member of the consulting board of the State Hospital at Rittersville, and of the American Institute of Homeopathy.

Dr. MARVIN WALLACE VANDENBURG of Mount Vernon, N. Y., a graduate of the New York University Medical College in 1879, died on Dec. 9, at the age of seventy-eight years. He was a member of the American Institute of Homeopathy and a Civil War veteran, having been wounded at the battle of Gettysburg.

Dr. JOHNSON C. LINDSAY of Los Angeles, Cal., a graduate of the Miami Medical College in 1872, died on Nov. 23, at the age of seventy-seven years.

Dr. JOHN F. BUTLER, a retired physician who practised medicine for more than sixty-five years and a Civil War veteran, died at his home in Keene, N. H., on Nov. 30, at the age of ninety-one years.

Correspondence.

UNFITNESS OF THE MALE PRACTITIONER FOR TREATING WOMEN AND CHILDREN.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Allow me to enter a protest against the publication by a medical journal of the dignity and excellence of the MEDICAL RECORD of such an editorial as found space in your issue of Nov. 26, under the title, "More Vicious Legislation."

To quote the vulgar and inane remarks of Senator Reed of Missouri, remarks to which vigorous exception was taken by his senatorial colleagues, is unworthy of your columns.

To a brain capable of such an editorial only similar argument will appeal. May I ask that the writer will give me one instance of a male member of the profession who, at any time, anywhere, under any circumstances, gave as a reason for refraining from practice of the specialties of obstetrics, gynecology, and pediatrics, the absolutely theoretical nature of his knowledge of maternity and infancy? As a member of the profession who has, for thirty years, upon every possible occasion, endeavored to bring her brother practitioners to a realizing sense of their natural unfitness for these fields, the answer to this question will be to me of especial interest.

Seriously, it is a matter for rejoicing that at last, in the march of social and political evolution, a public fund (small though it be) for the amelioration of maternity and infancy, is to be administered by persons possessing not only the highest social and medical training, but also the inherited instincts of age-long motherhood.

INEZ C. PHILBRICK, M.D.

LINCOLN, NEB.

Mixed Tumors of the Parotid.—To the rather abundant literature of this subject has been added a graduation thesis by G. Roux, University of Montpellier, 1921. The author reports the microscopic finds in twenty-two cases. The research was inspired by Professor Forgue of the Surgical Chair, and was carried out in the Laboratory of Pathologic Anatomy.—*Le Bulletin Médical.*

THE NARCOTIC AGENT AND THE PHYSICIAN.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—At the meeting of the American Public Health Association, recently held in this city, it was officially decided that the present narcotic situation in this country was not a public health problem in the usual acceptance of the term, nor one which could properly be administered under rules and regulations laid down by lay and legal bodies having no scientific knowledge of the disease of drug addiction. The situation was decided by this important body to be one which demanded intelligent medical and police supervision and control—police control for the degenerate and the criminal, and medical control for the addicts who are not degenerate or criminal.

Following this declaration, the Weekly Bulletin of the Department of Health, City of New York, Nov. 19, 1921, publishes in full what may be described as a most remarkable thesis. This is entitled "New U. S. Treasury Rulings on Treatment of Drug Addiction," and reads as follows:

To Narcotic Agents in Charge and Others Concerned: In accordance with the recent decisions of the courts (summarized hereinafter in a footnote), *and the attitude of the medical profession on the subject generally, as indicated below*, [italics are mine] the provisions of M-Min. 2212, dated July 31, 1919, are hereby amended and the following provisions as to the proper procedure to be followed in the prescribing and dispensing of narcotic drugs are issued for the guidance of Narcotic Agents in Charge and others concerned. It should be borne in mind that these instructions must necessarily be general in their nature, as it is impossible to lay down an inflexible rule which will cover all cases; and that they are subject to modification through further interpretation of the law by the courts.

[Such interpretations and modifications of the law by the courts, it may be stated, are obtainable only at the expense and risk of the doctor after he has been placed in jeopardy for an alleged violation of these rules, according to the opinion of some official.]

1. *Use of Narcotics in the Treatment of Disease Without Reference to the Question of Addiction.*—Without reference to the question of addiction, a physician acting in accordance with proper medical practice may prescribe or dispense narcotics for the relief of acute pain or for any acute condition, such as influenza, pneumonia, renal calculi, broken limbs, etc.

[The court decisions summarized in a footnote, which consists of a whole page of closely printed matter, may not be criticised by a medical writer. Criticism may properly be offered, however, in the case of the acute conditions for which a physician is permitted to prescribe narcotics in the brief summary given above, which bears all the impress of being drafted by a legal rather than a medical authority. Medical men as a rule rarely use narcotics in influenza or pneumonia to any extent. In "broken limbs" the surgeon does so cautiously with full knowledge of their danger to his patient and with the possible reflection from their use upon the proper setting of the broken limbs for which he assumes responsibility. "Etc." is not sufficiently definite to discuss.]

2. *Use of Narcotics in the Treatment of Incurable Disease.*—A reputable physician directly in charge of bona fide patients suffering from diseases known to be incurable, such as cancer, advanced tuberculosis, and

other diseases well recognized as coming within this class, may in the course of his professional practice, and strictly for legitimate medical purposes, dispense or prescribe narcotic drugs for such diseases, provided the patients are personally attended by the physician, that he regulate the dosage, and prescribes no quantity greater than that ordinarily recognized by members of his profession to be sufficient for the proper treatment of the given case. Physicians will be held accountable if through carelessness or lack of sufficient personal attention the patient secures more narcotic drugs than are necessary for medical treatment, and devotes part of his supply to satisfy addiction. The physician should clearly set forth on each prescription the date issued, and the full name and address of the patient, and describe in indisputable terms the exact nature of the ailment for which issued. It would not be lawful under any circumstances to place in the hands of an addict, through prescription or otherwise, a sufficient quantity of narcotic drugs to last a week. In incurable and aged and infirm cases, geographically isolated, where it would otherwise work extreme hardship, and where there is no danger of maladministration or diversion to illegitimate use, the physician in charge may, at his own risk, upon obtaining permission from the Narcotic Agent in Charge of the District, prescribe or dispense a week's supply or more, safeguarding the same by placing it for administration in the custody of a responsible nurse or attendant. Accurate records must be kept of such prescribing and administration.

[In this paragraph the sufferer from incurable disease like cancer, advanced tuberculosis, and other such states, passes by insensible, if not unseemly gradations, into a combination, at the end, of sufferer and addict, and his physician from an alleviator of suffering into a potential maladministrator of narcotic drugs. These he has to give during this "last scene of all" *at his own risk* and *after obtaining permission* from the narcotic agent in charge of his district. In certain localities, this agent, it may be mentioned, has arisen to his present state through various adventitious circumstances such as the resignation, suspension, dismissal, indictment, and alleged murder of some of his immediate superiors and associates. This experience should qualify him to act with discretion in an office wherein he is given absolute and unappealable authority in dealing with the matter of narcotic drug prescribing and narcotic drug addiction in this city.]

3. *Use of Narcotics in the Treatment of Addiction Only.*—Mere addiction alone is not recognized as an incurable disease. It seems necessary, however, to divide the addicts not suffering from an incurable disease into two classes: (a) those suffering from senility, or the infirmities attendant upon old age, who are confirmed addicts of years standing, and who in the opinion of a reputable physician in charge, require a minimum amount of narcotics in order to sustain life; and (b) those whose addiction is not complicated either by incurable disease or by the infirmities attendant upon old age.

["Mere addiction alone is not recognized as an incurable disease." This prognosis, though given over the signature of R. A. Haynes, Prohibition Commissioner, approved by D. H. Blair, Commissioner of Internal Revenue, is the reverse of that given by the Health Commissioner of the State of New York at the hearing before Governor Miller on the Fearon-Smith narcotic drug bill, of which bill the new rules and regulations of the Treasury Department might pass for a replica. At this hearing the State Commissioner of Health testified that he had never seen a case of drug addiction which he could pronounce cured. Medical and lay opinion was so opposed to this bill, which would have forced compulsory hospitalization upon drug addicts in this State, that the Governor vetoed it. This mode of treatment has been repeatedly shown to be absolutely impossible and impractical of adoption under existing conditions.]

(a) Aged and Infirm Addicts.—Addicts suffering from senility, or the infirmities attendant upon old age, and who are confirmed addicts of years standing, for all intents and purposes, may be treated in the same manner as addicts suffering from incurable disease. In such cases, where narcotic drugs are necessary in order to sustain life, a reputable physician may prescribe or dispense the minimum amount necessary to meet the absolute needs of the patient. As in the treatment of those addicts suffering from incurable diseases, physicians will be held accountable if through carelessness or lack of sufficient personal attention the patient, by securing more narcotic drugs than necessary for his medicinal treatment, is able to devote part of his supply merely to satisfy addiction. In this class of cases the physician issuing the prescription should make a statement on the prescription to the effect that the patient is aged and infirm, giving age and certifying that the drug is necessary to sustain life.

(b) The Ordinary Addict.—It is well established that the ordinary case of addiction yields to proper treatment, and that addicts will remain permanently cured when drug taking is stopped and they are otherwise physically restored to health and strengthened in will-power. This bureau has never sanctioned or approved the socalled reductive ambulatory treatment of addiction, however, for the reason that where the addict controls the dosage he will not be benefited or cured. The good faith of the physician and the bonafides of his treatment in a given case will be established by the facts and circumstances of the case and the consensus of medical opinion with regard thereto, based on the experience of the medical profession in cases of similar nature. The following resolution passed by the Council on Health and Public Education of the American Medical Association at its meeting on November 11, 1920, is pertinent in determining the period over which narcotic treatment should be extended in purely addiction cases: "Be it resolved that the Council on Health and Public Education of the American Medical Association endorse the principle expressed in the California law (section 8½) which forbids the use of opium and its derivatives in the withdrawal treatment of those addicted to the use of these drugs for a period of more than thirty days after the commencement of the withdrawal treatment."

This bureau cannot under any circumstances sanction the treatment of mere addiction where the drugs are placed in the addict's possession, nor can it sanction the use of narcotics to cover a period in excess of thirty days, when personally administered by the physician to a patient neither in a proper institution nor unconfined. If a physician, pursuant to the socalled reductive ambulatory treatment, places narcotic drugs in the possession of the addict who is not confined, such action will be regarded as showing lack of good faith in the treatment of the addiction, and that the drugs were furnished to satisfy the cravings of the addict.

Doubtful cases, or those not falling within any of the above instructions, upon request, will be investigated and special instructions based upon the recommendations of the inspecting officers will be issued.

R. A. Haynes,
Prohibition Commissioner.

Approved:
D. H. Blair,
Commissioner of Internal Revenue.

Under these rules and regulations "good faith" is no longer a protection to the physician in the treatment of incurable disease or of drug addiction. For this there has been substituted in some localities the dictum of a "narcotic agent" whose business is to work up cases against the doctors and one of whom was credited with the statement that

he would put every physician out of business who was treating an addict. It was this which led up to conditions resulting in the death of Dr. Christian J. F. Laase, according to the belief of his family. A physician of the highest standing and a scientific student of drug addiction, Dr. Laase was indicted on the investigation of this agent. He was acquitted by a jury on the ground of his good faith in every phase of his practice. Despite all this he was warned he would practise further at his peril when freed of the charge. He died shortly after, a medical martyr—a fact which is inscribed upon his tomb.

In considering the resolutions indorsing the California law limiting the period to thirty days in which opium can be used in the withdrawal treatment of drug addiction, it will be noticed that no names are attached to the resolutions. The sponsors of a form of medical treatment so dogmatic as never to be seriously considered until it was evolved by the passage of a law, and which the U. S. Government has adopted as a specific, should in all reason be made known to the medical world. These names have probably been withheld because if published they would not be seriously received by real students of the subject of drug addiction. Incidentally they now carry no weight.

This set of new rules regarding restrictions upon the legitimate use and prescription of opium are as impractical as they are inhuman and oppressive, as well as conducive of gain to the smuggling traffic. This gain is exclusive of that which may arise from blackmail, oppression, and extortion; all recognized evils capable of development under existing drug laws.

JOHN P. DAVIN, M.D.

117 WEST SEVENTY-SIXTH STREET,
NEW YORK CITY.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, November 24, 1921.

The First Operation for Relapsing Appendicitis.—Sir Alfred Fripp, in supporting a vote of thanks to the chairman, Sir Charters Symonds, at the first meeting of the Physical Society held in London a short time ago, asked if it were not the case that the first operation undertaken for appendicitis in the relapsing stage had been performed by him and in Guy's Hospital. The chairman replied by a silent nod, but the editors of *Guy's Hospital Gazette*, thinking that it would be interesting to learn more of the matter, gives the following extracts from the original paper and from the Historical Summary given by Dr. Howard Kelly of Johns Hopkins Hospital. Howard Kelly, in his work on "The Appendix and Its Diseases," which opens with a complete history of the subject, thus writes of the operation for appendicitis in the relapsing form: "Charters Symonds, an Englishman, did what is undoubtedly the first internal operation for appendicitis, making a lateral incision without opening the peritoneum." He quotes from the paper in the Transactions of the Clinical Society, Vol. 18, which was read on May 9, 1885. He gives many of the details, including the remark that the suggestion came from Dr. Mahomed, and gives in extenso Mr. Symonds's comments as to the part he took in the undertaking as follows: "I believe I am correct in saying that this is the first case in which a concretion or calculus has been removed from the appendix vermiformis without at the same time opening an abscess, and the credit of whatever value rests in the procedure must be given to my lamented colleague, Dr. Mahomed, at whose suggestion the operation was undertaken, and who advocated the inguinal incision in opposition to that along the linea semilunaris proposed by myself." Referring to the original account, it is interesting to note that the patient was admitted into Guy's Hospital on July 16, 1883, under the care of Dr. Mahomed, and that the operation was performed on August 24, in the same year and not in 1885, as stated by Howard Kelly. Dr. Mahomed died from typhoid fever in 1884.

Official Definition of a Voluntary Hospital.—The British Voluntary Hospitals' Commission define such an institution thus: "An institution other than an out-patient dispensary managed by a responsible committee and wholly or mainly supported from voluntary sources, including income derived from endowments or investments, the object of which is to provide medical or surgical treatment of a curative character; an auxiliary institution such as a convalescent home being eligible for assistance only insofar as it increases the facilities of hospitals from which it receives patients.

Clinical Meeting of the Medical Society of London.—At a clinical meeting of this society held on November 14 Dr. F. J. Poynton and Dr. W. B. Maurice showed an interesting case of arachnodactyl with organic heart disease. The patient was a girl aged 16, and she showed some of the peculiar features of a heart affection. Both parents were healthy, and there was no history of miscarriage. At birth she was 22 inches in height and weighed 10-11 lbs. She was fed on patent food. At six years of age she had tonsillitis, and then a musical murmur was heard for the first time. Three years ago she had measles severely, and spinal curvature commenced at the same date. This improved greatly under massage and rest. Two years ago partial flexion of her fingers was noted by her mother, and there was a rapid growth of long bones, and this had persisted, being apparently confined to the bones of the upper and lower extremities, including the shoulder and the pelvic girdle. When she stood erect the tips of her fingers reached to within 4 inches of her knees. She had a feeble musculature. She was very nervous, but could do domestic work. The heart was hypertrophied and there was a loud musical systolic murmur. The present was the oldest case of the kind ever shown in this country.

Mr. I. Izod Bennett showed a case of dwarfism with congenital ocular effects. The child was aged 7. There was another child of 11, healthy, both parents were living and well, and there had been no still-births. When the patient's mother was four and a half months in pregnancy, she fell downstairs, and attributed to that accident the child's condition. The boy was very small at birth, but had grown steadily. The eyes were the only actual abnormalities discovered, except for the facial bones in the pterygoid region being undeveloped. With regard to the ocular condition, Mr. Affleck Greeves

reported the presence of nystagmus, right ptosis, and external strabismus. There was deficient upward movement of the right eye, and both eyes were microophthalmic. A dense persistent pupillary membrane covered both pupils, and the fundi were not seen. The condition of the eyes suggested an arrest of development in utero.

Honor for Dr. Adami.—Dr. J. G. Adami, late Professor of Pathology in McGill University Medical School and now Vice-Chancellor of Liverpool University, has been admitted to the freedom of the City of London, through the Patten Makers' Company.

Obituary.—William Stoker, F.R.C.S.I., Senior Surgeon to Jervis Street Hospital, Dublin, died in Dublin on the 14th of November. Mr. Stoker, who was one of the best-known surgeons and teachers of Dublin, and a native of that city, received his professional education and training at Trinity College, Dublin, and in the Royal College of Surgeons of Ireland. He was admitted Licentiate and Fellow of the Royal College of Surgeons in 1873 and shortly afterward appointed one of the surgeons to Jervis Street Hospital, a post which he held up to the time of his death. He was for many years a member of the Council of the Royal College of Surgeons of Ireland. In his early days Mr. Stoker was a distinguished athlete, and although at the time of his death he had reached the age of seventy-eight showed few signs of age.

While crossing a street of the West End of London on the evening of November 22 last, Sir Sidney Beauchamp was knocked down by a motor omnibus and killed almost on the spot. During 1919-20 he acted as medical officer to the British Delegation at the Paris Peace Conference and received his knighthood in the latter year.

1. The Action of Quinidine Sulphate in Heart Disease, to Abolish the Circus Movement of Auricular Flutter and Fibrillation.—Paul D. White, Harold M. Marvin, and C. Sidney Burwell review the literature in this subject and state that in May, 1921, quinidine sulphate was first given at the Massachusetts General Hospital in the treatment of disturbed heart action due to auricular flutter and auricular fibrillation. In five and one-half months 35 cases have been so treated, 33 cases of fibrillation and 2 of flutter. Of this number 25 cases, including one of flutter, have shown at least a temporary restoration to normal rhythm (71 per cent.). The duration of the normal rhythm has varied from a few hours to over four months, in the latter case still continuing. In several cases repeated courses have been given, in two cases a third case of quinidine succeeding when the first two courses had failed. The treatment is being found to be more successful than when first tried because the dosage is being increased in some resistant cases. Of the last 12 cases 10 have been restored to normal rhythm. During the course of these observations quinidine has been tried in all kinds of cases with auricular fibrillation, old and young, rheumatic, arteriorsclerotic and thyroid. There have been successes and failures no matter what the type or age. But heart failure and long duration (years) of the auricular fibrillation are definitely unfavorable factors. The effect of the drug has been tried in six persons with normal hearts and in one case of complete heart block. There was no obvious effect of the drug in these cases. The dosage has consisted of 0.2 of a gram of quinidine sulphate given at two and four P. M. on the first day, and then if the patient has shown no toxic symptoms or signs from these test doses, 0.4 of a gram has been given five times on the second day, and on each succeeding day until normal rhythm has been restored or until toxic symptoms or signs appeared. The total course dose has varied from 0.8 gram in a successful case to 15.6 grams in an unsuccessful case. The experience in this series of cases to date suggests that the digitalized cases are more apt to respond to the quinidine and that it is better not to give both drugs together. In the main there seems to be in most successful cases three beneficial effects: (1) relief from the palpitation of the abnormal rhythm, (2) general improvement, and (3) cessation usually of need of continuing digitalis therapy. Some patients, especially those with much heart failure, are little if at all benefited and in these the normal rhythm is but a transient result. Further study and report are required before the drug can be recommended for general widespread use.

3. Appendicular Lithiasis. Report of a Case Unique in the Annals of Surgery.—Horace Packard, in a search of the literature, has found no instance of appendicular lithiasis, approaching in size and hardness the one here reported. The patient, a man 51 years of age, presented no alarming symptoms, but a distinctly located focus of tenderness over the normal location of the appendix. At operation, on palpating the appendix and carefully separatnig the adhesions, an extremely hard substance was found associated with the appendix. Careful finger dissection delivered an appendix which showed a ragged hole on one side through which protruded a large stone or irregular shape and with apparently the hardness of porcelain. There were two concretions, one measuring 1.5 cm. x 0.6 cm., and a larger one weighing 8 grams, and measuring 4 cm. in length and 2 cm. in width at one end. Both concretions were found to consist of inspissated fecal material and an amorphous crystal deposit of bile salts in an irregularly concentric arrangement.

4. A Note on the Preservation of Cells in Spinal Fluid as Measured by the Cell Count.—C. J. Campbell, L. M. Davidhoff, and G. P. Grabfield state that it has long been taught that cells in the spinal fluid disintegrate so rapidly that such fluids must be counted as soon as possible after withdrawal in order to obtain accurate results. They have carried out a study from which it is apparent that if *nonpurulent* fluids be preserved at room temperature or in the ice-box and *well shaken before counting* the cell count will be correct for at least five days after withdrawal.

1. The Diagnosis of Latent or Incipient Diabetes.—James W. Sherrill reports a study in which glucose tolerance tests were carried out with analyses of the blood and urine glucose in 16 subjects with normal assimilation, 15 with impaired assimilation with negative family history, and 23 tests in relatives of diabetic patients. The results of these tests are discussed with reference to their diagnostic significance and their theoretical and practical value. The conclusion is reached that provisionally, at least, we may regard the sugar tolerance tests made by the Benedict method as the most delicate and reliable which we now possess for diabetes, in both the negative and the positive sense. When there is distinctly abnormal hyperglycemia after mixed meals, and when the ingestion of 100 grams of glucose produces an elevation of blood sugar which exceeds the normal in both height and duration, a definite diagnosis of diabetes is afforded. The observations reported in this paper furnish three grounds to support this view: (1) The remarkable number of positive tests of this character in families with diabetes; (2) the insensible gradations by which the slighter degrees of impaired assimilation are merged with the cases of alimentary glycosuria and of frank diabetes; (3) the existence of mild diabetic symptoms in a high proportion of the cases which react positively and which clear up under antidiabetic diet, and under no other treatment. In discussing the theoretical value of the tests, Sherrill points out that the number of diabetics recognized has been greatly increased by these tests. It is probable that diabetes is several times as prevalent as indicated by any statistics heretofore, and that the number of actual and potential diabetics in this country probably amounts to several millions. The number of cases to be classed as hereditary is vastly increased by these tests as compared with any statistics based on the family histories as taken by ordinary methods, and this family incidence could doubtless be enlarged if a greater number of relatives of each patient were examined. The test enables one to seek more remote primary causes of diabetes than has often been customary. When a patient, for example, complains of nervous shock or exhaustion, and glycosuria is found, one need not consider the diabetes as due to the recent nervous disturbance, but may rather regard the nervousness as a symptom of a latent diabetes, the true origin of which may be sought many years back in some infectious pancreatitis. The tests have a very practical value in that they furnish a clue for the clearing up of more or less distressing symptoms. The series of cases studied proves that diabetes need not reach the point of glycosuria to cause symptoms, but in the stage of simple hyperglycemia may be responsible for neuritis, neurasthenia, feelings of weakness and weariness, etc.; and one may suspect that even at this stage, it may sometimes predispose to retinitis, cataract, gangrene, furuncles and carbuncles, and other serious complications. It is important that persons with such complaints be tested for their blood sugar. The most important use of the test lies in prophylaxis. It is improbable that all the persons showing hyperglycemia will develop diabetes. Early warning and prophylaxis will probably reduce the number of cases of diabetes to a degree never thought possible before.

2. An Eruptive Fever of Unusual Characteristics in Infancy and Early Childhood.—Dr. David J. Levy presents a report covering some thirty cases of an eruptive fever of late infancy and early childhood, characterized by a period of high fever, generally from 103° to 104° F., with no remissions or very moderate remissions for a period of seventy-two to ninety-six hours, followed by complete defervescence by crisis, and during the early hours of the post-febrile period, the appearance of a macular eruption. The disease is readily differentiated from scarlet fever, measles, German measles and the fourth disease. It has shown no definite seasonal occurrence, although it has been most frequently observed during those periods when infection in general is most prevalent. Neither has there been any coincident relationship between the occurrence of this disease and outspoken epidemics of other eruptive fevers, so the writer has been unable to explain it as the atypical instance, such as may occur during any epidemic of some other current infection.

3. A Febrile Exanthem Occurring in Childhood (Exanthem Subitum).—Borden S. Veeder and T. C. Hempelmann. (See MEDICAL RECORD, Oct. 15, c. 16, p. 698.)

4. Observations on the Cast Treatment of Gonorrheal Arthritis.—Clyde W. Collings states that from December, 1914, to May, 1921, 517 patients suffering from gonorrheal rheumatism were admitted to the urologic service of Bellevue Hospital. These patients spent 6741 days in the hospital at a cost of $20,233 to the city of New York; these figures make evident the economic importance of this condition. Twenty-six patients were treated by casts. Among these no relapse of the rheumatism has been noted without a new attack of gonorrheal urethritis. The prognosis of treatment by casts depends somewhat on the duration of the arthritis before treatment is started. In none of these cases has ankylosis resulted or an arthrotomy for suppuration been performed. Careful attention to orthopedic principles is of the utmost importance in applying the cast. As soon as possible after removal of the cast the limb is given heat therapy. Various vaccines, serums, drugs and operation on the seminal vesicles have proved inefficacious in the writer's hands. The cast treatment wholly and immediately relieves pain and cures the patient.

5. Trigeminal Neuralgia.—S. L. Silverman claims to have discovered that the buccal branch of the inferior maxillary division, though affected very often in trigeminal neuralgia, is hardly ever diagnosed, and different from the supraorbital, infraorbital and mandibular branches, the "trigger zone" is vague and may sometimes give the impression that the neighboring nerves are the affected ones. For want of better language the writer calls this the "mirrored trigger zone." He claims further that deep alcohol injections are more difficult, and less certain, even in the hands of experts, than are well-placed peripheral injections. Since the buccal nerve is affected in nearly all cases of trigeminal neuralgia that have gone for a year or more, either it should be injected at the tip of the inner surface of the coronoid process, or it can be blocked a centimeter below and behind the mouth of Stenson's duct. Both points are reached intraorally. The extraoral method, however, is easier for the average physician to master. By this method the needle is inserted through the cheek beneath the most prominent portion of the zygomatic bone, and advanced backward to reach the inner surface of the tip of the coronoid process. One cubic centimeter of alcohol has been found to be sufficient. In a series of fourteen cases relief has been afforded by this method in every instance.

7. Modern Footwear as a Cause of Fatigue, Muscular Rheumatism, and Flat-Foot, with Notes on an Improved Type of Boot. S. D. Fairweather.

1. Presidential Address on the Medical Aspects of Some Urinary Diseases.—Thomas Horder, in this address, does not deal with any particular type of case, but brings out the importance of taking broad views of the pathology underlying several types. Cases of staphylococcus infection are of great importance, because of their frequent obscurity and also because of their great gravity. Both the urinary infection and the perirenal abscess that may develop are manifestations of a pyemia, and although prompt surgical measures are of the utmost value in draining foci when these are established, the main onus of treatment is medical in coping with the underlying septicemia. The mere discovery of microorganisms in the urine of a patient can no longer be regarded as indicating an infection within the urinary tract; this is sufficient to establish the thesis that all cases should be considered to have possible medical bearings until this is proved

not to be the case. Micro-organisms in the urine may indicate one of the following conditions: (1) A mere elimination of these from the blood stream without any urinary infection at all; (2) a focal infection at some point in the urinary tract; (3) a focal infection outside the urinary tract, but communicating with it either by gross continuity or by lymphatic spread; (4) a diffuse infection of the urinary tract; (5) that the urinary tract is a "carrier" of the microorganism, as seems the nature of some cases of bacilluria. With all these possibilities before one it is clear that a wide view should be taken of any case with which one has to deal.

2. Observations on Postural Proteinuria.—G. A. Harrison urges the importance of very careful investigation of cases of postural proteinuria lest a patient in the early stages of disease be allowed to pass untreated. Four cases are reported and data compared which lead to the following conclusions: (1) "True Proteinuria" probably never reappears in the recumbent position in cases of cyclic proteinuria. If proteinuria reappears while the patient is lying in bed an organic lesion should at once be suspected. (2) Posture appears to be an important factor in the causation, but not the only factor, because in three of the cases studied protein disappeared from the urine while still in the upright position. One of the cases is regarded as organic for the following reasons: Proteinuria occurred while recumbent on several occasions; a few granular casts and a few degenerate pus cells were found more than once; the patient, a boy 15 years of age, had an evening temperature of 99° to 100° Fahr., and a leucocytosis of 21,600, for which no cause was found unless it was kidney disease; occasionally the boy passed large amounts of protein. (4) The albuminuria of a small organic kidney lesion may be postural in type, or in other words, the amount of protein may fluctuate in organic albuminuria so as to simulate a condition of functional cyclic albuminuria. (5) It is possible that in certain cases of mild organic disease of the kidney (or other part of the urinary tract) the proteinuria is postural in type simply owing to the drainage of the foci of disease in the erect attitude. (6) The fact that in postural proteinuria the "albumin" may appear, then disappear, and then reappear (the erect posture being maintained throughout) should make one very chary of claiming cures as a result of any particular treatment.

3. The Essential Causes of Adenoids and Their Association with Rickets.—H. Merrall claims that the chief cause of adenoids, excluding the exanthemata, is the mainly disregarded frequently recurring colds. A nasopharyngeal catarrh results which extends into the alimentary tract and affects both digestion and assimilation. Hitherto the cause of rickets has in the main been held to be dietetic. Even if the two conditions are separate and distinct—about which there is at least an element of doubt—the gastric disturbances and defective assimilation held to be the causes of rickets may be due to the catarrhal condition of the mucous membrane lining the alimentary tract, rather than to starchy food. Extension of catarrhal inflammation into the stomach and intestines accounts for many of the symptoms of both adenoids and rickets, and has, in the writer's opinion, a much more pernicious influence than that caused by the swallowing of infected mucus. Such a catarrhal condition of the alimentary tract leads to exaggerated lymphocytosis, and the swollen lymph glands rapidly lose their protective influence owing to fibroid changes. The swallowing of large quantities of infected mucus causes a drain on the system from over-production of lymphocytes which causes anemia. At the same time, there is the abnormal secretion of the connective tissue element containing mucin and a lessened alkalinity of the blood.

7. Modern Footwear as a Cause of Fatigue, Muscular Rheumatism, and Flat-foot.—S. D. Fairweather states that when the heels are raised even a quarter of an inch from the ground the center of gravity is thrown forward, the plumb-line falling opposite the crown of the arch or even further forward, according to the height of the heel from the ground. In healthy feet the higher the internal malleolus is naturally from the ground the easier it is for the internal malleolus group of muscles to do their work, getting as they do a straighter pull than when the malleolus is low down. Artificially raised heels might therefore be expected to make the work easier, and this would undoubtedly be so were it not that the center of gravity is thrown forward, giving the muscles too much *constant* work. To relieve the strain of a misplaced center of gravity the feet are instinctively splayed, with the result that the muscles capable of making the arch strong and elastic are prevented or discouraged from acting effectively. To prevent and cure flat-foot and the other evil effects of heels, the boots should be so constructed that the metatarso-phalangeal joint of the big toe, all the toes, the outer side of the sole, and the heel shall rest on one place parallel to the ground. Under the arch of the foot the sole should be curved with the convexity upward and should be fairly flexible. The leather sole should conform to the natural shape of the foot, and the heel and sole must be of the same thickness. The mode of walking with this type of shoe is quite different from the modern artificial walk. Such a shoe is now on the market. A series of exercises for the correction of flat-foot is outlined.

2. An Investigation into the Circulation through the Lungs.—S. W. F. Underhill has imitated in animal experiments, as far as possible, the condition of embolism of one main branch of the pulmonary artery as it occurs in man, in the hope that new light might be thrown on the circulation in the lungs during collapse or consolidation. He summarizes his experiments as follows: (1) Ligature of the left pulmonary artery in cats (with the chest open and under artificial ventilation) causes a rise in pulmonary blood pressure of from 25 per cent. to 60 per cent., usually about 40 per cent. There is no effect on the carotid blood pressure, pulse rate, output of the heart, or its state of dilatation. (2) The healthy heart, therefore, can accommodate itself without difficulty to sending the same volume of blood through one lung only in a given time, as it previously sent through both. (3) No mechanism producing slowing of the heart from rise of pulmonary blood pressure was demonstrated in these experiments. (4) If the chest is closed after the artery has been ligatured, the animal remains in good condition—in fact, frequently its condition is improved. Its respiratory rate is usually faster than normal, frequently about double, but the depth tends to be shallow. (5) The saturation of the blood after ligature is about 75 per cent.; if the artificial ventilation is increased (within normal limits), complete saturation can be obtained. This has not been the case, however, with animals in which the chest has been closed and the artificial ventilation discontinued; in these the saturation remains at about 70 per cent. (6) Examination of the lungs shows an increased quantity of blood in the right lung, due to twice the normal volume flowing through it in a given time. The left lung after ligature of the left pulmonary artery, under artificial ventilation, contains almost no blood, except a little in the veins; on the other hand, after the chest has been closed and the animal allowed to breathe naturally, it contains usually more blood than the right lung, exhibiting a varying degree of congestion. This blood comes from the bronchial arteries and stagnates in the pulmonary capillaries. (7) Ligature of the right bronchus (in cats with the chest open and under artificial ventilation) causes a small immediate rise in pulmonary blood pressure without affecting the carotid pressure. (8) The saturation of blood has always been under 90 per cent., even when the artificial ventilation has been increased. (9) There is, therefore, presumably still a certain amount of cir-

culation through the right lung under these conditions.

5. Discussion on Hemochromatosis.—John Shaw Dunn describes this condition, which is characterized by accumulation of free iron containing pigment in certain parenchymatous organs and in the skin, associated with interstitial fibrosis of the liver and pancreas; in a certain number of cases glycosuria develops (bronzed diabetes). The earlier stages of the condition, so far as is known, are unassociated with any symptoms, and for any information in regard to them we are dependent on accidental post mortem findings in patients dying from other maladies. Three such cases are reported and the question brought up as to whether the pigmentation or the cirrhosis is the primary factor in the hemochromatosis. So far as these cases show anything neither factor is causative of the other, and presumably the two are due to some third unrecognized cause. Chemical analyses of the organs in hemochromatosis have thrown a certain amount of light on the pathology of the disease. In advanced cases of hemochromatosis there is no evidence of alteration in the total amount of iron in the blood, while the excess in the organs is very great. It is not exceptional for the iron in the liver to amount to 7 per cent. of the dried substance of the organ, that is about 100 times the normal percentage, and for the total amount of iron in the liver to exceed 30 grams. Considering the large size of this organ, it no doubt contains a large proportion of the total iron in the body, but the amount present in others is not negligible. If one considers the liver alone, and estimates the iron in the diet at 30 mg. a day—a figure well in excess of the known analyses—it would then take 1000 days for the accumulation of the 30 grams in the liver, assuming that none was excreted. From the few observations made on the iron metabolism in hemochromatosis it would seem that the period during which we must assume that a part of the alimentary iron undergoes retention must be greatly lengthened to explain the conditions found in advanced hemochromatosis. As regards the immediate source of the iron in the viscera in hemochromatosis, it was at first assumed to be derived from an excessive breakdown of hemoglobin in the blood, on the analogy of pernicious anemia and other hemolytic conditions where free iron is deposited in the organs. However, in the majority of cases of hemochromatosis which have been described, there has been no important alteration in the blood, and where the bone marrow has been examined it has shown no compensatory hyperplasia such as accompanies severe anemias. Certain observers have noted excessive fragility of the red corpuscles in their cases, but this cannot be taken as proof that *in vivo* the red corpuscles were being destroyed more rapidly than normal. The condition in hemochromatosis is very different from that in pernicious anemia, and even if the iron which accumulates in the viscera has first passed through the form of hemoglobin there is still some unrecognized factor which causes it to be retained in the system.

W. H. Maxwell Telling also writes on this subject. He says it is still an unsettled question whether hemochromatosis is a separate disease or just a stage of development of certain forms of cirrhosis of the liver. The tendency at present is to regard it as a separate morbid entity. He calls attention especially to the fact that there is little in the English medical literature about the disease, and that it cannot be doubted that many cases escape recognition owing to the disease being relatively unknown as well as rare. By placing early cases on record, particularly with the striking eventuation in malignant disease, more general attention will be directed to the disease, which will then probably be found to be less rare.

8. The Blood Picture in Scurvy, with Particular Reference to the Platelet.—S. Phillips Bedson reports that in scurvy produced experimentally in guinea-pigs and monkeys and in one human case the platelets were found to be normal in number. It is possible that very transient fluctuations in the platelet count occur in scurvy, and that it is during this period of platelet deficiency that the hemorrhages occur. It is hardly conceivable, however, that in making a comparatively large number of platelet observations such fluctuations should have been completely overlooked. Demmer cites a case of purpura hemorrhagica in which fluctuations in the platelet count, preceding the outburst of hemorrhages, occurred in a most regular manner. The red cells in some of the writer's cases showed an increase in number, this condition coinciding with a "prescurvy" or incipient scurvy stage. No variations in the total and differential leucocyte count were observed.

5. The Nucleus in the Human Restiform Body. K. Hirose.

1. The Swelling of the Arm After Operations for Cancer of the Breast—Elephantiasis Chirurgica—Its Causes and Prevention.—William Stewart Halstead for many years has held the view that although blocking of the lymphatics and occasionally also of the veins was the underlying factor in causing swelling of the arm (sometimes a year or more after operation for cancer of the breast) infection played a conspicuous part in the determination of the amount of the swelling and the time of its manifestation. From observations in his own clinic and from the testimony of surgeons elsewhere he has been led to conclude that swelling of the arm follows the plastic operations in greater proportion and in more pronounced form than is seen in the cases treated by skin grafting. A study of cases operated on by the newer method has brought out the fact that the excision of the axillary and supraclavicular glands plus resection of the subclavian and axillary veins is rarely followed by noticeable swelling of the arm. On the other hand, it cannot be denied that obstruction of these lymphatics and venous channels might conceivably alone, without infection, suffice occasionally to produce a moderate amount of edema. But it is assuredly impossible to assert in any case that infection has played no part in the swollen arm. It is therefore important to discard operative methods which clearly predispose to infection, quite aside from the fact that these methods—the plastic ones—tend to deter the surgeon from sacrificing a sufficient amount of skin or, if perchance enough skin has been excised, to increase the danger of swelling and of restricting the range of movement of the arm. A recent search of the records of the Johns Hopkins Hospital for cases of swollen arm following operation for cancer of the breast supports the above views. If this view as to the cause of swelling of the arm following operations on the axilla should prove to be correct the term *surgical elephantiasis* might be an appropriate one. The writer reviews the clinical and experimental evidence bearing on the part played by streptococcal infection in the production of elephantiasis and elephantoid conditions as summed up by Matas, who says, "Lymphatic stasis, by itself, does not cause elephantiasis. The obstruction may cause lymph edema, but not a true hypertrophy of the edematous tissues. If an inflammation (infection) is acquired in a closed area of lymphatic congestion, an event which may result as the consequence of the slightest traumatism, elephantiasis will then develop."

4. Studies on Some of the Non-Lipoid Components of the Blood in Relation to Its Antihemolytic Properties.—Hallie M. Clark, Rhea H. Zinck, and Frank A. Evans, in this study of a substance or substances in the blood serum upon which the protective power against hemolysis depends, conclude as follows: (1) Treatment of serum which alters the physical state or removes all or a part of the proteins diminishes the protective power of the serum against hemolysis by sodium oleate and saponin. (2) Calcium alone is not the substance in serum upon which the protective power of the serum against hemolysis by sodium oleate and saponin depends. (3) Dextrose and soluble starch have no power

to protect against hemolysis by sodium oleate and saponin *in vitro*, and probably, therefore, carbohydrates exert no such influence in the blood. (4) Boric acid added to serum diminishes the protective power against hemolysis by sodium oleate, but does not influence the protection against hemolysis by saponin.

5. **The Nucleus in the Human Restiform Body.**—K. Hirose describes a nucleus which he has found in the restiform body of the human brain. Tracing the transverse section of the brain from below upward, the nucleus appears where the vago-glosso-pharyngeal root begins to disappear, and disappears where the accessory auditory nucleus begins to appear. This nucleus is found at the dorso-medial part of the restiform body on transverse sections, and extending in an elongated shape in the medulla oblongata. The nucleus has no definite shape and shows a considerable amount of variation in growth. On transverse section, the transections are different in form. Some have a hilum extending toward the medial direction, while the others present themselves as long masses extending from the dorso-medial direction to the ventro-lateral. Some of them also show the incomplete hilum-like parts in them, whereas others show only round masses. The nerve cells of the nucleus are practically identical in shape with those of the inferior olive. The nucleus is probably a portion of the inferior olive.

2. **Infection with Flagellates.**—Elliott C. Prentiss states that in the Southwest patients harboring the *Trichomonas intestinalis* and other flagellates are very frequently seen, in fact, form a very considerable percentage of all patients seen by a physician limiting his practice to gastrointestinal work. In the last 112 patients seen by him, and whose feces were examined microscopically, twelve, or 10.7 per cent., had this infection. It is probable that these infections become more common as one goes further south. While many persons may harbor these organisms and never have any symptoms resulting from them, they certainly can, under conditions which we do not yet fully understand, produce a very severe catarrh of the whole intestine, which may even end fatally. When bacillary dysentery is suspected a culture of the feces should clear up the doubt. To confirm the diagnosis, administration of drugs injurious to the flagellates should quickly put a stop to the diarrhea, while it would not do so in cases of amebic dysentery, unless large doses of bismuth were given. While the diarrhea is usually stopped by the administration of methylene blue, bismuth, and other drugs, it is quite another matter to get rid of the parasite completely. The copper salts are extremely injurious to the flagellates, being fatal to them in a dilution of 1 part to 5,000,000 at least, and probably as high as 1 to 20,000,000. The writer uses the arsenite and gives it in doses of 1/100 to 1/50 of a grain three or four times daily. It usually has a decidedly good effect therapeutically, but does not kill all the parasites, as it is apparently readily absorbed and does not satisfactorily reach the organisms adhering to deep folds of the mucous membrane. Calomel he has used in a number of cases, two of which he reports, and while a cure was not obtained, the parasites were reduced in number and the toxemia was much benefited. He has not been able to kill all the parasites by means of hypertonic saline solutions given by duodenal lavage, as recommended by Dr. Anthony Bassler.

4. **Two Cases of Leprosy Cured by Anthrax Vaccine.**—J. N. Roussel reports two cases of clinical leprosy, in one of which the acid-fast bacilli were found, while in the other no bacilli were found. Both were clinically cured by the hypodermic use of liquid anthrax vaccine, administered for several weeks at intervals of four days. The writer does not claim that the use of anthrax vaccine in leprosy is original with him. It was first suggested by Dr. Campos of the State of Colombia in South America, who in turn does not claim originality. Whether the vaccine will cure all cases of leprosy remains to be seen, but that it will cure some there is no doubt in the writer's mind.

Brazil Medico.

Vitamine-Hormone Deficiency.—Riedel calls attention to dysharmonies in laboratory experiments along this line of investigation. Deprivation of the so-called vitamine of rice cortex may cause a beriberi syndrome in one genus of animal and a scorbutic syndrome in another. If the withheld substance is fed back to the animal, beriberi is relieved while scorbutus is not affected. These demonstrations by a Bahia physician whose essay was awarded a prize in 1917 seem to have passed unnoticed. Here is clearly evidence of the existence of specific deficiencies, showing the fallacy in reasoning from the behavior of one animal to that of another, and of hasty generalizations. We may speak, as the author does, of an Eijkmann's disease of pigeons and fowls due to withholding rice cortex, but not of a general condition affecting birds, mammals, and man due to the same cause. This specificity of action tends to make the subject one of biochemistry in which the molecule of the socalled vitamine must be studied in relation to the peculiar metabolism of the animal tested. Different animal species doubtless split off different aminoacids from their food; perhaps also the endocrine products of different species differ among themselves. Certain experiments appear to show that the endocrines are involved in the mechanism of deficiency diseases. In simple inanition there is a formation of various antienzymes, as shown by Abderhalden's reaction, evidently an expression of a defense reaction. These antienzymes have also been found in experimental scorbutus. The author has recently obtained positive reactions in pigeons with beriberi for liver, thyroid, and adrenal tissue. There is evidence that thyroid substance can antagonize fowl polyneuritis.

Hygiea.

October 31, 1921, lxxxiii, 20.

Mercurial Angina.—Almkvist states that formerly mercurial angina and mercurial stomatitis were considered together and that certain old clinicians such as Oppert and Dieterich gave full accounts of the former. At the present day there is but little literature on the subject. A general bibliography of works consulted by the author since 1860 shows but few specific accounts of mercurial angina. In 1908, Glawsche, a Russian, and Lanz, also a Slav, each published one. These were succeeded by a third by Magnus Möller (1911) and a fourth by the present author in 1912. Writers on diphtheria and Vincent's angina sometimes mention the mercurial form in differential diagnosis. The author has found notes of twenty-six cases since 1906. The angina is simply the same process as mercurial gingivitis with a different localization. The process apparently starts with infection of the tonsillar crypts by albumin-decomposing bacteria, just as the gingival lesion originates in the similar infection of gum pockets. The contents of the crypts and pockets in question are identical, and in both concrement formation may occur. Spreading of the infection and ulceration are seen in both conditions. Finally the treatment is identical—disinfection of the tonsillar crypts, as ordinarily carried out on the gingival pockets.

Arsenic and Tar Cancer.—Epithelioma in paraffin workers is naturally grouped with the same lesion in coal tar and wood tar workers; but since it has been shown that tar contains arsenic it must be proved that the latter is not responsible.—*Annales de Dermatologie.*

Book Reviews.

ELECTRO-THERAPEUTICS FOR PRACTITIONERS. By FRANCIS HOWARD HUMPHRIS, M.D. (Brux.), F.R.C.P. (Edin.), M.R.C.S. (Lond.), etc., etc. Second Edition, Revised and Enlarged. New York: Oxford University Press, American Branch, 1921.

THE original edition of this work appeared in 1913 and comprised 243 pages. The present volume contains an even 300, and comprises new chapters, including those on "Galvanism, Faradism, and the Sinusoidal Currents" and "Radiotherapy." The seven chapters on Static Electricity have been but little abbreviated. This amount of space seems disproportionate, for a single chapter covers the entire subjects of galvanism, faradism, and the sinusoidal currents; a single chapter covers diathermy and radiotherapy, respectively. There is but one chapter on phototherapy, and high frequency electricity receives no separate discussion, being covered in part under diathermy. Of the 30 chapters in the book, 16 are devoted to the treatment of disease and unusual modalities in treatment receive consideration under this head.

INFECTIONS OF THE HAND A Guide to the Surgical Treatment of Acute and Chronic Suppurative Processes in the Fingers, Hand, and Forearm. By ALLEN B. KANAVEL, M.D., Assistant Professor of Surgery, Northwestern University Medical School; Attending Surgeon, Wesley and Cook County Hospitals, Chicago. Fourth Edition, Thoroughly Revised. Illustrated with 185 Engravings. Price $5.50. Philadelphia and New York: Lea and Febiger, 1921.

THE title of this book is well chosen; it explains exactly what the book contains. It is a veritable "guide to the surgical treatment of acute and chronic suppurative processes in the fingers, hand, and forearm." The author's work is based on a thorough anatomical foundation reinforced by an ample clinical experience. The anatomical sections are of special value and show the relations of the various fasciæ, synovial sheaths, and tendons; the lymphatics of the parts are also thoroughly exhibited. These are all well illustrated by numerous cross-sections of each finger separately, and of the hand and forearm. The value of this work to the surgeon is obvious, but there are others who would do well to make themselves acquainted with it; such are physicians employed in places where the employees are liable to accidents involving the hands, and all who are interested in the questions of re-education and restoration of function after infections of the hands. The outstanding characteristics of this book are its practical character, its thoroughness, and its tone of authority.

INDISPENSABLE ORTHOPÆDICS. By F. CALOT, Chief Surgeon to the Hôpital Rothschild, Hôpital Cazin, Hôpital du Departement de l'Oise, Institut Orthopédique de Berck, etc. Second English Edition, Seventh French Edition. Translated by A. H. ROBINSON, M.D., M.R.C.S. Two Volumes. Price $14. St. Louis: C. V. Mosby Company, 1921.

THESE volumes present a rather unusual contrast to present-day medical literature in that they are emphatically the expression of the author's personal opinions alone. The views of others who possibly might be regarded as his peers are either ignored or mentioned only to be rejected. The reviewer cannot but feel that the occasional recognition by name of the originators of various operative and therapeutic procedures of which Doctor Calot makes use would have been an acknowledgment which might have mitigated somewhat the acerbity of his comments upon the methods which he discards.

The construction of the work is loose and its style colloquial. The emphasis throughout is upon therapeutics, while etiology and diagnosis are rather summarily dismissed. The first volume is practically entirely devoted to bone tuberculosis and its treatment by plaster of Paris apparatus at Berck sur Mer. The operative treatment of Pott's disease is not mentioned. The second volume is expansive upon congenital dislocation of the hip, and dismisses scoliosis, Little's disease, clubfoot, fractures, etc., very briefly. In the chapter on acute chronic osteomyelitis there is no reference to the Carrel-Dakin treatment.

The book is frankly written by a specialist for the general practitioner, and thus, perhaps, Dr. Calot has included only such material as he feels his audience qualified to digest. From the practitioners' standpoint the details of the technique of the proper application of plaster retention apparatus and the conservative treatment of bone and glandular tuberculosis cannot but be of value. No advocate of rest, fresh air, and sunshine can lead one very far astray. To the specialist the book will be of interest as an exposition of the views of an authority in whose mind plaster of Paris and orthopedics are practically synonymous.

THE CLINICAL EXAMINATION OF THE NERVOUS SYSTEM. By G. H. MONRAD-KROHN, M.D. (Shristiania), M.R.C.P. (Lond.), M.R.C.S. (Eng.), Lecturer in Neurology at the Royal Frederick University, Christiania; Physician to the Neurological Section of the State Hospital, Christiania; also in charge of the Hospital's Out-Patient Department for Nervous and Mental Diseases. With a Foreword by T. GRAINGER STEWART, M.D., F.R.C.P., Physician to Out-Patients, National Hospital for the Paralyzed and Epileptic, Queen Square; Physician to the West London Hospital; Physician to the Central London Ophthalmic Hospital; Neurologist to the Special Surgical Hospital (Ministry of Pensions). Price six shillings. London: H. K. Lewis & Co., Ltd., 1921.

IN this little book the author describes the routine method of examination which he has used in his neurological clinic; he also gives an outline of the various clinical tests which he has found to be the most serviceable. Some such method as this is absolutely necessary for the practitioner; and this is particularly so in the case of nervous and mental diseases. The author is careful to emphasize the importance of clinical work; by this alone can proficiency be obtained. He assumes that the student of neurology is also a student of psychiatry, and he, therefore, includes an outline of the examination of the mental state of the patient. An unusually complete index renders the contents of the volume readily available.

DIAGNOSTIK UND THERAPIE DER LUNGENTUBERKULOSE. Von HEINRICH GERHARTZ. Dritte, verbesserte Auflage. Price, 72 marks. Berlin and Vienna: Urban & Schwarzenberg, 1921.

THE first edition of this work appeared in 1913 and the second, issued the following year, was merely a reproduction of the first due to unexpected exhaustion of the latter. The present edition contains considerable new material, both personal and alien, while many sections have been completely rewritten. There are nearly 300 pages of text with 67 text illustrations and 16 colored plates and radiographs. One hundred and forty pages are devoted to diagnosis and 143 to treatment, including a list of the leading sanatoria.

ROENTGEN INTERPRETATION—A MANUAL FOR STUDENTS AND PRACTITIONERS. By GEORGE W. HOLMES, M.D., Roentgenologist to the Massachusetts General Hospital and Instructor in Roentgenology, Harvard Medical School; and HOWARD E. RUGGLES, M.D., Roentgenologist to the University of California Hospital and Clinical Professor of Roentgenology, University of California Medical School. Second edition; thoroughly revised; illustrated with 184 engravings. Price, $3.25. Philadelphia and New York: Lea & Febiger, 1921.

IN its second edition Holmes' and Ruggles' Roentgen Interpretation presents a moderate enlargement and some revision and correction of the few imperfections presented by the first edition. A conspicuous change is the addition of arrows pointing out the site of pathology in those illustrations where the novice may mistake the lesion. The already extensive bibliographic list that characterized the first edition is in many cases considerably augmented.

The authors modestly claim for their book the presentation of essentials of roentgen interpretation in a comprehensive and compact form for those seeking a working knowledge. It is manifestly obvious that their claim has been met; and those who master the principles outlined in the text, and who refer with diligent study to the bibliography, will acquire a sound and intensive training from which only expert *x*-ray ability can result.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held November 17, 1921.

THE FIRST VICE-PRESIDENT, DR. CHARLES H. PECK, IN THE CHAIR

THIS meeting was held under the auspices of the Section on Medicine.

Exercise in the Treatment of Hypertension.—Dr. C. WARD CRAMPTON made this presentation, which was illustrated by lantern slides. He defined hypertension as a symptom rather than a disease, a hypertonic state of the bloodvessels, particularly those of the smaller caliber. This state was a physiological reaction of the bloodvessels to vasotonic influences which were usually toxic and acted directly upon the arteries or indirectly through the nerves. These vasotonic influences were in turn caused by (1) infections; (2) enterogenous poisons; (3) exterogenous poisons; (4) strains; (5) metabolic and endocrine (primary and secondary) disharmonies. There were two stages of hypertension, namely, the functional and the structural. Hypertension might be complicated or uncomplicated. The treatment of hypertension should be directed toward: (*a*) The hypertension, for it in itself might do harm; but no greater mistake could be made than to treat the hypertension alone. (*b*) The associated diseases of the arteries, kidneys and heart and the nervous system. (*c*) The sources of the symptoms and diseases, as mentioned in the five classes above. The errors to be avoided were: (1) Treating the symptom and neglecting the underlying pathological process. (2) Treating the pathological process and neglecting the patient. (3) Giving up in despair. (4) Relying on any one drug or even on any one line of treatment. (5) Fads, cranks, electricity, exercise, as panaceas. Before treatment there must be a thorough medical search of the whole patient, and one should not rest content with the finding of but one cause. There must be a thorough search of the daily life, including diet, rest, exercise, habits, particularly sex habits, etc. This should include a thorough testing out of the circulation. The information that could be gained of the heart and arteries with the patient at rest is incomplete; functional tests serve to reveal more of the probable future of the circulation. The tests used were carefully graduated loads, such as the Barringer test, and those of Schneider, Sewell and Crampton. The various procedures to be used in the treatment of hypertension include drugs, surgery, electricity, psychotherapy, massage hydrotherapy and exercise, diet and rest. Exercise, Dr. Crampton pointed out, was used less than it should be because of the relative unfamiliarity of physicians with the subject, the ignorance of physical training teachers despite their extravagant claims, and the apathy and absorption of the patient. The dangers incurred from exercise not regulated and restricted with sufficient care were (*a*) increase in tension; (*b*) fatigue or excitement beyond repair ability of the body to perform; (*c*) increase of an existing pathological process. Dr. Crampton then described and showed illustrations of typical exercises, including bed exercises, breathing exercises, anti-constipation exercises and recreative exercises, and stated most emphatically that while exercise was an important element to be considered in the treatment of every case showing hypertension, under no circumstances should it be put forward as a treatment sufficient in itself or even as the most important element in the treatment of the case. However, it had a place in the treatment of most cases of hypertension and in some cases a very large place; its omission was frequently the only barrier to recovery. Dr. Crampton's favorite prescription was for from three days to three weeks in bed and the use of purges, salines, vasodilators, digitalis, atropine, thyroid and radium according to indications. Important points to consider in prescribing exercise were: (1) A clear understanding of the results desired from the exercise; (2) selection of the best exercise adapted to the purpose in view; (3) clear and explicit instructions to the patient as to all the details, laying special emphasis on breathing with effort to prevent closure of the glottis, intervals of rest, intervals of breathing exercises. Exercises should be varied, mixing games and formal work and an endeavor should be made to supply the patient with motives and incentives to exercise. To this end the assistance of others—competitors, masseurs, teachers—should be enlisted. The further advanced the disease the milder the exercise should be. In the earlier stages the full program of the adult should be used: 1. Morning exercise, twelve minutes. 2. Walk three-quarters of an hour. 3. Vigorous exercise with sweating three times a week. 4. In the open half a day. The results of systematic carefully prescribed exercise were: 1. Decrease in diastolic blood pressure and later in systolic blood pressure. 2. Improvement of muscular tone. 3. Improvement of digestion and nutrition. 4. Improvement in posture. 5. Improvement in arterial state. 6. Improvement of myocardium. Improvement of *psychological* state. As an illustration of the results brought about in hypertension, Dr. Crampton cited the case of a man sixty-eight years of age who had a systolic blood pressure of 240 to 200 mm. and a diastolic pressure of 110 to 120 mm., who, after four months' treatment along the lines described, showed a systolic blood pressure of 140 mm. and a diastolic pressure of 90. Other cases, previously refractory, dropped from 220 systolic to 130; 190 to 135; 215 to 140, etc., and promised to remain there.

DR. THEODORE B. BARRINGER, Jr., said he thought Dr. Crampton had done a distinct service in calling our attention to the possibility of treating hypertension by exercise. He felt that if exercise was ever to become a rational means of treatment in certain selected cases of hypertension considerable clinical experimentation would be necessary to place it on a sound basis. It might be well to recall that in normal people the effect of exercise, no matter what the exercise was, was to raise the blood pressure during and for a brief period after exercise, the pressure then rapidly subsiding to normal. In people with low blood pressure the same results were observed, namely, a rise in blood pressure during exercise and after exercise the pressure returning to about the same level it was before. These statements were based upon experimentation. Patients with hypertension reacted differently to exercise. For instance, a man forty years of age, apparently in good health, and playing golf, eighteen holes twice a week, had a blood pressure of diastolic 210, and systolic 110 with normal urine. On climbing a flight of stairs fifteen feet in height his systolic blood pressure rose from 210 to 236. This exercise was repeated twice. Five minutes after the last exercise it had subsided to diastolic 180, systolic 102. That was not at all an unusual reaction in certain cases of hypertension. The longest time he had seen it stay down was one-half hour. In the present state of our knowledge considerable discrimination in the selection of cases suitable for treatment by exercise should be employed. His experience in this matter was limited to a comparatively small number of patients and was well illustrated by the following case. The man, forty-five years of age, had a blood pressure of diastolic 170, systolic 90 with normal urine and blood findings. He was given regular graduated exercise with dumbbells and put on a diet for weight reduction. At the end of a month he had lost ten pounds in weight and his blood pressure was diastolic 120, systolic 70. Possibly the loss of weight was a significant factor in bringing about the improved condition. The main point he wished to emphasize was that considerable discrimination must be used in selecting cases of hypertension suitable for treatment by prescribed exercises. His belief was that only those cases showing a minimal amount of kidney trouble, no myocardial involvement and no angina were suitable for this form of treatment.

DR. ELI MOSCHCOWITZ said that Dr. Crampton's paper had struck a sympathetic chord in his mind. Dr. Moschcowitz had discussed the use of exercise in the treatment of hypertension in a paper published some years ago. Exercise in the treatment of hypertension had its indications, and contraindications, as both Dr. Crampton and Dr. Barringer had emphasized, and to his mind the indications were quite clear. Patients with hypertension had their phases of compensation and decompensation, just as patients with valvular dis-

ease. In the compensated phases exercise was indicated, in the decompensated phases it was obviously contraindicated. As Dr. Crampton had insisted, exercise was only a part of the broader treatment of hypertension. How it acted beneficially, Dr. Moschcowitz did not know precisely, but it seemed to him that the effects could be explained in two ways. First, in reducing the patient's weight and so relieving the patient's heart. The vast majority of patients with hypertension were above weight, and it was quite remarkable to witness the beneficial effect of even the loss of a few pounds in weight in such patients. Second, exercise was of value in such patients in introducing the element of play into their lives. Patients with hypertension, as a rule, were of a characteristic type, as Dr. Moschcowitz had pointed out some years ago. Briefly, these patients might be described as the antithesis of the child type. They were tense, nervous individuals, with a narrow mental range, but within this range terribly intense. Anything, therefore, which took the patient out of this intensity must necessarily be of value. That was why Dr. Moschcowitz emphasized the value of play in these people's lives. Dr. Moschcowitz made one more point, and that was that the benefit of exercise was sometimes of positive value even though the effect on the blood pressure was not marked. The patient's efficiency was certainly improved even though the patient's systolic pressure remained the same, while the diastolic pressure sank but a few points. As a rule, it was the diastolic pressure rather than the systolic that was affected by exercise and was the better index of the efficiency of the individual.

Dr. H. O. MOSENTHAL said it was not possible to formulate an answer, applicable to every case of hypertension, to the problem of whether or not exercise was to be employed as a therapeutic measure. The treatment of increased blood pressure presented many phases, all of which had to be given due attention if physical exertion was to be considered as a means of treatment. It had been established today that in the majority of instances of hypertensive disease renal insufficiency was not the cause of the altered blood pressure. As far as we know the increased arterial pressure compensated for no organic pathological state and we were therefore perfectly justified in attempting to reduce the blood pressure. This attitude was entirely different from that which was adhered to a few years ago, when it was believed that a hypertension was a compensatory phenomenon which should not be interfered with if the best interests of the patient were to be considered. Today we had very good grounds for attributing a more or less constant increase in arterial tension to a faulty nervous control of the vascular mechanism. The heart might beat with greater force than usual, bringing about an increased systolic pressure, or there might be an augmented tone in the smaller peripheral vessels, which would cause a rise in both systolic and diastolic readings. Exercise, as Dr. Barringer had mentioned, and as Dr. Ernst Boas had noted in a recent publication, would effect a rise in blood pressure followed by a drop which often fell considerably below the level existing before the physical exertion took place. Thus a therapeutic effect was brought about. It was worthy of note that in young, strong individuals vigorous exercise, such as a hard tennis match, was often followed by a sense of well being. The findings of Dr. Barringer and Dr. Boas might serve to explain this. In most instances certainly mild exercise was to be preferred to the more exhausting forms of physical effort. There were two reasons for this: In the first place, it was a fact, established especially by the statistical publication of the late Theodore C. Janeway, and since then amply confirmed by clinical experience, that most individuals suffering with hypertension met their end because of a failing heart. In the second place, in most patients the blood pressure was a barometer of their nervous tension; irritation was accompanied by a rise and mental relaxation by a fall in blood pressure; a drop or rise of 60 points within five minutes, according to the nervous and mental stimuli the patient was receiving, was not unusual. It became obvious that exercise in these cases must be adjusted to the capacity of the heart muscle and to the temperament of the individual. There were still other sides to this problem that deserved careful consideration. An increased blood pressure was often the accompaniment of obesity and here exercise had its obvious place in treatment. On the other hand, hypertension in the long run was followed by arteriosclerosis and apoplexy, angina pectoris, and arteriosclerotic kidneys; if these conditions existed or gave indications of becoming serious factors in the management of any case, physical exertion must be adapted to the individual. From what we had heard tonight it was evident that no formula for exercise could be made which would meet the needs of every case of increased arterial pressure. Each patient presented symptoms and signs which had to be met. Physical exertion properly regulated and adjusted would fill some of these needs. Exercise skilfully interwoven with other forms of treatment such as rest, diet, and drugs and properly adjusted to the requirements of the individual patient was of inestimable value in the treatment of hypertension.

Dr. CRAMPTON, in closing the discussion, said there were one or two points he wished to bring out. First, he wished to emphasize that exercise was a two edged sword; it would cut right or wrong, depending upon the handling of the particular implement. We must learn about it so as to use it efficiently. There were some exercises which elicited local vaso-dilatation without central stimulation of the heart and splanchnic area, which were the two means of raising blood pressure. It was their duty to know the uses of exercise which would not increase the blood pressure but would elicit a local reaction without a central stimulation; such a local response caused an opening of the peripheral vessels and a drop in the blood pressure. In other words, physicians ought to know they could, if sufficiently skilful, lower blood pressure by exercise without first raising it. Of course, it must be remembered that if a patient had bad kidneys he should not be given the same kind of exercises as the patient with a simple hypertension, and the same was true of myocardial involvement and angina. The point brought out by Dr. Moschowitz in reference to the advantages of play was excellent, and Dr. Mosenthal's expression of "exercise skilfully interwoven in the scheme of treatment" was the best characterization of the whole subject.

The Cardiac Mechanism After Administration of Quinidine to Patients with Auricular Fibrillation, with Consideration of Certain Toxic Effects of the Drug.—Dr. ROBERT L. LEVY presented this study from the Hospital of the Rockefeller Institute for Medical Research. He said the introduction of quinidine into clinical medicine as a cardiac remedy might well be regarded as the most important advance in the drug therapy of heart disease since Withering's account of the foxglove in 1785. Furthermore, this alkaloid was unique as a pharmacotherapeutic agent, since it served to restore to normal a disturbed physiological mechanism. In 1914, Wenckebach reported two cases of auricular fibrillation in which, after administration of 1 gram of quinine, the normal rhythm was restored for a short period of time. Stimulated by this observation, Frey, in 1918, undertook a systematic study of various cinchona derivatives in patients with auricular fibrillation. The most effective therapeutic agent was quinidine, and because of its better solubility, quinidine sulphate, rather than the pure quinidine alkaloid, was chosen for more extensive use. In his first communication Frey reported ten cases, in six of which he was able to convert the fibrillatory mechanism into the normal sinus rhythm. During the past three years about 200 cases of auricular fibrillation treated with quinidine had appeared in the literature; in approximately 50 per cent. the normal rhythm had been restored. Factors determining the success or failure of treatment were not yet clear. The present report dealt first with a detailed study of the cardiac mechanisms which had been observed in the first eleven cases which had received quinidine in the hospital of the Rockefeller Institute, and second, with certain toxic effects of the drug and their significance for clinical medicine. Five hundred and seven electrocardiograms were made in these eleven patients. After a small preliminary dose to test for idiosyncrasy to members of the cinchona group, quinidine sulphate, 0.4 gm., was administered by mouth either three times daily or every two hours until either the onset of normal rhythm or the appearance of toxic symptoms indicated the cessation of therapy. Curves were made, usually every two hours, on

the days on which the drug was given, and at least once daily during the period of subsequent observation. When a change in rhythm was anticipated, electrocardiograms were taken as often as every five minutes. In three patients who received, in all, ten courses of quinidine, restoration of the normal mechanism was accomplished nine times. The first effect noted was usually an acceleration of ventricular rate, this being followed at times by the appearance of premature beats arising commonly in the right, but occasionally in the left ventricle. If electrocardiograms were taken at sufficiently frequent intervals, the transitional mechanisms, in the common order of their appearance, were: Coarse fibrillation, which might be taken to indicate a slowing of auricular rate, impure flutter, flutter, and normal rhythm. In one patient the transition from auricular flutter to the normal rhythm was photographed in the second lead. The change was rather abrupt, there being noted a period of fluctuating auricular activity, slowing of ventricular rate for several beats, a relatively long period of asystole of both auricles and ventricles, and then prompt resumption of the sinus rhythm. During the time the normal rhythm prevailed it was common to see occasional auricular premature beats. At times these, together with ventricular premature contractions, when these were present, could be abolished by giving more of the drug. The T wave often tended to reverse its direction and change its voltage after the normal rhythm was restored, returning to its original form after the reversion to the fibrillatory mechanism. In one patient paroxysms of ventricular tachycardia preceded the onset of impure flutter, which, in turn, was followed by the normal rhythm. In this same patient, sino-auricular block and paroxysms of auricular tachycardia were also observed when the sequential rhythm prevailed. The duration of the normal rhythm after a single course of quinidine varied from a few hours to twenty-three days. In one patient it had been possible, by means of properly spaced intermittent quinidine therapy, to maintain the normal rhythm for six months, with coincident marked clinical improvement. In eight patients, eleven courses of quinidine were administered without success as concerned resumption of the sinus rhythm. As in the group just described, tachycardia was commonly the first effect. Slowing of auricular rate, as evidenced by coarser fibrillatory oscillations, was seen. In two cases auricular flutter occurred. Paroxysms of ectopic ventricular tachycardia were noted three times. Although of short duration, they served to indicate that quinidine, as a therapeutic agent, was not to be administered indiscriminately, for ventricular tachycardia occurring in dogs poisoned by digitalis or strophanthin was not infrequently the precursor of ventricular fibrillation. In one individual quinidine caused marked increase in ventricular rate, with onset of symptoms of heart failure without alteration in the cardiac mechanism; these symptoms were promptly relieved by digitalis medication. Cases had been described in which, following resumption of normal rhythm after quinidine, embolic phenomena had occurred, presumably as the result of expulsion of portions of clot from the auricles. The possibility of the occurrence of this accident must be borne in mind, though it was apparently a rare happening. For the present it would seem wise to administer quinidine to patients who were either in a hospital or at home in bed under proper nursing care.

Dr. H. E. B. Pardee stated that they were all indebted to Dr. Levy and the Rockefeller Institute for this study of quinidine. It was a revelation to know that auricular fibrillation could be stopped in 50 per cent. of the cases. Now what they desired to know was: "What does it do to the patient?" He had not had the opportunity of following patients with the electrocardiograph, as Dr. Levy had done, so he could not speak except in approbation of the work. However, he had been treating a number of cases with quinidine for about six months. He had been unable to maintain any in normal rhythm for the full period; though it had been possible to return them to normal rhythm, they went back to fibrillation. All the patients he had treated were ambulatory cases. He had given them 0.4 of a gram of quinidine three or four times a day, depending on their toleration as tested by a single dose. He had treated some patients in the hospital with 0.4 gm. every four hours, and these had complained of dizziness, headache, nausea, and vomiting, and were so uncomfortable that he had stopped giving the quinidine at such frequent intervals. Nor did the frequent intervals seem necessary, for quinidine was absorbed very soon after administration, and only one-half of the dose was excreted in the next six hours, so one should be able to produce the effect by giving it at the longer intervals. That the lesser dosage was effectual for the purpose was shown by the fact that he had had the usual percentage of returns to normal rhythm, in fact, 60 per cent., but he attributed the additional 10 per cent. simply to luck. He had not found that digitalis exerted any effect either in favoring or inhibiting the action of quinidine. All of his patients were under digitalis at the time they were given the quinidine, as it was customary for him to keep cases of auricular fibrillation digitalized. Since in auricular fibrillation they were dealing with a fundamental pathological condition of the auricle, it was not surprising that one could not maintain these hearts at a normal rhythm by the drug. Extrasystoles developed and the fibrillation returned. Some unpleasant happenings had occurred in connection with the administration of quinidine. One patient fell in the street at the time of loss of normal rhythm and return to fibrillation. Another complained of great discomfort. In none was he able to maintain the normal rhythm continuously, but he had not attempted to give the drug continuously because of the symptoms induced. There was only one patient who was better physically when he had sinus rhythm than with the fibrillation. Where with fibrillation his rate without digitalis was sixty or under, and he had frequent dizzy attacks and faint spells, after return to normal rhythm the rate ran about seventy, and he did not have dizziness or fainting. In one patient quinidine apparently produced harm. The drug was given for the purpose of changing an auricular fibrillation to a normal rhythm; the heart did not go back to normal rhythm, but the patient developed a degree of cardiac failure which made rest in bed advisable. In this case, as in Dr. Levy's, the harm might come perhaps because of the rapid heart rate which often resulted from quinidine. It might be that quinidine had a direct harmful action on the muscle; he could not say. There were two other patients whose general condition became worse during or just after quinidine administration, though he could not be sure that their decompensation might not have been due to another factor. The situation at the present time might be summed up by saying that we had a powerful drug which we did not yet know how to handle properly. When we knew how to give it we might be able to maintain the sinus rhythm for a considerable length of time and we might then be able to accomplish great benefit. It was not necessary to have the patient in bed when the drug was given if the doses were not too large. He had seen no harm result from giving it to his series of eighteen ambulant patients. So he could agree with Dr. Levy that the drug marked a great advance in cardiac therapeutics and hoped that in a short time they would be able to use the drug so as to maintain normal rhythm for a considerable length of time.

Dr. Alfred E. Cohn said that he had nothing to add either in detail or as to the theory to the account Dr. Levy had given. He thought it would be more interesting to say something on the pharmacology of the drug and of its relation to the general problem of fibrillation of the auricles. The history of experiments dealing with fibrillation was a long one. It was a pleasure to recall that experiments dealing with it, and having a clinical bearing, were begun as early as 1912 in America by Garrey and completed by him in 1914. Simultaneously, G. R. Mines came on the basis of his experiments to conclusions having the same direction as Garrey's. It was Garrey's idea that fibrillation depended upon a circus movement of the excitation wave in muscle, the maintenance of the circuit depending upon three things: first, the length of the circumference of the circle, followed by the excitation wave; second, the rate at which the excitation wave traveled; and third, whether the muscle was still refractory at the time when the excitation wave returned to the point at which it started. If the

muscle was still refractory at that time, it would, of course, resist re-excitation. Since then, within the last two years, Lewis and his assistants have done genuinely brilliant work in elucidating this problem, following the theory of Garrey and of Mines, by experiments on the hearts of dogs. More recently they have extended the application of this theory to the actual condition of flutter and fibrillation of the auricles in the human heart and had come measurably close to demonstrating that the theory held in the clinical condition. The depressant action of drugs of the cinchona group was mentioned by other speakers. Dr. Cohn called attention to the experiments performed by him and Dr. Levy with quinidine on the hearts of dogs, in which it was shown that there was an increase in the degree of muscle shortening when quinidine was injected intravenously. In the sense, therefore, that this represents an augmented action in the muscle, it was scarcely correct when speaking of this cardiac function to regard the action of the drug as depressant. It might be pointed out that in those experiments in which a depressant action was reported the hearts of the animals operated upon were isolated. This difference in the experimental technique might account for the difference between the results of other investigators and those now described. The action of quinidine on the contraction wave was different from that of hemorrhage or of histamine, so that the conclusion might be drawn that the fall in blood pressure which quinidine occasioned and which came on simultaneously with its injection was not due to effects such as resulted from hemorrhage and from injecting histamine. Other experiments were now in progress dealing with the more detailed examination of the action of quinidine on auricular muscle. These effects had to do with the refractory period and the conduction time. These were the phases of muscular action now generally regarded as at the basis of the fibrillatory process, but time did not permit of an account of these experiments.

Dr. CARY EGGLESTON said that in the last seven cases of auricular fibrillation in which he had attempted to administer quinidine, giving 0.2 of a gram every two hours, three cases were unable to take the drug because of cinchonism. He was inclined to agree with Dr. Pardee, in so far as his experience went, namely, that he questioned seriously the uniform benefit, at least clinically, of changing the fibrillation back to sinus rhythm. Some patients had been changed from a high degree of cardiac failure to a degree of compensation with the restoration of sinus rhythm, and the change was accompanied by diuresis and relief of cyanosis and a general improvement. On the other hand, one or two had not been improved by a return to sinus rhythm. One difficulty was the inability to foretell whether one was going to get a return to normal rhythm or not. In the paroxysmal cases one might anticipate that the drug might be more effective. He had not yet studied many cases of this kind in connection with the action of quinidine, but in the last case of the paroxysmal type the administration of quinidine had no influence; the heart still fluctuated spontaneously. As to the administration of quinidine, he did not think enough was known about it to administer it with safety to ambulatory patients. He believed the patient should be under constant observation until we had learned more about the action of the drug before it could be considered a safe clinical agent.

Dr. LEWIS A. CONNER said that his experience with the drug had not been that of Dr. Eggleston, who had failed to see much clinical benefit from restoration of the normal heart rhythm. Dr. Conner had followed several cases in which the improvement in the symptoms had been great. In one case observed over a period of five months there had been the gradual disappearance of marked dropsy and orthopnea and the restoration of a considerable degree of compensation. While it was true that not all cases seemed to be benefited, some of them certainly were. We were so accustomed to feel that when once auricular fibrillation had been firmly established no return to normal rhythm was possible, that the sudden restoration of the normal rhythm under the influence of a few doses of quinidine in hearts which had been fibrillating for months or years was a most dramatic and astounding event. Although we were only at the threshold of our knowledge of the possibilities and the limitations of quinidine, he was disposed to feel with Dr. Levy that the use of quinidine might prove to be the most important contribution to the medicinal therapeutics of heart disease since Withering's discovery of digitalis.

Dr. B. S. OPPENHEIMER said he agreed with Dr. Levy that the discovery of the action of quinidine in arresting fibrillation of the auricles marked an epoch in cardiac therapy. Dr. Cohn had called attention to the work of two investigators, Mines and Garrey, but we could feel also a justifiable pride in the still earlier demonstration of circus waves in 1908 by an American biologist, Alfred G. Mayer. With Dr. Huber Mann he had observed twenty-seven unselected cases of auricular fibrillation at Mount Sinai Hospital, twelve of which had responded to quinidine administration by a change to normal sinus rhythm and two by transitions to impure or pure flutter. If one added these cases to those already published in the literature, there were now 205 cases of auricular fibrillation treated with quinidine, in 104 of which the fibrillation had been interrupted or abolished. Dr. Mann and his experience in regard to toxic effects had been similar to that of others. The patients had sometimes complained of flushing, headache, palpitation, vomiting, of motiveless laughing and crying; one case of exophthalmic goiter had developed a mild psychoses; but no grave or alarming symptoms such as had been described by Frey were observed. As to the increased danger of embolism during the transition from fibrillation to coordinate contraction of the auricles—a possible danger pointed out by Sir James Mackenzie—that was to be seriously considered. With Dr. Felberbaum of Montefiore Hospital he had quickly collected six cases of auricular fibrillation which had developed symptoms of embolism during their fibrillation; four of these had suffered from cerebral embolism. One woman had had a cerebral embolism with crossed paralysis about a year ago; recently while at Montefiore Hospital she had been given quinidine and her fibrillation had changed to sinus rhythm, but no embolic phenomena had followed the change. Since by permitting the fibrillation to continue uninterruptedly the danger of embolism was not avoided, he thought it was justifiable to administer quinidine if there were indications. There was still the doubt in many minds whether the patient derived any benefit from the change from fibrillation to sinus rhythm. On the whole, they could say the patients were better off during the periods of normal rhythm, but much depended upon the underlying condition which had played a rôle in producing the incoordination. In such instances of fibrillation as had been associated with temporary etiological factors, as trauma, thyrotoxicosis, etc., it was possible that the abolition of fibrillation might prove to be permanent. The duration of normal sinus rhythm following a single series of quinidine had been variable; one case was still regular five and one-half months, another four and one-half months after a single series of quinidine. Other cases, however, required interrupted treatment. It had been impossible to predict which cases would respond and which would not. There had been success and failure in the three ordinary groups of cases, valvular, cardiac-vascular-renal, and thyrotoxic. One man with fibrillation associated with thyrotoxic adenoma had developed a regular rhythm after a single dose of 3 grains of quinidine and his mechanism had remained regular for six days. Dr. Oppenheimer called attention to the explanation of Sir Thomas Lewis and his collaborators of the fact that 50 per cent. of the cases responded to quinidine by change to sinus rhythm; in these they supposed the effect of quinidine in prolonging the refractory period predominated over its tendency to slow the rate of conduction. Finally, he had one case in which quinidine, in sufficient dosage, caused the disappearance of previously persistent extrasystoles of ventricular origin; the premature beats tended to reappear on discontinuing quinidine.

Dr. E. LIBMAN expressed the opinion that one need not have much concern in regard to embolism. A study of embolisms in the lung shows that these were but very infrequently due to thrombi on the right side of the heart. They were most frequently due to the presence of thrombi in the veins of the lower extremities or the pelvis.

The Relation of Blood Cholesterol and Protein Defi-

ciency to Basal Metabolism.—Dr. ALBERT A. EPSTEIN and Dr. HERMAN LANDE made this contribution. They stated that the material presented showed a relationship existing between the metabolic rate and the blood cholesterol in thyroid disease. The blood cholesterol was low when the metabolic rate was increased and high values were obtained when the basal metabolism was depressed. This might be due to differences in the rate of combustion or oxidization of the lipoids and fats occurring with changes in the basal metabolic rate. However, it might be the result of changes occurring in the mechanism regulating the synthesis and destruction of fat and lipoids in the body. Wasting diseases other than hyperthyroidism were associated with a low blood cholesterol, hence the diagnostic value of a low cholesterol must be uncertain, but a normal or elevated figure of cholesterol in the blood was undoubtedly a rare finding in exophthalmic goitre or hyperthyroidism. When the question of hyperthyroidism or thyrotoxicosis was once established the cholesterol findings in the blood had a prognostic significance. In myxedema the cholesterol in the blood was very much increased. Upon the administration of adequate amounts of thyroid extract the cholesterol fell inversely as the basal metabolism rose, and hence the blood cholesterol could serve as a guide in the therapy of such cases. In nephrosis, a condition believed to be closely allied to myxedema, the basal metabolism was reduced. Thyroid therapy in such cases, as an adjunct to high protein feeding, was indicated by the basal metabolism determinations and the corresponding increase in blood cholesterol. The subnormal metabolism found in these cases was not necessarily due to a hypothyroidism but to a defective protein metabolism, with its associated diminution of the specific dynamic energy normally imparted by products of protein catabolism. In this way the basal metabolism determinations served as an indirect measure of protein deficiency. The authors believed that the beneficial effect of thyroid was not due entirely to its stimulative action on the rate of oxidation, as a subnormal metabolism in itself was not sufficient to produce edema. The effect of thyroid in promoting the utilization of protein probably explains its ultimate influence on edema.

Dr. EUGENE F. DU BOIS stated that they were very much indebted to Dr. Epstein and Dr. Lande for this important demonstration of the inverse relationship between blood and cholesterol and basal metabolism. The subject was extremely complicated and, as Dr. Epstein had said, we must be very cautious in making hypotheses. Personally he did not feel that the relationship between blood cholesterol and basal metabolism had been explained. It was difficult to conceive of these two factors as cause and effect. It was quite probable that they were both caused by some unknown factor. We must be cautious in taking the blood cholesterol as an index of thyroid function until we had more figures. So many estimates of thyroid activity had been made and then found to be unreliable that we must use particular caution in making such estimations. The observations made in regard to the menopause were very interesting because they were the first that showed a distinct increase in the metabolism associated with the menopause. They should be taken into consideration in estimations of basal metabolism made in this period of life.

Dr. LIBMAN said that, as Dr. Du Bois had brought out and as Dr. Epstein himself maintained, some of the points which the latter had made were definitely proven and the others were put out as suggestions. In fact, Dr. Epstein had made many suggestions of value for other investigators who wished take up this line of study. Dr. Libman said it was interesting to note that the age at which the cholesterol content of the blood normally increased (the menopause) was the same age at which atherosclerosis was apt to develop. The lipoids were believed by some to have a relationship to the development of atherosclerosis. Because of the increase in cholesterol at the time of the menopause, it was unwise to lay stress on increased cholesterol content of the blood for the purpose of diagnosing cholelithiasis. It was pointed out by Dr. Libman that when Dr. Epstein first introduced the high protein diet in the treatment of nephrosis the method was rather scoffed at in this country, but was taken up abroad. Now it was being more and more employed by clinicians in this country and rapidly increasing evidence of its value was at hand. It could be regarded as one of the most valuable contributions to therapy made in recent years. As a rule, the method was used only after all other methods had failed. It was important to get a method by which one could determine when it should be the first method of treatment to be tried. Dr. Epstein's attempt to get data for this purpose was a valuable one. If one had ever seen one of these cases yield to treatment by the use of the high protein diet he would consider it one of the most remarkable clinical phenomena he had ever witnessed. The conception of nephrosis was not yet a clean-cut one. The fact, however, that there were cases which on the high protein diet lost not only the edema but also the albumin casts, indicated that there was a group of cases which could not be considered to properly belong to the class of cases which were called nephritis.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS OF WYOMING.

Cheyenne, June 6-8, 1921.

ANATOMY AND HISTOLOGY.

1. Give the nerve supply of the arm, forearm, and hand.
2. Describe the stomach.
3. Give the origin, insertion, and nerve supply of the following muscles: Deltoid, sternocleidomastoid, digastric, sartorius, quadriceps extensor.
4. Give the histology of the skin.
5. Name the veins of the upper extremity.
6. Describe the coverings of the brain.
7. What is protoplasm?
8. Name the bones of the wrist.
9. Name the branches of the abdominal aorta.
10. Give the origin, course, and distribution of the right and left phrenic nerve.

PHYSIOLOGY.

1. Name the cranial nerves and state the functions of each.
2. What are the functions of the liver?
3. What is blood pressure? State the physiological causes of alteration in blood pressure.
4. Describe the process of the coagulation of the blood.
5. Classify foods according to their chemical character and give an example of each in a common diet.
6. What are the salivary glands? What part does saliva play in digestion? What is its active ferment?
7. What are the ductless glands? State the functions of each.
8. State the mechanism involved in referred pains.
9. Describe metabolism.
10. Following certain spinal injuries the nerve tracts of the cord will degenerate either above or below the injury. What causes this? What is this called? Name the tracts of ascending and those of descending degeneration.

ANSWERS.

ANATOMY AND HISTOLOGY.

1. *The nerve supply of the arm.*—Median, ulnar, musculospiral, and musculocutaneous nerves.

The nerve supply of the forearm.—Median, ulnar, radial, and posterior interosseous nerves.

The nerve supply of the hand.—Ulnar, median, and radial nerves.

2. The *stomach* is that pouch-like portion of the alimentary canal which is situated between the esophagus and the small intestine. It is conical, with base to left side; the upper border is concave, and is called the *lesser* curvature; the lower border is convex, and is named the *greater* curvature. The left extremity is known as the *fundus*, above and to the right of which is the *cardiac* orifice, and the right or small end is termed the *pyloric* extremity. It occupies left hypo-

chrondriac and epigastric regions. Its *orifices are cardiac*, above, communicating with the esophagus; *pyloric*, at the right extremity, passing into the duodenum. It is 10 to 12 inches long, 4 to 5 inches in diameter at widest part. Its *left* or *cardiac end* is fixed by esophagus and gastrophrenic ligament to diaphragm, lying beneath the seventh left costal cartilage, one inch from sternum; it is connected with the spleen by the gastrosplenic omentum. The *right* or *pyloric end* reaches the gall-bladder, touching under part of quadrate lobe of liver; is very movable; when stomach is empty is in midline four inches below tip of gladiolus. *Anterior surface*, which also looks upward, is in contact with, from left to right, diaphragm, abdominal parietes (epigastric region), under surface of liver. *Posterior surface* is separated from pancreas, crura of diphragm, aorta, vena cava inferior, and solar plexus, by lesser sac of peritoneum. *Superior border* is attached to liver by small omentum. *Inferior border* gives attachment to great omentum. *Coronary* and *pyloric* arteries run along lesser curvature; *right* and *left gastroepiploic*, along inferior or greater curvature; *vasa brevia*, from the splenic to fundus. *Right pneumogastric* nerve supplies the posterior surface; *left pneumogastric*, the anterior surface; *sympathetic* from the solar plexus, both surfaces.—(*Aids to Anatomy.*)

3. DELTOID. *Origin:* From the outer third of anterior border and upper surface of the clavicle, from the outer margin and upper surface of the acromion process, and from the lower edge of the spine of the scapula. *Insertion:* Into the deltoid impression on the middle of the outer side of the shaft of the humerus. *Action:* It raises the arm from the side so as to bring it at right angles with the body; its anterior fibers draw the arm forward; its posterior fibers draw the arm backward. *Nerve supply:* The circumflex.

STERNOMASTOID. *Origin:* Upper and outer part of the anterior surface of the manubrium sterni, and upper surface of the clavicle at its sternal end. *Insertion:* Outer surface of mastoid process of the temporal bone, and outer part of the superior curved line of the occipital bone. *Action:* To flex the head to the same side as the muscle; the two acting together flex the head on the thorax and also raise the upper thoracic wall in forced inspiration. *Nerve supply:* The spinal accessory nerve and a branch from the cervical plexus.

DIGASTRIC. The posterior belly arises from the digastric groove on the internal surface of the mastoid process of the temporal bone; the anterior belly from a depression on the inner surface of the lower border of the inferior maxilla, near the symphysis. These two bellies are connected by a central tendon which perforates the stylo-hyoid, and is bound down to the greater cornu of the hyoid bone by a process of fascia. *Action:* It raises the hyoid bone and depresses the lower jaw. *Nerve supply:* The posterior belly is supplied by the facial; the anterior belly by the mylohyoid branch of the inferior dental.

SARTORIUS. *Origin:* Anterior superior spine of ilium and upper part of notch. *Insertion:* Internal surface of shaft of tibia, just behind the tubercle. *Action:* It flexes the knee joint, the hip joint, and the pelvis upon the thigh; it is an internal rotator of the leg, and an external rotator and abductor of the thigh. *Nerve supply:* Anterior crural nerve.

QUADRICEPS EXTERIOR is composed of:

(*a*) VASTUS EXTERNUS. *Origin:* Neck, and great trochanter, and line from great trochanter to linea aspera of femur, and from intermuscular septum. *Insertion:* The common extensor tendon, and outer side of patella. *Nerve supply:* Anterior crural.

(*b*) VASTUS INTERNUS. *Origin:* Linea aspera, and lower part of spiral line on femur, and tendons of adductor longus and adductor magnus. *Insertion:* The common extensor tendon, and inner side of patella. *Nerve supply:* Anterior crural.

(*c*) CRUREUS. *Origin:* Upper two-thirds of the anterior and outer surfaces of the shaft of femur, and lower half of the external intermuscular septum. *Insertion:* The common extensor tendon. *Nerve supply:* Anterior crural.

(*d*) RECTUS FEMORIS. *Origin:* Anterior inferior spine of ilium, and the groove above the acetabulum. *Insertion:* The common extensor tendon, and upper border of patella. *Nerve supply:* Anterior crural.

The common extensor tendon is inserted into upper border and two sides of patella and is also continued into the ligamentum patellæ.

4. "The *skin* is composed of two parts, the epidermis and cutis vera. The *Epidermis* consists of stratified squamous epithelium, the cutis vera of fibrous tissue. Processes of these interdigitate. The deeper layers of the epidermis are soft, and constitute the rete mucosum, or stratum Malpighii. The cells of the deepest layer are columnar in shape, and in dark races they contain pigment. In the layers above the cells become polygonal or rounded. Narrow clefts between the cells are bridged by fine protoplasmic processes (prickle cells). The superficial layers are horny. In the layers of cells (stratum granulosum) next the stratum Malpighii granules of a substance called "eleidin" accumulate. In the layers superficial to this (stratum lucidum) the cells contain large droplets of a similar substance (kerato-hyalin), which tend to run together and obscure the characters of the cells and render their outline indistinct, giving the layers a clear appearance. The surface layers take the form of long, thin, flat cells, whose nuclei have been obscured by kerato-hyalin. These constitute the stratum corneum. Cells of the surface layer are always being lost, and are replenished from the cells of the deeper layers. The young cells formed in the deep layers push the older cells toward the surface, and as they pass outward the cells begin to accumulate granules, and then become transformed to the type found in the stratum corneum. The *Cutis Vera* is composed of dense fibrous tissue, which rises up into papillæ, indenting the epithelium. In the deeper part the fibrous tissue becomes looser, and merges indefinitely into the reticular tissue of the subcutaneous layer. In the papillæ are loops of capillary vessels, and in the palm and sole there are tactile corpuscles. Bloodvessels form a capillary network near the surface of the true skin, and send up loops into the papillæ and supply branches to the hairs, sweat glands, etc.; but vessels do not pass into the epidermis. Nerves pass into the Malpighian layer, and some of the varicose branches form flattened menisci between the layer of cells. Medullated nerves end in touch-corpuscles in the fibrous papillæ."—(*Aids to Histology.*)

5. The VEINS OF THE UPPER EXTREMITY consist of two sets, the superficial and the deep. *The superficial veins*, are: Radial, anterior ulnar, posterior ulnar, median, median cephalic, median basilic, cephalic, and basilic. *The deep veins*, are: Axillary and subclavian.

6. The COVERING OF THE BRAIN. "The *Dura Mater*, the most external, is a dense fibrous membrane, which is closely attached to the bones of the skull, forming their internal periosteum. The inner surface is smooth, and covered with endothelium. It is continuous with the dura mater of the spinal cord through the foramen magnum. The fibrous part of the dura mater is divided into two layers, an outer, forming the periosteum, and an inner, lying under the endothelium, forming certain processes, and which, by its separation in certain situations, forms the *sinuses*. On the upper surface, near, and projecting into the longitudinal sinus, are the *Pacchionian bodies*, which are enlarged villi of the arachnoid projecting through the layers of dura mater.

Processes of the dura mater:

"The *falx cerebri:* placed vertically between the two hemispheres of the cerebrum, attached in front to the crista galli, behind to the upper surface of the tentorium, and between these above to middle line of internal surface of skull, while the lower border is concave and free. In relation with it are the superior and inferior longitudinal and the straight sinuses.

"The *tentorium cerebelli* is a crescentic fold of dura mater placed between the cerebrum and the cerebellum. It has an outer convex border, by which it is attached in front to the posterior clinoid processes, superior edge of the petrous bone, and behind to the margins of the groove for the lateral sinus. The inner concave border is free posteriorly, and forms the opening through which the crura cerebri and the posterior cerebral arteries pass from the posterior into the middle cranial fossa; in front this border passes over the attached border, and is attached to the anterior clinoid processes. The tentorium is a tent-like process, high-

est above and in front, at its most anterior point of attachment of the falx cerebri by which the tentorium is suspended, and from this point descending on all sides. In relation to it are the lateral, superior petrosal, and straight sinuses.

"The *falx cerebelli* reaches vertically from the tentorium to the foramen magnum, dividing the two hemispheres of the cerebellum. It is attached posteriorly to the vertical crest of the occiput, where it encloses the occipital sinus, and below to each side of the foramen magnum.

"The *pia mater* consists of a delicate stroma supporting bloodvessels, and closely invests the brain, dipping into the sulci. At the transverse fissure it is prolonged into the lateral ventricles and over the 3rd ventricle, pushing the endothelial lining of those cavities in front of it, and forming the *velum interpositum* (tela choroidea) and choroid plexuses of the lateral and 3rd ventricles. It is prolonged over the roof of the 4th ventricle, sending inwards two vascular fringes, the choroid plexuses of that cavity.

"The *arachnoid* is a thin membrane lying outside the pia mater, but is not so closely applied to the brain, as it passes over the sulci without dipping into them. Between the pia mater and the arachnoid is the *subarachnoid space*, containing the cerebro-spinal fluid. The space between the dura mater and arachnoid is now known as the *subdural space*."—(*Aids to Anatomy.*)

7. *Protoplasm* is living substance; it is said to be the physical basis of life; it is not a single substance, but is composed of several substances. It is generally viscid, almost transparent and colorless, and somewhat fluid.

8. *The bones of the carpus or wrist*, are: Scaphoid, semilunar, cuneiform, pisiform, trapezium, trapezoid, os magnum, and unciform.

The bones which enter into the wrist joint, are: Radius, scaphoid, semilunar, and cuneiform.

9. *The branches of the abdominal aorta*, are: Inferior phrenic, celiac axis (giving off gastric, hepatic, and splenic), suprarenal, superior mesenteric renal, spermatic (or ovarian), inferior mesenteric, lumbar, middle sacral.

10. The *phrenic nerve* is derived from the third, fourth, and fifth cervical nerves; it lies in front of scalenus anticus, descends inward on it in front of subclavian artery to enter the chest, having crossed the internal mammary artery at origin, behind the subclavian vein. In the thorax it descends in front of the root of the lung, being between the pericardium and the mediastinal pleura, to the diaphragm, which it perforates, and is distributed on its abdominal surface. The *right* nerve lies outside right innominate vein and superior vena cava. The *left* nerve in the neck is crossed by the thoracic duct, and below crosses the arch of the aorta and left pneumogastric, and is longer than the right. Filaments from each supply the pericardium and pleura. *Deep branches*, are: *Communicating:* to spinal accessory in sternomastoid and trapzius muscles. *Muscular:* to sternomastoid, levator anguli scapulæ, scalenus, and trapezius.—(*Aids to Anatomy.*)

PHYSIOLOGY.

1. CRANIAL NERVES WITH FUNCTIONS: 1. *Olfactory*, special sense of smell. 2. *Optic*, special sense of sight. 3. Motor oculi, motor nerve to muscles of the eye. (Superior rectus, inferior rectus, internal rectus, inferior oblique and levator palpebrarum muscles). 4. *Trochlear*, motor nerve to superior oblique muscle of the eye. 5. *Trifacial: First, or ophthalmic branch*, supplies sensation to conjunctiva and skin of upper eyelid, cornea, skin of forehead and nose, lachrymal gland, and skin of nose. *Second, or superior maxillary branch*, supplies sensation to skin and conjunctiva of lower eyelid, nose, cheek, upper lip, upper teeth, and palate. *Third, or inferior maxillary branch*, supplies sensation to external auditory meatus, side of head, mucous membrane of mouth, anterior two thirds tongue, lower teeth, and skin of lower part of face. This branch, in addition, supplies motion to the muscles of mastication (Masseter, temporal, external, and internal pterygoids), and the mylohyoid and anterior belly of the digastric. 6. *Abducens*, motor nerve to the external rectus muscle of the eye. 7. *Facial*, motor nerve of the muscles of expression, also of the platysma and the buccinator; it also supplies the muscle of the external ear; the stylohyoid, and the posterior belly of the digastric; through the chorda tympani it is a nerve of taste and a vasodilator of the vessels of the submaxillary and sublingual glands. 8. *Auditory*, special sense of hearing. 9. *Glossopharyngeal*, motor to muscles of pharynx; sensation to tympanic cavity and posterior third of tongue; special sense of taste to posterior third of tongue. 10. *Pneumogastric* (1) *motor* to the pharynx and esophagus, stomach, and intestines, to the larynx, trachea, bronchi, and lungs; (2) *sensory* and, in part, (3) *vasomotor* to the same regions; (4) *inhibitory* to the *heart;* (5) *inhibitory* afferent impulses to the *vasomotor center;* (6) *excito-secretory* to the salivary glands; (7) *excito-motor* in coughing, vomiting, etc. 11. *Spinal accessory*, motor to sternomastoid, trapezius, and muscles of larynx. 12. *Hypoglossal*, motor to muscles of the tongue.

2. The *functions of the liver* are: (1) the secretion of bile; (2) the formation and storage of glycogen; (3) the formation of urea and uric acid; (4) the manufacture of heat; (5) the formation of creatinine; (6) the production of antithrombin; (7) the conversion of poisonous and harmful into inert material; (8) it is also a reservoir for blood on its way to the heart.

3. *Blood pressure* is the pressure of the blood due to the ventricular systole, the elasticity of the arterial walls, and the resistance of the capillaries. The normal arterial blood pressure varies; the systolic pressure being (in males) about 120 to 150 mm. of mercury, and the diastolic from about 90 to 120 mm. of mercury. In females, the pressure is from 10 to 15 mm. lower. Blood pressure is *maintained* by the contraction of the heart, the peripheral resistance, and the elasticity of the arterial walls.

Blood pressure:

May be raised—	May be lowered—
1. By the heart beating more quickly.	1. By the heart beating more slowly.
2. By the heart beating more powerfully.	2. By the heart beating more feebly.
3. By contraction of the arterioles.	3. By dilatation of the arterioles.
	4. By deficient supply of blood to the left ventricle.

4. When blood is withdrawn from the blood vessels of the living body, it first becomes viscid, then sets, and is converted into a jelly-like mass. This is due to the formation of fibrin. The jelly contracts, forming the clot; and at the same time the serum is squeezed out from the clot. Various circumstances and conditions will hasten or delay the process of coagulation. In man, the blood generally becomes viscid in from two to three minutes; it forms the jelly-like mass in from five to six minutes; a few minutes later the serum begins to appear: and the whole process is completed in from twenty-four to thirty-six hours. The clot then floats in the serum. The process is thus summed up by Halliburton: In the plasma a proteid substance exists, caller Fibrinogen. From the colorless corpuscles a nucleo-proteid is shed out, called Prothrombin. By the action of calcium salts prothrombin is converted into fibrin ferment, or Thrombin. Thrombin acts on fibrinogen in such a way that two new substances are formed; one of these is unimportant and remains in solution; the other is important, viz., Fibrin, which entangles the corpuscles, and so forms the clot.

5. *Foods are divided into:*

I. Inorganic. { Water. / Salts.

II. Organic. { Non-nitrogenous. { Carbohydrates. / Fats. } / Nitrogenous—Proteids.

Examples of each: *Carbohydrate*, sugar and starches; *Fat*, fat of meat, and butter; *Proteid*, flesh of animals, and white of eggs; *Salt*, sodium chloride, and calcium phosphate.

6. The *salivary glands* are the two parotids, two submaxillary, and two sublingual glands. *Saliva* converts cooked starches into maltose and dextrose. The active ferment is ptyalin.

7. The *ductless* glands are: The spleen, thymus, thyroid, parathyroids, suprarenals, carotid, coccygeal, pituitary, and pineal glands.

The function of the spleen: The following theories have been held: (1) It is a source of production of the white blood corpuscles; (2) it is a source of production of the red blood corpuscles during fetal life; (3) it is a place where the red blood corpuscles are destroyed; (4) uric acid is produced in the spleen; (5) an enzyme is produced in the spleen and is carried by the blood to the pancreas, where it converts the trypsinogen into trypsin.

The function of the thyroid is not definitely settled: (1) it has some trophic function, regulating oxidation in the body, and it is supposed to have also a special influence on the vasomotor nerves, the skin, the bones, and on the sexual functions; (2) it is supposed to antagonize toxic substances, and (3) it produces an internal secretion.

The *function of the thymus* is not settled; it is said: (1) To be a blood-forming organ; (2) to have influence on growth and nutrition; (3) in hibernating animals it is supposed to store up materials which can be utilized during the period of inactivity.

The function of the suprarenals is not definitely settled; they produce an internal secretion which is probably necessary to life. This secretion causes constriction of arterioles, raises blood pressure, and stimulates muscle fibers which are supplied by the sympathetic system. There is supposed to be some connection between the adrenals and the thyroid and pituitary bodies.

The function of the pituitary body: Complete removal of whole gland or of anterior lobe is followed by death; the anterior lobe is connected with growth, if the gland hypertrophies there follows overgrowth of the skeleton, and partial removal leads to failure of development of the body as a whole and of the sexual glands. The posterior lobe is believed to cause constriction of arterioles, rise of blood pressure, contraction of the involuntary muscles in many viscera, increased flow of urine, and increased secretion of milk.

8. *Referred pains.*—"It is found that after opening the abdominal cavity under local anesthesia, cutting and suturing of the viscera may be continued without causing any pain. When the viscera are inflamed however, and under certain conditions of stimulation, such as the distention of the bile ducts with biliary calculi, or the violent contraction of the intestines, excruciating pain may be evoked. This pain is frequently not localized in the viscera, but is referred to certain parts of the surface of the body, and it has been shown by Mackenzie and by Head that it is referred to the area of skin which is supplied with sensory nerves by the same segment as that to which the afferent autonomic fibers of the particular viscus run. It has further been shown that vascular disease may cause sensitivity of the corresponding cutaneous areas."—(Macleod's *Physiology and Biochemistry.*)

9. *Metabolism.*—"The food-stuffs, after being digested and absorbed into the blood or lymph, are carried to the tissues, in which they pass through a series of complex chemical transformations, the end products of which leave the tissues and are removed from the body by the lungs and kidneys. This series of chemical changes constitutes *metabolism*, and the metabolic activities of the tissues are of two kinds. On the one hand, the living tissues are constantly undergoing changes whereby a portion of their substance is broken down and removed from the body; on the other hand, this loss is replaced by the building up of fresh tissue from the nutritive materials supplied in the blood. The former of these processes is called *katabolism*, and the latter *anabolism*.

"These changes involve the consumption of a large amount of oxygen, and the evolution of energy in the form of heat and muscular work. The food-stuffs are protein, fat, and carbohydrate, 90 to 94 per cent. of those consumed on an ordinary diet being absorbed into the blood stream, and the remainder being lost in the feces. The fats and carbohydrates are completely converted into carbonic acid and water, and the proteins partly into carbonic acid and water, the nitrogen, being excreted as urea and other incompletely oxidized substances in the urine. The carbonic acid is removed from the body almost entirely through the lungs, and the water by the lungs, kidneys, and skin. The changes undergone by the food-stuffs in the body may, therefore, be studied in three ways, namely (1) by measuring the total amount of heat evolved in their oxidation, (2) by determining the quantity of oxygen required for the carrying out of these oxidations, and (3) by measuring the amount of the end products which are formed. We may also attempt to follow out the series of changes taking place in the individual food-stuffs in the tissues themselves."—(Bainbridge and Menzies' *Essentials of Physiology.*)

10. The *cause* of the degeneration is that the nerve tract involved is cut off from the nerve cells which nourish it. This degeneration is called Wallerian degeneration.

Tracts of ascending degeneration.—Column of Goll; column of Burdach; Lissauer's bundle; direct cerebellar tract; anterolateral ascending tract.

Tracts of descending degeneration.—Direct pyramidal tract; crossed pyramidal tract; rubrospinal tract; olivospinal tract; comma tract; cerebellospinal tract of Lowenthal.

(*To be continued.*)

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE GLANDS REGULATING PERSONALITY. By LOUIS BERMAN. 300 pages. Published by The Macmillan Company, New York.

THE SPHYGMOMETER. By WILLIAM RUSSELL, M.D. 145 pages with illustrations. Price, $2.50 net. Published by William Wood & Company, New York.

MEDICAL RECORD VISITING LIST FOR 1922. Sixty patients. Price, $2.00. Published by William Wood & Company.

THE STOMACH AND ABDOMEN. By WILLIAM RUSSELL, M.D. 329 pages with illustrations. Price, $4.00 net. Published by William Wood & Company, New York.

THERAPEUTIC IMMUNIZATION. By W. FORD ROBERTSON. 278 pages. Price, $4.00. Published by William Wood & Company, N. Y.

VETERINARY HYGIENE. By R. G. LINTON. 429 pages with illustrations. Price, $6.00. Published by William Wood & Company, New York.

RADIOGRAPHIC TECHNIQUE. By T. THORNE BAKER. 196 pages with illustrations. Price, $3.50. Published by William Wood & Company, New York.

ESSENTIALS OF VETERINARY PHYSIOLOGY. By Drs. PATON AND ORR. 674 pages with illustrations. Price, $6.50. Published by William Wood & Company, New York.

TEXT-BOOK OF EMBRYOLOGY. By F. R. BAILEY. 663 pages with illustrations. Price, $6.00. Published by William Wood & Company, New York.

LOCAL ANAESTHESIA. By NORMAN BLACK 73 pages. price, $1.50. Published by William Wood & Company, New York.

DISEASES OF THE SKIN. By HENRY W. STELWAGON, M.D. 1313 pages with 401 text illustrations and half-tone plates. Price, cloth, $10.00. Published by W. B. Saunders Company, Philadelphia.

THE SPLEEN AND SOME OF ITS DISEASES. By SIR BERKELEY MOYNIHAN. 129 pages with 13 full page diagrams. Price, cloth, $5.00. Published by W. B. Saunders Company, Philadelphia.

TRAITÉ D'UROLOGIE.. Vols. I and II. By G. MARION. 1052 pages with 418 figures and 15 colored plates. Price, 120 francs. Published by Masson & Cie., Paris.

PRINCIPLES OF MEDICAL TREATMENT By GEORGE C. SHATTUCK, M.D. 309 pages. Published by W. M. Leonard, Inc., Boston.

Medical History.

NEW BOOKS AND OLD.

XX. WILLIAM WITHERING AND HIS BOOK ON THE FOXGLOVE.

BY JOHN RUHRÄH, M.D.,

BALTIMORE, MD.

WITHERING has not come in for his due share of biographical notice. Five short sketches and the usual notes in the ordinary sources are all I have discovered, though my search has been none too diligent: Kolipinski in the MEDICAL RECORD for July 14, 1914; Moschowitz in the *Medical Pickwick* for February, 1915; Cushny in the Proceedings of the Royal Society of Medicine, section on the History of Medicine, March, 1915; and Boulger in the Dictionary of National Biography. There is also a sketch of his life by his son prefacing the Miscellaneous Tracts. From the first four I have borrowed extensively.

William Withering was born March 17, 1741, at Wellington in Shropshire, England. As in the case of so many family names there were variations in his and previously it had been spelled Witherings, Widdrington, and Witherington. On his mother's side he had people of ability, witness Richard Hurd, Bishop of Worcester. His father, Edmund Withering, was an apothecary in Wellington, and his mother's brother a physician in Lichfield. This relation to the medical profession probably influenced him in the choice of his life's work. Having decided to become a physician he went to Edinburgh, at that time the ranking British School of Medicine. This was in 1762. Here he studied assiduously, working especially in chemistry and anatomy. After a year or two he started writing and produced papers on Topical Bloodletting, Inflammation of the Pericardium, on Dropsy, and on Rickets. His inaugural dissertation was on "De Angina Gangrenosa." On July 31, 1766, he was graduated M.D.

While at the University Withering sat under such teachers as Hope, the botanist; Monro *secundus*, the anatomist; Whytt in medicine, the author of one of the most remarkable medical monographs ever written "On Dropsy of the Brain." Cullen perhaps influenced him most of all. He was Withering's instructor in chemistry. Cullen in his treatise on Materia Medica did not describe digitalis at all but referred the reader to Withering's book, which he said should be in the hands of every practitioner of physic.

Withering was no recluse. He enjoyed human society and during his Edinburgh days numbered among his friends were Fowler, whose solution of arsenic is still used; Percival, afterward a reformer in sanitation at Manchester; Arnold, who later wrote about insanity, and Rogerson, who became physician to Catherine of Russia.

Leaving Edinburgh Withering traveled, visiting Oxford, London, and Paris. In France he had difficulties with the language and when his traveling companion died he returned to England.

He began practice in Stafford in 1767 and continued until 1775, but from a financial standpoint this period was not a success, so when Dr. Small of Birmingham died he repaired thither and soon built up a practice as large as any enjoyed by the physicians of London. Patients from afar sought him out and among those of note is the name of Benjamin Franklin.

His leisure while at Stafford was profitably employed in studying plants. Part of this enthusiasm may have been due to the lady who subsequently became his wife, as much of his collecting was done for her. In botany he was a distinct success, modifying the Linnæan system somewhat and publishing in 1776 "A botanical arrangement of all the vegetables naturally growing in Great Britain, according to the system of Linnæus; with an easy introduction to botany." This become very popular and a second enlarged edition appeared in 1787, a third volume was added in 1792, and a fourth in 1796. This work went into eight editions, the last appeared in three volumes in 1852. He also aided John Talbot Dillon with chemical and botanical notes to his "Travels through Spain." In 1778 he published his "Scarlatina Anginosa." In 1783 he translated Sir Torbern Bergmann's "Sciagraphia Regni Mineralis" which he published with notes by himself under the title of "Outlines of Mineralogy."

In 1790 he had an attack of pleurisy and pneumonia, from which he suffered the following year. This led to two trips to Portugal which he did not consider an ideal health resort. While there he wrote of the mineral waters and continued the study of botany which resulted in the "Floræ Ulyssiponensis Specimen" published in 1792.

He was a free mason, played the flute and harpsichord, wrote poetry, belonged to the Society for Promoting the Abolition of the Slave Trade, and did all the things of a man in active professional life. He was a member of the famous Lunar Society, so called because of the monthly meetings, which included such men as Priestley, the chemist, James Watts, and Matthew Boulton. In 1791 he was made a member of the Linnæan Society. His studies in chemistry and mineralogy were rewarded by a fellowship of the Royal Society, to which he was elected in 1784 and his work on barium carbonate led to the name of Witherite for that mineral. L'Héritier named one of the *Solanaceæ* after him, the Witheringia, which with the foxglove is graven on his tomb in Edgbaston. For thirteen years Withering was Physician in Chief to the Birmingham General Hospital, the buildings of which were completed in 1778, largely through his efforts. He did not mingle in politics. Indeed it is said he declined an invitation to the famous dinner at Priestley's house, given to celebrate the anniversary of the French Revolution. This led to a riot or was at least the pretext for one during which Priestley's house was sacked and partly destroyed. Withering was threatened and left his house hurriedly carrying off his books and botanical specimens in wagons, under piles of hay or straw. The animosity against him did not last long.

His portrait was painted by Frederick William Breda and comes down to us in his "Miscellaneous Tracts," published in 1822 by his son, in the engraving by W. Bond. The portrait was also engraved by Ridgley for Thornton's "Sexual System of Linnæus," 1801.

In 1776 he had fever and was far from well, but it was not until 1790 that his health grew much worse. After trying the Isle of Wight with little result, he purchased Priestley's house, "The Larches," formerly sacked by the mob. Here he passed his days indoors in an artificial temperature of 65° F. From now on he suffered from hemorrhage and dyspnea. During this time some one perpetrated the ghastly pun that "The flower of physicians is indeed Withering." He died October 6, 1799. He lies buried in the church at Edgbaston. His tomb bears the following inscription and poetic effusion:

Sacred
to the Memory of
William Withering, M.D., F.R.S.
&c., &c.,
Who Was Born March 28, 1741,
And Died October 6, 1799,
Aged 58 Years

While heav'n born Genius drops on earth a tear,
And Science, drooping, mourns o'er Withering's bier;
While Pity sighs to find that bosom cold
Where late she reigned, dispensing good untold;
While Memory's voice each virtue telling o'er,
But deeper wounds the peace she would restore;
Hope smiles serene, her eye upturned to Heav'n,
Where Virtue's never-fading crown is giv'n,
Sheds o'er the weeping sorrowers below,
That calm a Christian's grief alone can know.
Yes! on that day, when Nature's ruin'd frame
Shall form a grave for each illustrious name,
And Science's star, on earth so seeming bright,
Shall be eclips'd in universal light;
Then shall the sainted sage that bliss receive,
Which here no tongue can paint, no heart conceive;
While Angel choirs with plaudits justly giv'n
Proclaim his triumph to the hosts of Heav'n.

He was a good observer, a clear thinker, and an industrious worker, three of the essentials for a successful physician; that is successful in the true sense of the word. Withering passed in Stafford his lean years. In Birmingham he stepped almost at once into the "cakes and ale" stage. His financial success equalled his medical labors and his practice reached as high as two thousand pounds a year.

Space prevents going into his work more fully but some idea of his remarkable power of observation may be gained by what he wrote of pulmonary consumption: "and not many medical men are sufficiently aware that phthisis is contagious. Though some writers positively deny that phthisis pulmonalis is infectious, the contrary fact is to me indisputable."

In 1785 there appeared a little book entitled "An Account of the Foxglove, and Some of Its Medical Uses, with Practical Remarks on Dropsy and Other Diseases," by William Withering, Physician to the General Hospital at Birmingham, "*nonumque prematur in annum*," Horace. This little book is one of the great medical classics and insures Withering a place in the foremost ranks of the medical benefactors of mankind. Practically unaided he gave to the world one of the few reliable medicines, one of the greatest boons ever conferred on mankind. From the preface of this remarkable work I quote the following:

After being frequently urged to write upon this subject, and as often declining to do it, from apprehension of my own inability, I am at length compelled to take up the pen, however unqualified I may still feel myself for the task.

The use of the Foxglove is getting abroad, and it is better the world should derive some instruction, however imperfect, from my experience, than that the lives of men should be hazarded by its unguarded exhibition, or that a medicine of so much efficacy should be condemned and rejected as dangerous and unmanageable.

It is now about ten years since I first began to use this medicine. Experience and cautious attention gradually taught me how to use it. For the last two years I have not had occasion to alter the modes of management; but I am still far from thinking them perfect.

It would have been an easy task to have given select cases, whose successful treatment would have spoken strongly in favor of the medicine, and perhaps been flattering to my own reputation. But Truth and Science would condemn the procedure. I have therefore mentioned every case in which I have prescribed the Foxglove, proper or improper, successful or otherwise. Such a conduct will lay me open to the censure of those who are disposed to censure, but it will meet the approbation of others, who are the best qualified to be judges.

. . . . . .

There are men who will hardly admit of anything which an author advances in support of a favorite medicine, and I allow they may have some cause for their hesitation; nor do I expect they will waive their usual modes of judging upon the present occasion.

. . . . . .

After all, in spite of opinion, prejudice, or error, TIME will fix the real value upon this discovery, and determine whether I have imposed upon myself and others, or contributed to the benefit of science and mankind.

Digitalis was not unknown. Withering quotes some of the writers who preceded him and Kolipinski gives other references. The drug had been used experimentally in turkeys but its real virtue was unsuspected until Withering, following a clue, found its true worth. The story of the discovery of the drug, one of the many wonderful stories in the history of medicine, he tells as follows:

In the year 1775, my opinion was asked concerning a family receipt for the cure of the dropsy. I was told that it had long been kept a secret by an old woman in Shropshire, who had sometimes made cures after the more regular practitioners had failed. I was informed, also, that the effects produced were violent vomiting and purging; for the diuretic effects seemed to have been overlooked. This medicine was composed of twenty or more different herbs; but it was not very difficult for one conversant in these subjects to perceive that the active herb could be no other than the Foxglove.

My worthy predecessor in this place, the very humane and ingenious Dr. Small, had made it a practice to give his advice to the poor during one hour in a day. This practice, which I continued until we had a hospital opened for the reception of the sick poor, gave me an opportunity of putting my ideas into execution in a variety of cases; for the number of poor who thus applied for advice, amounted to between two and three thousand annually. I soon found the Foxglove to be a very powerful diuretic; but then, and for a considerable time afterwards, I gave it in doses very much too large, and urged its continuance too long; for misled by reasoning from the effects of the squill, which generally acts best upon the kidneys when it excites nausea, I wished to produce the same effect by the Foxglove. . . . It was from this kind of experience that I ventured to assert, in the Botanical Arrangement published in the course of the following spring, that the Digitalis purpurea "merited more attention than modern practice bestowed upon it."

I had not, however, yet introduced it into the more regular mode of prescription; but a circumstance happened which accelerated that event. My truly valuable and respectable friend, Dr. Ash, informed me that Dr. Cawley, then principal of Brazen Nose College, Oxford, had been cured of a hydrops pectoris, by an empirical exhibition of the root of the Foxglove, after some of the first physicians of the age had declared they could

do no more for him. I was now determined to pursue my former ideas more vigorously than before, but was too well aware of the uncertainty which must attend on the exhibition of the root of a biennial plant, and therefore continued to use the leaves. These I had found to vary much as to dose, at different seasons of the year; but I expected, if gathered always in one condition of the plant, viz., when it was in its flowering state, and carefully dried, that the dose might be ascertained as exactly as that of any other medicine; nor have I been disappointed in this expectation. The more I saw of the great powers of this plant, the more it seemed necessary to bring the doses of it to the greatest possible accuracy. I suspected that this degree of accuracy was not reconcilable with the use of a decoction, as it depended not only upon the care of those who had the preparation of it, but it was easy to conceive from the analogy of another plant of the same natural order, the tobacco, that its active properties might be impaired by long boiling. The decoction was therefore discarded, and the infusion substituted in its place. After this I began to use the leaves in powder, but I still very often prescribe the infusion.

Further experience convinced me that the diuretic effects of this medicine do not at all depend upon its exciting a nausea or vomiting; but, on the contrary, that though the increased secretion of urine will frequently succeed to, or exist along with these circumstances, yet they are so far from being friendly or necessary, that I have often known the discharge of urine checked when the doses have been imprudently urged so as to occasion sickness.

If the medicine purges, it is almost certain to fail in its desired effect; but this having been the case, I have seen it afterward succeed when joined with small doses of opium, so as to restrain its action on the bowels.

. . . . . .

I use it in the ascites, anasarca, and hydrops pectoris; and so far as the removal of the water will contribute to cure the patient, so far may be expected from this medicine; but I wish it not to be tried in ascites of female patients, believing that many of these cases are dropsies of the ovaria; and no sensible man will ever expect to see these encysted fluids removed by any medicine.

It would be interesting to quote a number of the case histories. Space prevents, but I cannot refrain from two short ones.

Case XIII.—October 9. Mrs. B., æt. 40. An ovarium dropsy. Took a decoction of digitalis without effect. Her life was preserved for some years by repeated tapping.

Case XLI.—July 6. Mr. E., æt. 57. Hydrothorax and anasarca; his breath so short that he could not lie down. After a trial of squill, fixed alkaly, and dulcified spirit of nitre, I directed pulv. digital. gr. 2, thrice a day. In four days he was able to come downstairs; in three days more no appearance of disease remained; and under the use of aromatics and small doses of opium, he soon recovered his strength.

Withering's conclusions are remarkable, showing what a clear-headed genius he was. They are:

I. That the digitalis will not universally act as a diuretic.

II. That it does do so more generally than any other medicine.

III. That it will often produce this effect after every other probable method has been fruitlessly tried.

IV. That if this fails, there is but little chance of any other medicine succeeding.

V. That in proper doses, and under the management now pointed out, it is mild in its operation, and gives less disturbance to the system, than squill, or almost any other active medicine.

VI. That when dropsy is attended by palsy, unsound viscera, great debility, or other complications of disease, neither the digitalis, nor any other diuretic can do more than obtain a truce to the urgency of the symptoms; unless by gaining time, it may afford opportunity for other medicines to combat and subdue the original disease.

VII. That the digitalis may be used with advantage in every species of dropsy, except the encysted.

VIII. That it may be made subservient to the cure of diseases unconnected with dropsy.

IX. That it has a power over the motion of the heart to a degree yet unobserved in any other medicine, and that this power may be converted to salutary ends.

And now we must take leave of Withering and his book, but not without reprinting two of the poetical effusions in praise of digitalis.

Cushny quotes the following lines by "S. H.," which he found in a late edition of Withering's Botany:

The foxglove's leaves, with caution given,
Another proof of favoring Heav'n
Will happily display;
The rapid pulse it can abate;
The hectic flush can moderate
And, blest by Him whose will is fate,
May give a lengthen'd day.

Erasmus Darwin, author of the "Loves of the Plants" and "Zoönomia," like so many other good men of scientific turn of mind wrote verse, among other things a long poem entitled the "Botanic Garden." From this Kolipinski quotes the following lines to the Foxglove:

Bolster'd with down, amid a thousand wants,
Pale Dropsy rears his bloated form, and pants;
"Quench me ye cool pellucid rills," he cries,
Wets his parched tongue and rolls his hollow eyes.
So bends tormented Tantalus to drink
While from his lips the refluent waters shrink;
Again the rising stream his bosom laves
And thirst consumes him mid circumfluent waves.
Divine Hygeia from the bending sky
Descending, listens to his piercing cry;
Assumes bright Digitalis dress and air;
Her ruby cheek, white neck and raven hair;
Four youths protect her from the circling throng,
And like the Nymph the Goddess steps along.
O'er him she waves her serpent wreathed wand,
Cheers with her voice and raises with her hand
Warms with rekindling bloom his visage wan,
And charms the shapeless monster into man.
—Botanic Garden, Part 2, Canto 2.

Twenty-fifth Anniversary of the Foundation of the "Revista de Medicina y Cirugia de la Habana."—The anniversary issue of this well-known Cuban periodical comprises 744 pages, well printed and illustrated. In addition to its historical side, the volume is a directory to the medical and allied institutions of the island—hospitals, teaching bodies, laboratories, libraries, periodicals, sanitary formations, monuments, etc., etc. Most of the articles are illustrated. Among others we find beautiful monuments to Findlay, and to the distinguished urologist Albarran (whose work was done in France), the buildings of the Health Office, the Calixto Garcia Hospital, the Preventorium, the new and beautiful buildings of the San Francesco de Paola Hospital, the Masonic Hospital, the City Hospital, the Academy of Medical and Natural Sciences, the Military Hospital, and several private hospitals such as "La Benefica" and "La Purissima," which treat thousands of patients annually. There are a number of these institutions which appear to take over much of the work of public hospitals in northern cities. The report may not be exhaustive, as we see no mention of the Leper Hospital, the Pasteur Institute, and certain other medical institutions.

THE ABDOMINAL SYMPTOMS AND SIGNS OF THORACIC DISEASE.

BY HARLOW BROOKS, M.D.,

NEW YORK.

PROFESSOR OF CLINICAL MEDICINE, UNIVERSITY AND BELLEVUE HOSPITAL COLLEGE OF MEDICINE.

I HAVE selected this title for my paper to-day because the subject is of equal clinical importance for both surgeons and physicians and because that it is only by constantly calling to mind the frequency with which abdominal symptoms arise as a result of thoracic disease that we may avoid serious errors in diagnosis and in treatment.

The magnitude of the subject and the limit of my time prevent an attempt to go very intimately into the subject of differential diagnosis, nor do I believe that this is possible in any general way, for differential diagnosis depends in this problem so much on minute individual points that no general rules may be usually laid down.

Throughout we must always bear in mind that disease does not respect our anatomical classifications and that there are really very few pathologic processes which do not to a greater or lesser degree affect all parts of the body.

I cannot attempt to-day to go deeply into the theories and the physiology of the transference of signs and symptoms, but as a fellow practitioner I shall simply bring to your attention the chief clinical phases of the problem as they confuse and mislead me.

My paper is then virtually but an enumeration of the most frequent forms of thoracic lesions which are commonly confused because of their signs and symptoms with disease of the abdomen.

This complex is perhaps best first illustrated by those very numerous cases in which an acute dilatation of the heart, due to any cause, gives origin to a picture which the layman usually, and the medical man not infrequently, refers to as an "acute indigestion." Years ago, when I was doing a large number of autopsies, many of them being acute emergency cases, I was particularly struck with the frequency with which sudden death from cardiac disease had been diagnosed as "acute indigestion." Among these probably the most frequent lethal lesion was a coronary thrombosis or embolism. Others were acute myocarditis with dilatation, myocardial degeneration, especially from a fatty degeneration or fatty infiltration of the heart, acute syphilitic myocarditis, gumma of the heart wall, pericarditis, acute or chronic and with or without effusion or adhesions, and the like. Nor was the cause of death in these cases diagnosed as acute indigestion limited to heart lesions alone, some of them were found on autopsy to be instances of acute or chronic aortitis, rupture of the aorta, or of aortic aneurism or of acute mediastinitis.

Nor must we assume that a story of acute abdominal pain of sudden onset with prostration, nausea, and vomiting when due to thoracic disease need, therefore, be an indication of the acuteness of the mediastinal or cardiac lesion. In very many instances only the onset of symptoms is acute; the lesions, as in the case of aneurysm, may be chronic or of very long standing. Rather in such cases may we usually say that the termination is the only acute phase of the condition, for close analysis of the history will usually discover abundant premonitory warnings. Very often, however, a cardiac lesion which has been of very long duration, giving perhaps few or no classical indications of thoracic disease, suddenly terminates as from an acute gastric perforation, dilatation or distention, perhaps thus only the symptoms being of acute nature.

It is much more frequent to find that a long-standing history of gastric distress, as from a chronic ulcer, from a hyperacidity, or even from an achylia gastrica, is due in reality to prolonged cardiac or mediastinal disease. This last is particularly likely to be the course in angina pectoris in which, in several instances under my observation, the chief symptoms have been ascribed to gastric, duodenal, gall-bladder or pancreatic disease. I know of no symptom and of rather few signs of these mentioned diseases which may not be very closely simulated by cardiac disease. Even hemorrhage from the stomach may be due to ruptured varices of cardiac origin in the stomach or esophagus.

The pathologist is rather too apt to censure the clinician in diagnostic mistakes of this kind, chiefly because of his unfamiliarity with the very close simulation of symptoms and signs in the two conditions, but I am very certain that I do not need to point out to any experienced practitioner of medicine or surgery that they are differentiated only with the greatest possible difficulty in very many instances. This is particularly true in emergency cases, such as the general practitioner or ambulance surgeon is expected to diagnose and treat, usually with very little, and that frequently misleading, in the way of history.

Differentiation in many chronic cases may be only possible after long and careful study, and

*Read before the Keuka Lake Medical Society, July, 1921.

often only by the assistance of many of the finer methods of diagnosis, of the electrocardiograph, by *x*-ray studies of the mediastinum and its contents, of the upper gastrointestinal tract, and by chemical studies of the functions of the pancreas and of the gall tracts.

In a very considerable number of these cases gastric signs and symptoms are in reality due to actual gastrointestinal lesions, as in the case of varices of the gastric or oesophageal mucosæ due to a long-standing mitral lesion, to a myocarditis, or the like. Gastric distress after eating, gastric hemorrhage, often sufficiently severe to cause collapse, and the signs and symptoms of gastric perforation may then occur as a result of changes in the stomach mucosa primarily due to cardiac disease. In some of these patients the primary cardiac lesions may be so obscure and indefinite as to escape detection, while the secondary lesions, because of their striking character, distract the clinician. Such problems very frequently develop in myocardial degenerations and in instances of angina pectoris.

Another condition of circumstances which may cause the pathologist to quite unjustly censure the clinician in these cases is when cardiac collapse, dilatation or acute rupture is in reality induced by gastric defects. All of us, even in the most apparently robust and sound, realize the frequency with which cardiac distress, even rupture, may occur as a direct secondary result of an over-distention or of dilatation of the stomach. It is a most important thing for the cardiologist to remember that over-distention of the stomach in particular and, to a lesser degree, of any of the other hollow viscera of the abdomen throws a great additional strain on the heart. Those of you in doubt may try running or other vigorous exercise calling for cardiac reserve after a full meal has been taken. Animals know better than to attempt such feats, wise stock men will not permit it in valuable animals, and yet we often permit ourselves and our patients such indiscretions.

I much regret that time does not permit us today to enter into the question of the differential diagnosis in these instances. I think, however, that we are perhaps sufficiently schooled in the matter when we realize the great frequency of the condition, the close similarity of symptoms and signs, and the fact that associated lesions of diagnostic import are often, perhaps usually, present. We all realize that in every case in which time permits a very close and intimate study of both the mediastinal structures and of the upper abdomen must be made before we decide in any given instances that the signs are solely due to cardiac or to upper abdominal lesions.

We must never forget the great frequency and assistance in a diagnostic way of associated lesions, not necessarily directly secondary, as for example, a syphilitic gastritis in association with a syphilitic myocarditis or coronary disease.

Dyspnea is a most important sign or symptom which almost constantly indicates either cardiac and mediastinal disease or inadequacy. I feel that in every case in which it is of a degree out of proportion to the exciting exercise under which it appears it should always be assumed to indicate cardiac disease or inadequacy. There are exceptions to this general statement, but if the sign is held well in mind it will frequently discover cardiac or mediastinal disease in cases in which the preponderance of signs and symptoms indicate abdominal disease. There are very few cases of mediastinal disease giving striking abdominal signs and symptoms which do not show more or less dyspnea, often quite out of proportion to the apparent grade of thoracic symptoms otherwise indicated in the case.

A careful physical examination of the mediastinal space is clearly indicated in every instance of apparently acute inflammatory or hemorrhagic disease of the upper abdomen, and no case of chronic disease of this region should be placed under final treatment before cardiac disease has been fully considered.

Although in part already considered, I believe that it is wise for us to especially consider the frequency with which the symptoms and signs of even an early angina pectoris are occasionally referred almost exclusively to the abdomen. This is particularly true of those patients in whom the anginal paroxysm commonly arises after eating, and in whom hyperacidity, gastric flatulance, and especially the sharp pain located in the epigastrium are the most constant manifestations of the angina. These cases are very frequent, and in a good many instances the detection of the true basis of the complaint is difficult; it often demands a most exhaustive study of both digestive and circulatory systems. As a rule in these cases one will find in some other, perhaps more readily detectable tissue, evidences of arterial disease, such as sclerosed retinal or conjunctival arteries, thickened radials, temporals, or brachials.

In more than few cases of this kind, of course, true gastric disease, particularly in achylia gastrica is associated with the angina, perhaps due to the same basic lesion, as, for example, to a syphilitic or gouty arteritis. In several cases I have found verified at autopsy marked associated disease of the pancreas in which anginal attacks of the pancreas were associated with undoubted vessel spasm of the coronaries. From the pancreatic standpoint this may be clinically verified by the existence of pain, often typically anginal in character, occurring without much modification in the heart rhythm or sound quality and with marked tenderness, usually a zone of head hyperesthesia at that level. Temporary appearance of sugar in the urine is also seen in some of these cases. As I have said, I am convinced that in certain patients whom I have studied both coronary and pancreatic arterial spasm were present, but the error which all of us are likely to make is to neglect the one or the other. The recognition of grave cardiac involvement is usually dependent on a poor heart muscle tone, but arrythmias and marked pulse deficit may be also present.

Pleural disease, and particularly the acute inflammatory lesions of the pleura, cause with great regularity the appearance of abdominal signs and symptoms. This is a fact which has been recognized for a very long time, and yet few, indeed, are the surgeons or internists who have not fre-

quently confused acute pleural disease with serious inflammatory disease of the abdomen, notably with acute gall-bladder inflammations and with appendicitis. Theoretically the differentiation is, or should be, easy, but as a matter of clinical fact it is most difficult and in very many instances quite impossible without calling into the conclusion the very important factor of *time*.

Obviously the confusion is most difficult to eliminate when the pleurisy is of the diaphragmatic membrane. In this location the definite signs of pleurisy may remain in abeyance for some days except for the abdominal manifestations. Temperature may or may not be present in either condition, leucocytosis may alike be present or absent. In either instance the respiratory movements are limited, usually more so on the chiefly affected side, though not at all infrequently one finds that the rigidity and tenderness of the abdomen is of the side opposite to that in which the pleural lesion is located. Of course, in the usual case the rigidity of the abdomen is more marked in the upper quadrants, but I think that all of us have seen instances in which the rigidity is as sharply located at McBurney's point, for example, as ever seen in true acute appendicitis. Not only do we find localized points of rigidity, often with a definite sense of intraabdominal mass, but tenderness may be also present and the sign of peritoneal irritation manifested by a sharp thrust of pain on the quick removal of the palpitating hand.

Abdominal zones of Head hyperesthesia may be present in some of these cases. It is very much easier, as a matter of fact, to detail the points of resemblance which may appear in instances of acute pleurisy with active abdominal disease than to point out points of differentiation. One point which has been of considerable assistance to me, though it, like all others, is often absent, confusing, or even misleading, is the fact that in the pleural lesion respiration is more frequently accelerated than in the true abdominal lesion. This point is best determined when the patient is asleep, though it may be made out sometimes in the waking hours.

Although these abdominal symptoms are much more likely to be seen in acute and in inflammatory lesions of the pleura, they may also appear in the more chronic ones, and I have seen cases operated for chronic appendix or for chronic gall-bladder disease in which the final explanation of the symptoms was found to depend on pleural adhesions, chronic inflammatory processes or even on pleural neoplasm. Symptoms leading to a possible diagnosis of ulcer of the duodenum may be also closely simulated by pleural disease, and in some cases chronic hyperacidity of the stomach has its true explanation in an old pleural lesion.

Of course, the *x*-ray, and particularly the study of the respiratory movements and shadows under the fluoroscope are of tremendous assistance in the differentiation of these cases, so also may the diagnostic tap be in those cases in which effusion is present. Frequently, however, particularly in the early phases of the process, in just the period in which conclusive diagnosis is most desirable from the surgical standpoint, the area of pleural disease may be small, and it may be further located at the very dome of the diaphragm, in which place detection is most difficult even under the best of circumstances.

Another point of importance to recollect is that, while one may be able in certain of these cases to demonstrate old adhesions, effusion, or even definite acute inflammatory lesions of the diaphragmatic pleura, this finding by no means definitely excludes the coexistence of abdominal lesions of perhaps insistent surgical importance. I saw a case this past spring in which the symptoms had been that of an old appendicitis of months' standing, in which apparently an acute exacerbation had occurred. On going over the case preparatory to operation, an area of dullness was demonstrated at the right base, *x*-ray plates showed the presence of supra diaphragmatic effusion and diagnostic tap showed the presence of pus. The patient was operated for an empyema, the diagnosis being confirmed at the operation, but the patient died, and the autopsy showed an old chronic appendicitis which had, as first diagnosed, perforated, causing a retroperitoneal abscess which had aparently secondarily infected the pleura. I am still at a loss to say in what manner we might have more wisely managed this case from the evidence presented; unquestionably the abdominal condition was the important one and that demanding the first and most thorough attention. We must never forget that, though all these various thoracic conditions may cause abdominal signs and symptoms, so also do peritoneal lesions not so very infrequently give rise to apparently more insistent thoracic signs and symptoms.

Not only do lesions of the pleura give abdominal signs and symptoms of very striking and confusing character, but what is even more difficult to explain on a physiological basis is the occurrence at times of striking abdominal signs and symptoms in disease of the lung without any pleural lesions which are detectable on autopsy. Of course, in most cases of pneumonia a pleurisy is also present, and it is very simple to assume, especially where the pneumonia occurs in the bases and then becomes overlaid with a pleurisy, that the symptoms of abdominal location are due to the pleural irritation, but as I have just said, we find cases in which the pneumonic process is located deep in the central portions of the lung and in which no apparent involvement of the pleura is then present.

In instances such as this we find early fleuroscopy or *x*-ray plating of the chest of great assistance, and in several instances in which surgical investigation of the abdomen seemed indicated, the discovery in my service of deep central pneumonic foci has saved us from the serious error of a laparotomy. In yet other instances, however, as every expert radiographer and internist knows, definite signs and symptoms of a pneumonia, perhaps one manifested by abdominal symptoms very largely, may be present and yet the most searching fleuroscopic and *x*-ray examination show nothing. In such a chest I have been able to demonstrate but a few hours thereafter extensive areas of consolidation.

Every experienced clinician realizes the tremendous difficulty with which differential diagnosis is accomplished in instances of this kind—very frequently it is a quite impossible matter, and in such instances the policy of the wise practitioner should be to wait until differentiation is possible. The mortality rate in cases of pneumonia which have had an unnecessary laparotomy imposed upon them is very high. The condition is, of course, not necessarily fatal, but add to the shock of the operation and the irritation of the anesthetic, the toxemia, and serious mechanical lesions of a pneumonia and the chances of recovery are greatly diminished.

What, then, are we to advise in those cases which develop acutely, simulate an acute inflammatory lesion of the abdomen and yet give rise to a persistent suspicion of a developing pneumonia? My experience has led me to feel that the wisest procedure is to wait until differentiation is possible. The icebag may be applied to the abdomen, the patient may be elevated in bed, so tending, the surgeons tell us, to the localization of an abdominal abscess, should it form; localization of the suspected abdominal inflammation may be also favored, after the method of the older clinicians, by the giving of opium. The abdominal inflation and to some extent the pain may be relieved by the giving of high colonic irrigations or by ordinary enemata, but never in these suspected cases should we permit an active cathartic to be used, even though we feel reasonably certain that the real basic condition is a developing pneumonia.

Of course, one is going to lose some cases by following out this cautious method of treatment; in by far the larger number, however, in case of mistake and the surgical neglect of an abdominal disease, subsequent drainage will at least save life, but when the opposite method is followed out the surgeon is quite certain to lose a good many more cases from his overzeal. He may, of course, solace his soul in the diagnosis of a postoperative pneumonia, but he is not going to increase his own self-respect or his reputation with the lay public, all too prone to condemn any operative procedure which is followed by death, quite irrespective of the cause.

My rather extensive autopsy experience in the past has convinced me that very many cases of postoperative pneumonia in abdominal cases were really due to failure of diagnosis of a developing pneumonia, due to the predominance of its abdominal signs and symptoms. In most of these cases a reasonable delay would have given the correct diagnosis. From my own experience I have no just ground to condemn error in this difficult differentiation, but I have had abundant experience to justify me in asking for a reasonable time for observation in all doubtful cases. I have certainly regretted my haste many more times than I have delay in these cases.

Several instances of pulmonary infarction have come to my service with a history of sudden stabbing pain in the right or left upper quadrant of the abdomen. Usually in these cases it is found that there is a definite rigidity, often with an area of tenderness in the abdomen and in the presence of an endocarditis or of a general sepsis I have diagnosticated renal or splenic infarction, when either closer physical examination or subsequent course or autopsy has shown the basic lesion to have been an infarction of the lung, usually of the basal portions. In cases of this type, however, one must exercise much care and close study, because of the frequency of pulmonary infarction, after serious abdominal disease and notably after operations on the appendix, gall ducts, colectomies, and the like. Here, again, the internist is frequently puzzled to decide if he is dealing with a postoperative or anesthetic pneumonia or with a postoperative pulmonary thrombosis.

I wish also to call your attention, basing my remarks on mistakes into which I have been led, to the frequency with which obstructions of the esophagus, malignant or otherwise, are manifested by indications of gastric disease. This particularly refers also to the diagnosis of gastric ulcer or carcinoma, or of reflex vomiting. Early lesions of the esophagus are always very difficult of diagnosis, and in very many cases seemingly conclusive negative *x*-ray findings are very misleading. I have myself found my chief assistance in the exclusion of esophageal lesions as the explanation of possible gastric disease, in watching the act of deglution and, where possible, in the following of the globus of food or drink through the fleuroscope. Very extensive ulcerative lesions of the esophagus, especially of the lower one-third, refer pain nearly to the epigastrium rather than to the point of actual ulceration.

As every practitioner knows, one of the most frequent methods of onset in chronic ulcerative pulmonary tuberculosis is with gastrointestinal signs and symptoms. Of so definite a nature is this syndrome that Osler speaks of it as one of the characteristic clinical pictures of onset in this disease. It has been argued by many that the explanation of these symptoms is because of involvement of the peritoneum by the specific inflammation. Though, of course, this is occasionally found, it is by no means the rule, but rather the exception, at least until late in the infection, when its specific and pulmonary nature have usually become absolutely definite. Neither can we explain the frequency of the method of onset on the basis of a pleural involvement which acts reflexly as in the acute pleurisies. This also, of course, may appear, but it is as a rule not until relatively late in the infection, for pleural invasion is not an early but a late manifestation of this form of tuberculosis.

The importance of recognizing the fact that a complete picture of gastrointestinal symptoms may indicate pulmonary tuberculosis must be constantly borne in mind, for every gastrointestinal clinic is constantly seeing these cases. Many of them enter the hospitals under this diagnosis, and by no means infrequently surgeons see these cases under the tentative diagnosis of a gastric or intestinal carcinoma, chronic duodenal or gastric ulcer, and perhaps the differentiation is only evident on a full physical examination or when the roentgenologist in his examination of the abdomen checks up by a plate of the chest.

In very many of these cases the indications of pulmonary disease are few in number, indeed cough is either absent or infrequent, the asthenia, anemia, loss of strength and weight are accountable on the basis of the supposed gastrointestinal disease, so that correct diagnosis is only likely to be made from a complete physical examination or, in carefully studied cases, from the negative physical findings in the abdomen, which then, of course, leads to a proper examination of the chest. The frequency of this condition emphasizes the importance in abdominal disease of either a complete physical examination in all cases or on the finding of definite and certain physical lesions in the abdominal organs before resorting to operative measures. This is no field for exploratory laparotomy. Consulting internists are not infrequently called in to see cases diagnosed as gastric ulcer with hemorrhage, some time to consider the advisability of operation when complete investigation shows the hemorrhage to have originated from an advanced lung tuberculosis.

Perhaps many of you feel that I have, as it were, but led you into a slough of diagnostic despond, for I fear that I have given you but very little help in the all-important field of differential diagnosis. I frankly acknowledge this to be true, and I pose to-day not as an instructor but as one of your fellows who has found this field a most difficult study, and one to which he wishes to especially attract your attention. My desire briefly restated is to call to your attention the very great frequency with which various thoracic lesions give symptoms and signs indicative of preponderating abdominal disease; to point out the great difficulty of the diagnosis; its paramount importance particularly when acute inflammatory abdominal lesions are simulated, and especially to emphasize the very great necessity of close observation of these cases for a reasonable period of time before the thoracic origin of such a symptom complex becomes so certainly excluded as to determine operative interference. It is often a most difficult matter for the internist or general practitioner to keep his head in such instances. If I have encouraged some of you in your conviction as regards this matter that, when in doubt, hesitate, *don't operate*, I have at least helped you to a conclusion to which my experience has led me.

47 WEST NINTH STREET.

SYPHILIS FROM THE STANDPOINT OF THE CLINICIAN.*

BY SAMUEL FELDMAN, M.D.,

NEW YORK.

INSTRUCTOR IN DERMATOLOGY AND SYPHILIS, FORDHAM UNIVERSITY; ADJUNCT, BRONX HOSPITAL; ATTENDING PHYSICIAN, CORNELL DISPENSARY DEPARTMENT OF DERMATOLOGY AND SYPHILIS; CHIEF OF CLINIC, BRONX AND LEBANON HOSPITAL DISPENSARIES, DEPARTMENT OF DERMATOLOGY AND SYPHILIS.

OF the 375 patients admitted to my divided service at the Cornell Dispensary during the three years ending April, 1921, twenty-two were cases of primary lues, including two reinfections, one patient with four chancres on the penis, one had a chancre on one of his tonsils, and one had a chancre on the upper lip. There were two patients in whom scabies was apparently a predisposing cause. A girl about thirteen years old, afflicted with scabies, developed a chancre on the inner surface of the knee. She was a hat-check girl. Did the handling of possibly infected clothing have anything to do with her infection? The second patient had scabies with numerous lesions on his penis. He exposed himself to infection during that period. After a course of treatment for scabies, all lesions of that disease disappeared, except a small spot on the glans penis. The latter lesion, on the contrary, kept on increasing in size, and changing its appearance until a chancre was suspected. The latter diagnosis was confirmed by finding spirochetes in the lesion.

There is nothing special to note about the 25 patients with secondary lues, except that one of them had chills and fever for two weeks immediately preceding the appearance of the secondary eruption, and, in spite of a definite history of a chancre, the case was diagnosed and treated as malaria. The total number of primary and secondary cases combined was 47, and the approximate proportion of early to late lues was one out of eight.

In the four years preceding 1918, out of 998 cases of syphilis, 249 were primary and secondary cases, the proportion of early to late infections being one out of four. (See Feldman, "Treatment of Syphilis," *American Journal of Syphilis*, May, 1921.)

It has been the general opinion that syphilis is on the increase. The above figures seem to contradict that impression, for the only measure of the prevalence of syphilis that can be at all relied on is the number of fresh infections that continually take place. Syphilis, as well as all other chronic infections, would tend toward elimination, provided no new infections took place. Several factors might have entered in the real or apparent reduction of the number of primary and secondary cases of lues. During the war period many young men of the age when venereal infections are more prevalent were concentrated in camps and then sent across. All through that period any infection that took place among these men was treated by the army medical men, and until the prevalence of early infections in the army can be compared with that in civil life, no proper estimation can be made. It must, however, be remembered that army life may be either more or less rigid than the restrictions placed upon himself by any civilian according to his personal moral code, and the comparison would not be entirely a just one. On the other hand, if the war were the sole factor, with the return of the men from France, of necessity we would have to see early infections on the increase again. In fact, we could expect, for a short time at least, the proportion of infections to become greater than before the war as a sort of reaction against the rigid discipline of army life. As a matter of fact, that is not the case, as is borne out by the author's cases. In 1918, the year of the war,

*From the Department of Dermatology, Cornell Medical College. This article is based on three years' work at the Cornell Medical College Dispensary from April, 1918, to April, 1921. Read at a meeting of the Bronx County Medical Society, November 16, 1921.

we had a total of 12 cases of primary and secondary lues. In 1919, when the war was over and all the men had returned, we had 15 cases, and in 1920 we had 17 cases. As everyone will remember, 1918 was a poor dispensary year on account of the epidemic. The increase of 5 cases in 1920 over the former year is only a relative one, as there were a greater number of cases treated in the latter year than in the former, and the proportion of one out of eight remains the same. With the war factor eliminated, we again must return to the question: What accounts for the diminution in the number of infections that take place at present as compared with the prewar period? The only logical answer that may be given is that the campaign of education against syphilis, waged by the various national and State organizations and civil bodies, is being crowned with success. The diminution of venereal infections can be due to only two causes—namely, a better morality and a better understanding of personal hygiene. It is more likely that the public is learning how to take precaution.

That at present there may be a greater number of syphilitics under treatment than formerly cannot be denied, in spite of the fact that at Cornell it was much smaller. In the four years preceding 1918 there were 998 cases, or an average of 250 cases a year, while in the three years following there were 375 cases, or an average of 125 cases a year. If there is an increase at all, it must be in the number of old cases of lues, which have previously escaped detection and have now been put under treatment, thanks to the better understanding of the nature of the infection, especially in patients who present no superficial evidence of the disease. This will be clearly demonstrated later in the article.

Sixty patients of those admitted during the three-year period were latent. They had no other evidence of the disease except a positive Wassermann test. Thirteen were early cases, their infection dating back from a few months to a year; 25 gave a history of infection dating back more than one year and in many instances as long as 30 years; while 22 cases denied a history of infection. In 13 of the latter the disease was discovered accidentally, a Wassermann test having been made for the purpose of obtaining a food handler's certificate from the Department of Health, and 9 gave a history of a luetic husband, wife, or child, or repeated miscarriages or stillbirths. Of the latter we only had 2 cases, which is an extremely small number, as miscarriage is a very frequent condition in syphilis.

Out of the 118 patients with tertiary lues, 39 had skin gummata in various regions of the body and 19 had papular, serpigenous, and squamous syphiloderms. In one case the lesions were like tuberculosis verrucosa cutis, in another one, with lesions on the nose, the disease so strongly resembled lupus vulgaris that, in spite of a positive Wassermann test, the nature of the disease was not really established until after a number of salvarsan treatments as a therapeutic test. One patient, when first seen, had lesions on the upper lip and about the mouth which resembled lupus erythematosus. The border of the lesion was elevated, the center depressed, the surface shiny and, in places, covered with firmly adherent scales. This patient was treated for six months with radium and another six months with the alpine lamp by men high up in the profession. The writer must confess that he did not altogether doubt the diagnosis, but, as the lesions were not entirely typical, there being too much infiltration for a straight case of lupus erythematosus, a biopsy was made and the pathological findings were those of the latter disease plus a certain amount of round-cell infiltration, the latter containing a fairly large number of plasma cells. The patient was presented at one of the dermatological societies in this city, and the diagnosis was apparently concurred in. However, a Wassermann test was taken and it proved to be four plus, but, in spite of that, we still thought that we were dealing with a case of lupus erythematosus with the addition of a syphilitic infiltration until the lesions cleared up after a few salvarsan injections. One patient had skin lesions not unlike urticaria, but on a copper-colored base. Another one presented lesions on the arms and legs that, at a glance, were indistinguishable from erythema nodosum. On closer inspection, however, there were no signs of acute inflammation, there was no heat, pain, or tenderness, yet we were quite perplexed till the patient came to our aid by giving a history of luetic infection. We had several cases which serve strongly to emphasize the fact that surgical wounds in a syphilitic patient have no tendency to heal. A second-degree burn defied all efforts of the physician. There was not the least tendency to heal after four months of surgical treatment until a Wassermann test proved positive and antisyphilitic treatment was instituted. A bullet wound in a returned soldier showed no sign of healing. There was no history of lues, but a Wassermann test was positive, and the wound healed rapidly with antiluetic treatment. A case of orchitis was diagnosed as tuberculous. An operation was performed in one of the hospitals in this city. The operation wound would not heal. Here, also, a Wassermann test made on the patient's blood was positive and the wound healed rapidly after a short course of antisyphilitic treatment. Was that a case of tuberculous or syphilitic orchitis? A patient was treated for chronic articular rheumatism. He had joint pains and an *x*-ray examination of the patient's mouth revealed a focal infection in the root of one of his molar teeth. The tooth was extracted, but there was no relief of the articular pains and the extraction wound showed no tendency to heal. Here, again, a positive blood test put us on the right track and we were able to watch the rapid disappearance of the joint pains simultaneously with the healing of the wound as the patient received his first few antisyphilitic treatments.

Many of the following patients with tertiary lues did not come for treatment directly to the department of syphilis, but they first came with their complaint to other departments of the dispensary, where their condition had first been diagnosed, and were then transferred to the for-

mer department. The departments of medicine, surgery, eye, ear, etc., have each contributed their share.

Of patients with involvement of the mouth and the upper respiratory passages, three had ulcerations or perforations of the nasal septum, two suffered from leucoplakia, two others from interstitial glossitis, three from ulcerations of the soft palate, and four patients had either pharyngitis or laryngitis.

There were eleven patients with ocular lesions, five of which were cases of interstitial keratitis, four of iritis, and one each of iridocyclitis and choroiditis.

Of the patients with involvement of the genitourinary tract there was one case each of orchitis and erosions of the uterine cervix. One patient with a luetic history of nine years' duration remained practically untreated, until in 1916 he developed symptoms of chronic parenchymatous nephritis. He complained of backaches and his urine boiled almost solid. His Wassermann reaction was four plus. In spite of the fact that the older literature warns against the use of arsenic in nephritis, the patient was given small doses of salvarsan, even mercury injections, cautiously administered. His urinary symptoms cleared up completely after a short period of treatment, under which he remained nearly continuously for three years. His blood became negative and remained so for six months, when he finally disappeared from the clinic. Kolmar, Lucke, and Schamberg have recently demonstrated experimentally on animals (*Archives of Dermatology and Syphilis*, April, 1921), that arsphenamine has a special affinity for the liver, suprarenals, and the blood vessels, while mercury is more poisonous to the kidney and the brain. That does not mean that patients with positive blood reaction and with diseases of the kidney, liver, blood vessels, etc., should not receive antisyphilitic treatment. On the contrary, the symptoms will usually clear up under treatment. With this in mind, we treated all our luetics who had albuminuria, jaundice, or aortitis with salvarsan and we managed to get excellent results. The case is different, however, when a syphilitic patient who has previously no indication of trouble in the abovementioned organs suddenly develops albuminuria or jaundice. In that case the condition may be due to the drug, and treatment must be discontinued. Among the patients with lesions involving the abdominal organs there were two in whom the liver was at fault. One patient was transferred from the general medicine department with a diagnosis of hepatitis. He had a large liver, which extended two inches below the border of the ribs. The left lobe was especially involved. There was marked jaundice. The latter disappeared completely and the liver contracted to nearly its normal size before a four months' course of treatment was completed. The other patient came with a diagnosis of aortitis and hepatitis. His symptoms cleared up gradually, his blood reaction was negative after two courses of treatment and, although it remained so for 2½ years, treatment has not been discontinued. Two patients with skin gummata developed jaundice after a shorter or longer period of antisyphilitic treatment. The latter was discontinued and the patients watched for a while. Both, however, disappeared from further observation and the progress of their condition remains unknown to the writer.

Among the patients with lesions of the gastrointestinal tract, two were transferred to our department with a diagnosis of gastritis, and one complained of constant spitting, a lump in the chest after eating, and a bad taste in the mouth. He denied a history of lues, but had a four plus Wassermann reaction. All three improved rapidly under treatment. In a woman, who complained of indigestion, an *x*-ray plate revealed a circular constriction of the stomach. There was no luetic history and her blood gave a negative reaction, yet her case was suspicious and she was given antisyphilitic treatment as a provocative measure. The Wassermann reaction after the provocative was also negative, but curiously enough her subjective symptoms have improved. Besides the above cases there was one case each of fissure and of fistula in ano.

Of the patients with lesions in the lungs and cardiovascular system, one was referred from the internal medicine department, where he came after repeated pulmonary hemorrhages. He had a positive Wassermann reaction and an *x*-ray of his lungs showed a slight fibrosis. At the present time he has been under treatment for a short period only, yet his hemorrhages have stopped completely and he feels improved in general. Two patients were transferred with a diagnosis of syphilitic infiltration of the lung. The *x*-ray plate in one of them showed a marked infiltration at the hilum. Repeated examinations for tubercle bacilli revealed nothing, but the Wassermann reaction in each case was positive. Their subjective symptoms cleared up completely after a certain amount of antisyphilitic treatment. A second *x*-ray examination has not as yet been made. Besides the above, there also was one case each of arteriosclerosis with hemorrhages in the fundus of the eye, of high blood pressure, and of aortic regurgitation, and two cases of aortitis.

Patients with objective and subjective symptoms referable to the skeletal system: Osteitis, periostitis, and exostosis, two cases; pain in a number of joints, two cases; pain in the knee, in the hip joint, in the feet, in the shoulder, and muscular pains in the arms and shoulders, one case each; pain in the legs, four cases, and cramps in the legs, two cases.

Besides patients with pains in the skeletal system, there were a number who complained of pain referable to various regions of the body and in whom it was the sole symptom, there being no other evidence of lues, outside of a positive Wassermann test. They were as follows: Four patients with general pains, referable to several regions of the body and traveling from region to region; described by the patient as burning pains, two cases; pain in the chest, nine cases; pain and burning sensation in the region of the heart, one case; cephalalgia, nine cases; migrainous headaches, one; pain in the region of the spine with headaches, two; abdominal pains, two,

and gastric pains, one case. These cases, in which pain was the only evidence of disease, have been purposely classified in a group in order to make prominent the fact that probably all these pains represent syphilitic lesions in so early a stage as not to show any objective signs with the methods of diagnosis at present available. For example: The abdominal pains may be the first and the only sign of tabes before the degenerative processes are far enough advanced to show the well-known and distinctive signs of that disease; precordial pain may be due to coronary artery disease in its incipiency or to early tabes; the joint pains to early joint involvement, whereas shooting pains in the legs are characteristic of early tabes. Several of these cases have actually been traced to the central nervous system by positive findings in their spinal fluid and will be discussed later. A number of patients in this group, as well as some previously mentioned, have denied any history of lues in themselves or in their immediate family. Assuming that the statements of the patients have been made in good faith, which we have no reason to doubt, the absence of a luetic history in syphilitic patients may be accounted for in the following manner: There might have been at some remote period an innocent-looking papule or ulcer, which was overlooked by the patient or wrongly diagnosed by the physician and the incident entirely forgotten. Intraurethral chancres, vaginal and cervical lesions and lesions in the mouth and pharynx may have occurred without the subsequent appearance of any secondary eruption, and the condition was therefore overlooked or wrongly diagnosed. Some patients may have had hereditary lues, in whom the symptoms appeared late in life, with a forgotten history and without any stigmata of heredity. Lastly, a number of patients may have had direct infection of the blood stream and with the entire absence of primary or secondary lesions. The diagnosis of syphilis in these cases, as well as in patients whose sole complaint is general weakness, debility, anemia, nervousness or neurasthenia, dizziness or vertigo, of which we had 10 cases also in patients with gastrointestinal, joint, and muscular pains, as well as in patients with symptoms referable to the nervous system (which will be enumerated later), is extremely difficult, especially in the absence of a luetic history. An early diagnosis is but rarely made and the patients are treated for their symptoms or the disease which their symptom complex resembles in some instances for many years until the disease progresses so far that the diagnosis becomes apparent. For example: Two patients with joint pains were treated for a long time for chronic articular rheumatism and the anemic patient was treated with cacodylate of sodium with some degree of success, but without a diagnosis. Further illustrations of the above statement the reader will find in other places in this article. The result of improperly diagnosing these cases ranges anywhere between the tragic and the ridiculous. The welfare of the patient, nay his very life, may depend upon an early diagnosis. How can we arrive at it in syphilitics with these and similar obscure symptoms? When a syphilitic history is obtainable the diagnosis is a comparatively simple matter. A Wassermann test will usually tell the story. Even if the blood test proves negative we can still resort to the therapeutic test, which hardly fails us in clearing up symptoms. How shall we arrive at a diagnosis without the help of a history of lues? In the opinion of the writer, the only means in our possession for overcoming this difficulty is the routine Wassermann test. Every patient, except those whose condition is unquestionably nonluetic, should be subjected to it. As syphilis may simulate almost anything in medicine, with the possible exception of the acute infectious diseases, the number of patients in whom the absence of lues could be taken as a positively established fact would be comparatively small. By a careful examination of the list of cases enumerated in this article the reader can readily see what a variety of conditions are here represented. To illustrate what may be accomplished with a routine Wassermann test I will cite the following: Of late the general medicine department of Cornell is subjecting nearly every new patient to the test and, if the latter is found positive, the patient is at once transferred to the department of syphilis. In the three years upon which this article is based the record files in the latter department, in the writer's divided service alone, show 46 cases with pain as the only symptom of syphilitic infection out of a total of 375 cases of lues, or 12½ per cent., while in the four preceding years, in the same service, there were only 26 cases out of a total of 998 syphilitics, or 2½ per cent. The same increased proportion prevails in the entire group of cases that are apt to seek relief for their trouble of the internist rather than of the syphilologist. It is true that with the routine Wassermann test we cannot hope to detect all cases of syphilis, even if the latter be applied to every living human, for a number of patients with tertiary lues and more with syphilis of the central nervous system repeatedly give a negative Wassermann reaction, especially if untreated, and therefore a number of cases are bound to remain unrecognized.

This brings us to the question of the reliability of the Wassermann test as a test for syphilis. The cases in which the latter apparently or really fails us, can be divided into two groups: First, the cases in which the failure is only apparent, the results depending upon the skill of the serologist, the technique, and the antigen used. The probability is that this difficulty will soon be eliminated with the establishment of a proper standard for the test. There is, however, a group of cases, which are clinically unquestionably syphilitic, yet their blood is continuously negative. Neurosyphilis and, to a lesser extent, old tertiaries make up the bulk of this group. For example: out of 38 tabetics, 7 had negative blood reactions when we first saw them, or about 19 per cent. Four of them, however, became positive after one or more courses of treatment. Out of 118 cases of tertiary lues with gummata in the skin and various organs, two were negative on admission or about 1½ per cent., while out of 17 cases of hereditary lues, one started his dispen-

sary career with a negative Wassermann reaction. Cannot this phenomenon in syphilis be compared with the similar one in all other infections, when either the invading organism is too virulent for the host or the latter too weak to be able to set up a reaction against the former? What else is the Wassermann test based upon, outside of the reaction of the tissues of the host against the invading microorganisms? The fact that many of these patients give a positive reaction after a certain period of antisyphilitic treatment, bears out this contention.

It would be unscientific for any physician to discard the Wassermann test as worthless, because it is, in certain instances, inconclusive. It would be criminal for any writer to attempt to discredit it, because of its shortcomings. The harm done by discarding it or even by relaxing its rigid application would be incalculable. If a negative reaction is not an absolute proof of the absence of syphilis, a positive one is quite conclusive, especially in the presence of even the least suspicion of luetic infection. Fortunately, the great majority of syphilitics with negative reactions are those in whom the clinical evidences of the disease are well defined and the aid of the blood test is of secondary importance. Who would, at this late day, regard a clinical diagnosis of tabes as insufficient evidence of syphilis? The only time the test really fails us is when the symptoms are vague and indefinite and the reaction is negative at the same time. Judging by the percentage of well defined tertiaries with negative reactions, the number of patients with ill defined lesions and negative reactions must be comparatively small. Even in these cases, the task of arriving at a definite conclusion is not entirely hopeless, for we may still resort to the therapeutic test. That medicine has not yet arrived at the stage when every case can be correctly diagnosed, with the possible exception of the autopsy table, no one will deny. Why, then, should we expect more when we are dealing with syphilis than with any other disease? Why feel disappointed?

A small group of tertiaries were those with involvement of the nerves, both cranial and spinal. Of these we had two cases of peripheral neuritis; two of third nerve paralysis, one of seventh nerve paralysis, five cases of optic nerve atrophy, and two of auditory deafness. In passing, it is worth while to note that, while the clinical results from antisyphilitic treatment were very good in all but the last two conditions named, the latter showed not the least sign of improvement.

Of the forty-five patients with involvement of the central nervous system the predominating type was tabes, eighteen early cases and nineteen late ones with the following variations: Two patients were suffering from incontinence of urine, one from bladder irritability, and one from attacks of gastric crisis without any other tabetic symptoms. Further there was one case each of early tabes with colic and headaches, of early tabes with optic atrophy, of early tabes with cardiac hypertrophy and aortitis, and of early tabes with pain in the stomach. One patient had a pain and burning sensation about the heart and in spite of a definite syphilitic history, his blood Wassermann test was negative. His trouble, however, was traced to syphilis of the central nervous system by positive findings in the spinal fluid. A male patient, about 30 years old, suffered from loss of sex power. The writer must confess that he is not sufficiently posted on the subject of endocrinolog to question the wisdom and purpose of the surgeon who grafted horse testicle into the subcutaneous tissues of the patient's abdomen. What he could not accomplish with three successive operations, was done with a very short course of mercury and salvarsan.

Two cases of advanced tabes are remarkable examples of how often these cases are wrongly diagnosed and treated. One, a very old tabetic with paraplegia, was treated for chronic articular rheumatism for five years before his case was properly diagnosed. The other one had severe attacks of vomiting, which were not influenced by any medical treatment. A gastroenterostomy was performed for the relief of the vomiting, but without success. As might be expected, a Wassermann test of the patient's blood was made before the operation and it was negative. When the patient came to the clinic, he had all signs of advanced tabes, so that a spinal puncture was deemed unnecessary. It is needless to say that the vomiting stopped shortly after treatment was instituted, although his ataxia and the other tabetic symptoms were only slightly influenced by the treatment.

Among the other patients with central nervous system involvement were two cases of paraplegia, one of cerebral hemorrhage, one of luetic meningitis with paraplegia, two taboparetics, and three patients with cerebral lues, one of whom had attacks of unconsciousness and two had epileptiform attacks. A patient was admitted to the maternity ward of the Bronx Hospital. She was 17 years old and delivered herself of a syphilitic child. She denied any history of a primary lesion, but a fading roseola was still visible. On the fourth day of the puerperium, the patient was found under her bed. On being questioned, she remembered nothing of what had happened. The same day she had three convulsions, the first one lasting about two minutes, the second, five minutes, and the last one about thirteen minutes. The convulsions were epileptiform in nature, except that at times, instead of the hands being contracted into a fist, there was flexion at the wrist and extension of the rest of the joints of the hand. There were the unconsciousness, the biting of the tongue, the deep coma following the attack, and absolute lack of knowledge of what had happened. Between the attacks the patient's mind was more or less clouded. On the following day the patient had two attacks, each lasting about fifteen minutes. Salvarsan was administered during the interval between the two attacks and the patient slept quietly during the entire night. There was only a slight spasm on the next day. It lasted only a few seconds and was the last one of the convulsive seizures. The patient's mind cleared up gradually and five days after the last attack, she described what she thought she remembered about the attacks, namely, that she was in the act of flying and was kept back by a crowd of people

(the nurses who held her down). The nurses reported that they found her in the act of masturbation four times during her ten-day stay in the hospital. Her temperature and pulse were normal and her blood pressure was 110 systolic and 60 diastolic. Her blood Wassermann was four plus and her cerebrospinal fluid was negative to the Wassermann test and to all other pathological findings. It is clear that we were not dealing with an eclampsia or a cerebrospinal lues, but with a severe spirochetal toxemia.

An interesting family group of five members came under my care in the Lebanon Dispensary. The father had taboparesis with paraplegia, the mother and the oldest boy had tabes, and the younger boy cerebrospinal syphilis with paraplegia. An interesting observation on these cases was made by Dr. J. H. Leiner who kindly referred them to me from the neurological clinic, namely—that the first clinical symptom in each case was nystagmus. Another boy in the same family died in the City Hospital from cerebral lues. The Wassermann test was positive in all, except the fifth member of the family, a girl of thirteen, in whom it was negative, both clinically and serologically, on admission. After watching the child for about a year it was observed that her pupils had become somewhat uneven, that they were slightly fixed, and that nystagmus was present in her case as well as in the other members of the family. She was immediately placed under treatment. This was the largest number of patients with cerebrospinal syphilis in one family, observed by me during many years of dispensary work. I can recall only one other syphilitic family of five, but not a single member of that family had any central nervous system involvement. Two children of that family suffered from interstitial keratitis and one from exostosis of the clavicle. The parents were both latent syphilitics, each with a positive Wassermann reaction. What explanation can be given to the occurrence of neurosyphilis in all members of one family and in none of the other? It is evident that there must be some difference in the mechanism of infection. Either there is a lack of resistance on the part of the nervous system of the host, which may be hereditary and transmitted to the offspring, or there may be a special affinity of the invading germ for the cells of the nervous system of the host. The former cannot logically be considered the causative factor, in view of the fact that hereditary traits are not transmitted from husband to wife. The only logical conclusion one must arrive at is that there is a special strain of spirochetes with a special power to attack the cerebrospinal system. The fact that a large number of patients with neurosyphilis, unlike those with syphilis of other organs, give a negative Wassermann reaction, makes one think that that particular strain of spirochetes which is capable of producing neurosyphilis bears the same relation to the ordinary strain of spirochetes that the paratyphoid bacillus bears to the typhoid bacillus. The name parasyphilis, sometimes applied to neurosyphilis, seems justifiable.

While on the subject of tabes, it would be interesting to note at what period after the initial lesion the symptoms of that disease appear. In a selected group of cases, in which the history of the initial infection was stated definitely, the writer finds that out of 33 tabetics, three developed that disease before the fifth year, after the initial lesion; nine, between the fifth and the tenth; six, between the tenth and the fifteenth; seven, between fifteen and twenty; four between twenty and twenty-five, and four after that period, the average being thirteen years. Similarly a group of 49 selected cases of tertiary lues gave an average of 9½ years from the initial lesion to the appearance of the tertiaries, the earliest being one year and the latest thirty.

The most frequent tertiary lesions found on patients with hereditary lues were those involving the ocular structures, namely: three cases of keratitis, two of iritis and one case of optic atrophy, the total being six out of nineteen, or 31.6 per cent. One patient in the above group was of particular interest and deserves a fuller description, namely, a young man 24 years old, who, by appearance, would not be taken for more than about fifteen or sixteen years. He was short in stature and weighed about 85 pounds. He had a very large gumma in the supraorbital region, the right sternoclavicular joint was enlarged to about four times its normal dimensions, the liver reached below the level of the umbilicus, and the spleen was enormously enlarged. His mentality was that of a child. It was impossible to impress upon him the seriousness of his condition and the necessity of antisyphilitic treatment. He only appeared for treatment at intervals and within a period of three months he had only three salvarsan and eight mercury injections, yet it was almost miraculous to note the virtual melting away of the lesions after that small amount of treatment. The supraorbital gumma entirely disappeared, the liver and spleen greatly diminished in size, and only the clavicular exostosis was influenced rather slowly by the treatment. He gained in weight and instead of a small emaciated boy with a wizened face and a large tumor over the left eye, and a large protruding abdomen, he now looks like a well nourished, comparatively normal youth.

Until early in 1918, the dose of salvarsan given to all patients at Cornell, was never larger than 0.2 gm. Later it has been changed so that every patient, except children and adults who, for some reason or other, are unable to tolerate large doses of arsenic, receives a full dose of 0.6 gm. of salvarsan. In a previous article by myself it was demonstrated that, even with the small doses, the results of treatment were quite encouraging. It would be of value to draw a comparison of the results obtained from treatment with the larger and the smaller dose. There were not enough patients with primary lues, treated long enough, to be of value in such comparison. The result of treating secondary lues with the larger dose, however, was decidedly better. The same is true of latent lues. The poorest result, with respect of obtaining a negative Wassermann reaction, was obtained in tertiary lues. Yet, the results were better with the larger dose (see table). Some of the patients with tertiary lues were treated for many years and no negative reaction was obtained. The inability to

obtain results within a reasonable period of time taxes the patience of both the physician and the patient and the latter drops out in disgust. He may discontinue treatment for a long time, until something happens that frightens him back to it. The physician, not being able to follow many tertiary patients to a successful result, has developed the idea of the Wassermann-fast patient. Glancing over our records, I find, however, that a number of patients with tertiary lues, whose blood remained positive for years, in spite of the fact that they were uninterruptedly under treatment, became negative after ten or more courses or a period of approximately five years of treatment. It is gratifying to note that, once a negative reaction is obtained in these cases, it usually remains so, provided treatment is kept up. The explanation offered for the so-called Wassermann-fast patient is that he is really cured, but his tissues are so altered that lipoids are formed within the cell which give a positive reaction. The same idea is advanced by those who believe that patients with latent syphilis who give a positive reaction should not be treated. In the absence of positive proof to the contrary, the writer must accept the possibility of a cured patient, who is Wassermann-fast. However, this can not explain why a patient, whose disease has been latent for as long a period as thirty years, suddenly develops tertiary lesions. Repeated miscarriages in a patient who is entirely negative to physical signs is a direct proof that even the patient with apparently latent symptoms may be actively syphilitic. The impression gained from treating syphilitics is that there always is a possibility of curing the patient and that treatment should be continued until results are obtained. That brings us to the question, what constitutes a cure? The writer has on several occasions been challenged by sceptics to show one patient who has become negative after treatment and remained so for at least five years. The writer does not know why that figure should be the one to be taken as a criterion, at the same time he is happy to report that we have on record several such patients. Recent experimental work, done by von Wassermann (abstracted in the *Archives of Dermatology and Syphilis*, May, 1921), has made him come to the conclusion that the Wassermann reaction is not due to the presence of the spirochetes in the tissues, but to the presence of lipoids in the tissue cells, which in turn are produced by the presence of the spirochetes. Also that arsenic is purely spirochetidal, and mercury alone exerts its influence on the cells, which have been changed by the disease and on the inversion of the lipoid metabolism. It would be interesting to know whether this inverted lipoid metabolism can exist after the spirochetes have been destroyed by arsenic. In that case, Wassermann-fast cases are possible; also, in treating syphilis, one would be justified in choosing arsenic as the proper treatment for early cases of lues, whereas the combined method should be the one of choice in old cases.

We had very few reactions in the last three years, during which time we gave about 1,700 salvarsan and about 5,200 mercury injections. There were only two patients, who had more or less of a severe reaction of the so-called nitroid type, with congestion of the face, dyspnea, and low blood pressure. The color in one of the cases was of a peculiar brick color, rather than livid. Further reaction in both patients has been obviated by administering adrenalin before each salvarsan injection. Out of a total of 3,500 salvarsans, administered during the past seven years, two patients developed jaundice during the treatment. Two other patients were so susceptible to mercury, that after almost every injection of the latter drug they developed chills, high fever, and bloody diarrhea. Treatment of these patients with mercury has become impossible.

909 KELLY STREET.

HOW TO DETERMINE THE SEVERITY OF A CASE OF MORPHINISM.

BY C. B. PEARSON, M.D.,

CATONSVILLE, MD.

I USE the word morphinism because it is the most common form of opiumism. So far as my experience goes, the addictions to the various forms or derivatives of opium are essentially the same, whether used by mouth, needle, or opium pipe. The essential thing is the amount taken into the system and the duration of the addiction. To get an equal toxic effect, of course, there is a variation in

the gross amount of the various forms of the drug. But if the toxic effects are equal, it matters not what form of the drug is used.

One must be able to judge correctly the severity of a case of morphinism in order to treat it rationally. First, we should study the physical condition; second, the mental state of the patient; third, the history of the case. We should include in the history the family history, the preaddiction history, and the history of the case after the formation of the addiction. All this is very much like what we wish to know about any case of chronic illness. For instance, in tuberculosis the history is important on account of its bearing upon the present physical condition and because it gives us some data for estimating the probable vital powers of resistance. In morphinism the history is chiefly important because of the hints it gives us about the addict's mental and moral integrity. I am not so particular about the addict's physical condition providing it is good enough to enable me to withdraw the drug safely. The fact that the addict has one or more concurrent diseases, is a weighty reason for the withdrawal of the drug, providing it can be done without danger. If one has tuberculosis he is in a bad way. If he has tuberculosis and morphinism he is in a bad way indeed. The addict has practically no chance of recovery from tuberculosis unless first cured of his morphinism. The idea that morphine prolongs life when the addict has one or more concurrent diseases is absolutely false. The reverse is true. We can confidently look for a fatal termination of the case much sooner than if the patient were free from morphinism.

Although not germane to my subject, a word of explanation is needed at this point or some addict may be sent to his grave many years too soon. Any system of "quick treatment" administered to a tuberculous addict might prove fatal. Even a gradual reduction administered by one lacking the needed technical knowledge might well be dangerous. Technical knowledge and experience are needed in order to be successful in the treatment of morphinism. One should know the addict and his ways and even how he thinks. All this is just as necessary as it is for the surgeon to know anatomy, regional anatomy, surgical cleanliness, and all the ins and outs of surgical technic.

I have seen cases of morphinism complicated by tuberculosis gain from week to week during the reduction of the drug. Some of them after getting free from the drug recovered from the tuberculosis, at least they arrived at a point where all signs of the disease became negative. Others I have every reason to believe lived longer than would otherwise have been the case. And certainly the latter part of their life was made much happier. I remember well a patient whom I treated many years ago. She was a farmer's wife 45 years of age. She had used the drug twenty-five years. She ceased to menstruate at the third year of her addiction. There was a total cessation of the ovarian functions for twenty-two years. How can those who maintain that morphinism is not a disease account for such a long suppression of the menses? She was a woman of ordinary physique when she began the use of the drug. The ovarian functions are very important to a woman from the age of twenty to forty-five. The corresponding male organs are affected in the same way by morphine. Those best qualified by study and experience to give an opinion say that these organs have very important functions connected with the well being of the body outside of their use in the perpetuation of the race. The reckless manner in which ovaries were removed for several years not so long ago furnishes us with abundant material for study. Physicians who have given close study to this matter say that many changes take place in the body and mind of these women. They further say that these changes are not for the better. Those who have studied the eunuchs of the Far East have the same thing to say, i.e., that they are below normal mentally and physically. The practical cessation of these functions during morphine addiction must have something to do with producing some of the symptoms that we see in this disease.

It is more than likely that other glands of the body are affected adversely by the continued abuse of morphine. In reading about the results of hypothyroidism, I have seen the statement that there is an increase of adipose in conjunction with an increase of connective tissue. In the majority of cases the addict loses weight. There are a few cases where there is an increase of adipose tissue. I have palpated this tissue many times. The sensation is not what one gets from the palpation of normal adipose. Unless normal adipose tissue is excessive, one can see the outlines of the larger muscles. But in the addict where there is an increase of adipose these lines are obliterated. The arm has the appearance of a large sausage. I do not know that the abuse of morphine affects the thyroid gland and thus produces this peculiar adipose tissue. However, such a thing might well be probable. Further, microscopic examination of this tissue might reveal abnormality of structure. If so it would do away with the contention that the abuse of morphine produces no change of anatomical structure. There is no question about the abuse of morphine interfering with many of the functions of the body. To my mind gross interference with function means disease fully as much as change of tissue. Many think that the abuse of morphine interferes with the function of several of the endocrine glands. If so some of the mental and moral as well as physical changes could be explained in part in this way.

One of the pronounced physical changes seen in morphinism is malnutrition. This is just as evident in those who take on weight as in the majority of cases where there is a loss of weight. The appetite of the addict is abnormal. In most cases of chronic invalidism the appetite is poor as regards the quantity of food taken. With the morphine addict the appetite is abnormal in many different ways. It is poor as regards quantity. It is abnormal as regards the kind of food desired. The addict likes confections and other foods containing a good deal of sugar. The appetite is utterly erratic as regards time. The ordinary invalid usually eats three poor meals per day. The addict may eat almost nothing for three or four meals and then gorge himself at one meal. As a rule his breakfast is his poorest meal. Many of them eat more at a midnight lunch than they do during the balance

of the twenty-four hours. The more abnormal the appetite, other things being equal, the more severe the case.

Another important function is that of sleep. If there is anything that the public thinks that an opium addict can do to perfection it is to sleep. Like many other popular ideas this one is false. And there is nothing that irritates the average individual more than continuous loss of sleep. The addict differs from the normal person as regards loss of sleep in this respect, i.e., as long as he has morphine enough he is indifferent. It does not trouble him to lie awake at night. However his indifference does not protect him from the consequences of loss of sleep. I have watched many addicts while asleep. In some cases the respirations are very shallow; so shallow, indeed, that it would not take any great stretch of the imagination to suppose that the addict was dead instead of asleep. The addict is apt to be pale at any time. During sleep the pallor is so intense that it may best be described as the pallor of death. Some addicts sleep the normal number of hours. This does not at all mean that they sleep well. Their sleep has so little real rest in it that it is hardly equal to the abridged sleep of the nonaddict. In the majority of cases sleep is abridged in quantity as well as being poor in quality. Where the addiction has lasted many years, this has a profound meaning. I think that it accounts in no small measure for the fact that it is many months before the convalescent addict can endure a hard day's work with as little fatigue as the normal person of the same age.

In nearly all cases of morphinism we have continuous obstinate constipation. This means that we have a toxemia of equal duration with the addiction. Some writers maintain that one or more of the endocrine glands are injured permanently by toxemia occurring in such diseases as typhoid fever, pneumonia, etc. I do not know enough about these matters to say whether this is true or not. But if true it would be reasonable to suppose that the prolonged toxemia of morphinism would have an even more injurious effect upon these glands. But whether or not the toxemia of morphinism injures the endocrine glands, there can be no question as to its pernicious effects upon the body as a whole. Though we may not know the precise *modus operandi*, none of us who have had the care of these people for many years doubts for one moment that the continued toxemia is one of the main causes of the constant downward trend of morphinism. The greater the malnutrition, the loss of wholesome sleep, and the toxemia, other things being equal, the more severe the case. These three depressing factors are of the greatest importance. And how any physician who has a due appreciation of them can regard the addict as being other than an invalid, I do not understand. *Malnutrition, loss of restful sleep*, and constant toxemia, can have nothing less than a most profound effect for ill upon the human economy. Everyone knows that they do have in other cases, why not in morphinism? The contracted pupil, the lessened peristalsis of the intestines, and subesthesia point to the fact that morphinism is accompanied by tangible effects upon the nervous system. The first two might be supposed to be due to lessened motor impulses. However, I believe that the opposite is true. Morphine has such a paralyzing influence upon unstripped muscle that stronger motor impulses are needed to secure action at all.

We come now to a study of the mental symptoms of morphinism. In my belief the mental symptoms can all be accounted for by the physical condition of the patient. In spite of this, I regard the mental symptoms as being of greater importance as a means of determining the severity of the case than the apparent physical condition. Malnutrition, loss of sleep, and toxemia while manifestly present cannot well be measured. The mental symptoms as revealed from day to day by the addict's speech, manners, and actions can be pretty accurately measured. This being the case, we have in these symptoms our most available means of determining the severity of the case. Further, as the treatment of morphinism is as much a matter of psychiatry as it is a matter of physical therapeutics, we have in these symptoms our best guide for the treatment of the case.

We can see how the physical state of the patient causes more or less perversion of mind. The brain is the most important organ of the body. Proper nutrition of this organ is absolutely essential to the correct performance of its functions. Addicts are naturally sensitive along this line. I have often asked them this question, "How much of your waking time is given to morphine?" They generally answer, "About nine-tenths." Then I ask, "Do you not think that you would be more efficient if you were free to turn all your thoughts in some useful direction?" In malnutrition of the brain more or less perversion of function is the most reasonable thing to expect. Loss of restful sleep lasting for many years can have nothing but a harmful effect upon the brain. In toxemia we should remember that the blood current carries the noxious material to every cell in the body, brain cells included. What then can we expect of a brain when every cell in it is more or less poisoned? When we take into account the fact that during every hour of the addict's existence malnutrition, loss of refreshing sleep, and toxemia are constantly present we would not be very much surprised if the addict became very shortly a dement. Nevertheless, he rarely becomes a dement, or even insane, for that matter. For working purposes we say a person is insane when he is so far abnormal mentally that he cannot conform to the conventions of society. Ordinarily the addict does not become so far abnormal mentally as this. The only reason why he does not is that these bodies of ours are purposely built to withstand an enormous amount of abuse. The straight morphine addict is usually well enough able to care for himself to escape notice. He may easily lose this ability if he combines with morphine cocaine or whiskey. The same thing is true of veronal, hyoscine, paraldehyde, etc., combined with morphine. But however well the addict may be able to escape notice, I have yet to see one who on close observation over several days did not show both mental and physical deterioration, some to a very slight degree, others to a much greater degree. No one addict manifests all the symptoms that we see in morphinism. This as the reader well knows is true of typhoid fever and most other diseased conditions. How-

ever, when we take these cases in groups of twenty we see about all the symptoms that are ever observed.

The most important mental symptom directly due to morphine is self-depreciation. This accounts for the secretiveness so common in this class of individuals. The addict will always tell you that he is secretive because of the uncharitable attitude of the public toward the drug habitué. Such an attitude does exist to a greater or less extent. However it is not what others think that makes the addict secretive but what he thinks about himself. It is most likely also the direct effect of the drug upon the brain, since it is well known that slyness and secretiveness accompany many abnormal mental states. Another direct action of the drug is shown in the addict's tendency to seclusion. Secretiveness partly accounts for this. I believe, however, that there is more to the addict's seclusion than this. He likes to indulge in day dreaming. The chatter of his friends interferes with this and therefore irritates him.

Nearly every addict is more or less of a coward, some of them being extremely cowardly. The effect of the drug upon the sexual organs may account for this, since virility and courage have been associated together for centuries. This notion may be a popular mistake. I hardly think it is. I have never known of a sexual pervert among morphine addicts. But the fact that the drug does undoubtedly have a pernicious effect upon the sexual organs leads me to believe that they do have perverted sexual thoughts, at least some of them. I have heard them tell many absurd stories about this or that prominent person being a sexual pervert. A patient presenting these symptoms is a difficult case to treat so far as my experience goes. I believe this to be the case because perverted sexual thoughts may be taken as an index of advanced type of the disease.

We often see a pronounced tendency to prevarication among the victims of morphine addiction. Knowing their self-depreciation and secretiveness we should expect this to be the case with them. Many point to this fact to prove that the addict is utterly immoral. This view, however, is absolutely absurd. To me it is nothing more than a symptom of a pathological condition. The lies of addicts run true to form, as much so as the symptoms of measles. When they do not I conclude that the addict was a liar in his preaddiction days. Those who were not liars in their preaddiction days do not as a rule lie to hurt anyone. Self-depreciation accounts for some of their prevarication; secretiveness for nearly all the rest. They will try to conceal their addiction. This leads to a great variety of stories. Their self-depreciation is so great that they often speak of this or that prominent person being an addict. This is only a subconscious means of saving their face. They try to deceive themselves as to the harm the drug is doing them and usually succeed. Their lies along this line are told to brace up their courage, like the whistling of the superstitious person while passing through a graveyard. Though these lies like any other set of pathological symptoms run true to form, it takes close observation over a long period of time to appreciate this fact. Let alone, the addict rarely becomes a criminal. Well meant efforts to make the drug difficult and expensive to procure have most certainly driven many of the poorer addicts into petty criminality. The victim of a drug habit is so horribly afraid of being separated from full control over his drug supply that he is more circumspect than the nonaddict about doing anything that will land him in jail.

We see a lessened ambition among these people. This is not surprising when we recall the malnutrition, loss of restful sleep, and toxemia. I wish to emphasize that this lack of ambition applies equally to all sorts of activities. It affects the burglar and all other varieties of crooks as well as clergymen, lawyers, and physicians. I remember well a man who came to me for treatment several years ago. He had been using 60 grains of morphine per day. His associates were those of the underworld. Upon arrival he was almost a gentleman. As soon as he was cured all his original meanness reappeared. Any addict who was formerly interested in what was best in life becomes indifferent to these things, but as soon as he is cured he again renews his interest in them. This should be remembered, for many physicians and the public in general have erratic ideas along these lines. The point to be remembered is that all sorts of activities are diminished in morphinism. The burglar cannot carry on his business for very many years if he continually takes morphine to excess. Sooner or later he will be down and out. The above symptoms I believe are due directly to the daily use of the drug.

Many but not all addicts in time come to have obsessions. These I do not look upon as the direct effect of the drug, but as being due to the gradual growth of wrong ideas. Finally, instead of the addict holding these ideas he himself is held by them. The more pronounced the self-depreciation, secretiveness, the tendency to seclusion, and to prevarication, the more severe the case. The possession of well established obsessions means that the case is one of still greater severity. Many have the curious obsession that morphine prevents infections and infectious diseases. This idea holds the addict so firmly that plain evidence that the contrary is true has no weight with him. In not a few instances I have had an addict in the house who was suffering from an infectious disease and at the same time another with the obsession that morphine protects from such infection. The visible evidence that the obsession was false does not free the addict from his obsession. Morphine lowers the vital powers of resistance and thus makes the addict more liable to infections and at the same time makes him less able to endure an infectious disease.

Another common obsession among addicts is that the disease for which morphine was prescribed in the beginning still exists but is held in abeyance by the drug. And they further persist in thinking that as soon as the morphine is withdrawn this disease will come to life with all its misery and discomfort. There is no way of overcoming this obsession except to get the patient off the drug. Then he discovers much to his surprise that he is not suffering and in due process of time he comes to the rational conclusion that the disease no longer exists. The reader well knows that morphine loses its anodyne power in the case of the addict. The addict should

know this himself, but many times does not. Morphinism cannot hold any disease in abeyance. It can and does aggravate any concurrent disease.

Among my medical patients I have often met the obsession that morphine prevents waste; that it really preserves the body cells. And further that when the addict is cured his body is really no older than it was when the addiction was first formed. The truth is that morphine rapidly brings about a condition of presenility. I have frequently had patients in the house fifteen years younger than I. Everyone in the house would say that they looked older except the party in question—and I look my years all right. I think that most obsessions arise in the first place as a subconscious excuse for the continued use of the drug. In time these false ideas become an integral part of the addict's mentality.

There are a number of other obsessions besides the ones just described, but it is not necessary to burden the reader with a description of them. Many addicts whose addiction has lasted for many years do not have them. Their presence means, other things being equal, that the disease is severe and will require careful management.

The symptoms of general mental impairment which I will describe now indicate a still further severity of the disease. I look upon these symptoms as indicating the end products of morphinism and not like self-depreciation, secretiveness, etc., which indicate the peculiar direct effect of the drug upon the brain or as being like the obsessions which indicate the gradual growth of wrong ideas. The malnutrition, loss of sleep, and toxemia at last affect the brain as a whole. However it is rare that we see all these symptoms in cases of straight morphinism. In addition to the deteriorating influences just named we may get the ill effects of syphilis of the nervous system, or chronic alcoholism, the abuse of cocaine, or of the various hypnotics. In these cases there is a slowing down of the mental processes which in time prevents the addict from following any gainful occupation. These patients are apt to become indecent in speech and actions. Instead of having gratitude for services rendered, they are apt to show a hatred for those who try to serve them. They become morbidly suspicious. This in some cases degenerates into mild delusions of persecution. I have seen delusions of both sight and hearing among them.

In managing these cases I depend very largely for my success upon my ability to secure the voluntary cooperation of the patient. One can readily see how difficult it would be to secure the voluntary cooperation of this class of individuals, who, as a result of general mental impairment develop weird ideas about being able to get something on the physician or his assistants. They seem to think that if they do, they will be able to board in the sanitarium for the balance of their life; also that they can demand unlimited amounts of morphine if they can only get something on the doctor. I know that none of them ever succeeded in doing anything of the sort in my sanatorium. I have every reason to believe that no addict ever did so in any other sanitarium. Addicts of this type are almost always multiple drug and alcohol users and not a few of them are syphilitic.

The astounding thing is that some addicts do use all sorts of drugs and alcohol and still show but little mental impairment. It is among this last type of multiple drug users that I get my cures. I dislike to treat a case that shows extreme mental impairment as badly as the surgeon dislikes to operate on a hopeless case. It is among these who show great mental impairment that one finds the delusion that they can successfully blackmail those who try to cure them. The better class of morphine addicts suffer on account of this degenerate type. The more degenerate the addict the more he is in evidence. The better type of addict does not intrude himself upon people's notice.

About the only cases of straight morphinism coming under my observation who showed signs of extreme mental deterioration were those who in their preaddiction days were great users of alcohol; that is cases of morphinism where the brain had already been damaged by the abuse of alcohol. I know of no reason why the addict who never used anything but some form of opiate should not show signs of extreme mental impairment. But they are not so badly off in this respect as one would suppose.

The history in morphinism is important chiefly because of its bearing upon the moral and mental integrity of the patient. It is not often possible to get a correct history of the case at once. The addict's habitual secretiveness prevents him from giving a straight history of the case, even where he wishes to do so. I get the history little by little as time goes on. In the family history it is important to learn if there has been insanity, epilepsy, hysteria, or criminality. So far as my patients go the family history nearly always is of the very best.

Addicts always deteriorate to a greater or less degree. However, if their history shows that they at one time showed great persistency by their actual accomplishments, we may be sure that no matter how much they have deteriorated it is likely that they still retain a portion at least of their former capacity for persistence. Those who accomplished little or nothing in their preaddiction days are not likely to make good patients. Nature makes the cure in all cases. Nevertheless there are things that the patient needs to do for a long time in order that nature may have a fair chance. The doctor can assist nature in many ways. He can give the addict correct counsel; but if the addict is so irresponsible that he cannot follow correct counsel or willfully refuses to do so no good results can be expected. Our best guide as to what an addict will or can do is what he has done. Hence the preaddiction history is important.

An addict who appears to be very rugged often fails to make good, while one who seems to have one foot in the grave makes a fine cure. Those addicts who are in good physical condition get but little sympathy if they fail. To one who is able to appraise the case, there may appear to be more actual reasons for failure than in many a case that presents a most wretched physical appearance. The addict in apparent good physical condition may require more careful management in order to secure success than many that appear to be all in. Some of them are almost hopeless. This is because of mental and moral deterioration. Yet in these discouraging cases if the right line of treatment can

be carried out, we may get complete success. So we can see how important it is to be able to determine the severity of a case of morphinism. To do this one should be able to appraise the relative importance of each factor.

OCCIPITOPOSTERIOR PRESENTATIONS.*

By H. D. FAIR, M.D.,

MUNCIE, IND.

I BELIEVE a lecturer or essayist has as much right to take a text for his discourse as has a minister of the gospel, therefore I assert my conviction by quoting a verse from the American Text Book of Obstetrics, page 576, in which Barton Cook Hirst is quoted as follows: "If I were asked what one obstetric difficulty had caused most maternal and fetal deaths; what one had caused most maternal and fetal accidents not necessarily fatal—accidents, however, often making the rest of life worthless, or still worse than worthless, a tragedy—I think I would say, 'Occipitoposterior presentations where the occiput had rotated to the hollow of the sacrum, and which had been *improperly treated*.'"

I call your attention especially to the last phrase, "improperly treated." The very fact that Dr. Hirst uses this phrase implies that there is a proper way to treat these cases; but he goes further and puts the words in italics, making it doubly emphatic; therefore the purpose of this paper is to encourage us to analyze our methods of action and obstetric technique so as to determine, if possible, whether we are doing the best for the patient who puts her health, happiness, yea, her very life, for a time into our keeping.

Fortunately not more than 26 per cent. of all deliveries are occipitoposetrior presentations, and less than 4 per cent. of these fail to eventually rotate to the pubes; but this 4 per cent., undesirable as they are even in the most favorable cases, if left to themselves may not be so disastrous in their effects as are the cases that are bungled before nature has had a chance to perform final rotation; for an attempt to drag a head thus engaged down through the pelvis, either conforming to or ignoring internal rotation, may loosen the soft parts from their pelvic attachments and do irreparable damage to the urethra, bladder, or rectum. The fetus runs a grave risk; traumatism, prolonged strain on the heart, cerebral compression, and paralysis being some of the usual sequelæ.

If conditions are such that external examination reveals all that is necessary for us to know regarding presentation, well and good; but many times this is not sufficient. I am not at all in harmony with those who aver they never make a vaginal examination. I am perfectly willing to go on record as saying that any practitioner who is as competent to do obstetrics as he has opportunity of being, may safely make a vaginal examination at any stage of labor; and if the obstetrician is not doing the best work of which he is capable he has no business to pretend to care for parturient women.

I would not have it understood that a vaginal examination made at any stage of labor by even a safe and competent operator immediately removes all doubt as to the cause of dystocia. An occipitoposterior presentation is not always easy to diagnose with the tips of the fingers, particularly when our patient has a thick cushion of fat on her abdomen, and only a smooth area of scalp is palpable at the os. Whenever we are not certain as to the relation of the passenger to the passageway we have no right to attempt instrumentation or accouchement forcé. In this instance it is better practice to do nothing than to do the wrong thing.

Obstetric surgery has this peculiarity; its operations are carried on in the dark, our only guide being the information conveyed by the sense of touch. The mind's eye travels to the finger tips; the hand thus possesses an inestimable superiority over all other instruments. Its every movement is regulated by consciousness.

We might now inquire, what conditions may lead us to suspect an occipitoposterior presentation? I do not propose to offer insult to your intelligence and knowledge by quoting text-book findings, but will call your attention to one fact only. We know that in a normal presentation it is rare for more than two hours to elapse between the time of the completion of the first stage and the expulsion of the fetus; so on an occasion where the head is in the cavity of a normal pelvis, pains good, dilatation complete, with time rapidly progressing with little or no advancement, we may safely conclude that we have an occipitoposterior presentation with which to deal.

I wish to repeat an axiom that has appeared in every paper I have written on operative obstetrics during the past twelve years. It is this: *Every move in complicated labor should be an elective procedure and not an action of last resort.* After we are convinced that nature is unequal to the task —that something must be done in the way of assistance, the first step toward the desired end is to determine the actual situation and conditions. If the ordinary vaginal examination has failed to give the evidence needed, all instruments and appliances necessary for the requirements of a probable emergency should be prepared and within reach, then, *at the opportune time,* the patient should be anesthetized, if necessary, and the whole hand introduced into the vagina until an ear or some other landmark can be found, even though the quest be continued till the occiput rests in the palm of the examining hand. In most of these posterior presentations the occiput is to the right, therefore the left hand should be used in making the examination, as will be explained later. Now presuming that we have identified our occipitoposterior presentation, how should we handle it? If we are fortunate enough to see the patient before engagement occurs there is a simple way of converting posteriors into anteriors which is easy to perform when once understood. This maneuver is a modification of that recommended by Wm. D. Potter of Cincinnati. As already advised, the left hand is in the vagina; without withdrawing it the hand is inverted and passed to the left side of the pelvis (thumb toward the right), and the head is firmly grasped and pushed up till free. As the occiput rotates toward

*Read before the Muncie (Ind.) Academy of Medicine, 1921.

the pubes the hand rights itself, gaining strength as progress is made. The other hand or those of an assistant may be used externally to promote bodily rotation. I have used this method many times with excellent results. If a large part of the amniotic fluid is still in the uterus, rotation can be continued past the center and we will have the position most favorable of all, the L.O.A. We now withdraw the anesthesia and hold our position till one or more pains have forced the vertex into the cavity of the sacrum; then our principal difficulty has been overcome. If for any reason prompt delivery is indicated we can apply forceps and deliver.

I believe it to be a serious mistake to apply forceps to a large head when the occiput has rotated or shows a tendency to rotate to the hollow of the sacrum, and to attempt by main strength to pull the head through the perineum. When I arrive late on the scene and find the head so engaged that it cannot be pushed up out of the pelvis, and the patient and fetus appear to be in good condition, I am inclined to wait a few minutes till the vertex gets closer to the perineum before I attempt any aid, which would be to rotate with short forceps having a slight pelvic curve; *but* if the woman shows signs of exhaustion, fetal heart sounds convey a warning, or at any time pains or progress ceases, I apply forceps and bring the head down till one pole thereof is below the spine of the ischium; then I rotate till I have a R.O.A. I consider this much easier and safer than to attempt to rotate the head while midway between the superior and inferior straits.

The safest guidance is to be found in a careful study of the mechanism by which nature effects the rotation. If we do so it becomes apparent that it is only by imitating or assisting nature that we can hope for success. Rotation must be managed so that it is combined with a descent of the occiput and a corresponding retreat of the forehead.

You have undoubtedly observed that this paper thus far presumes that in each and every case rotation has taken place either early or late in labor. If, unfortunately, for any reason this has not been accomplished, and delivery must be completed with the occiput posterior, instruments for perineal repair should be in readiness, and a deep episiotomy done.

For the past fifteen years I have been earnestly endeavoring to improve the quality of my obstetric service, and my experience, meager though it be, warrants me in expressing these admonitions. I do not wish these axioms to sound more harsh to you than they do to me, for I am equally guilty, and when I refer to a group by the use of the pronoun "you," I include myself in that group.

1. No primipara with a full sized fetus can expel the head with the occiput posterior without sustaining serious damage to the vaginal and perineal structures.

2. It is bad practice to allow a patient to suffer hours or days, as sometimes happens, when a simple twist of the wrist may end her labor in a few minutes.

3. Never leave a puerperal woman till you have done all you can to place her as nearly in the antepartum condition as possible. Nearly every day we examine some woman with a gaping vulva who tells us that her obstetrician assured her that she was "not torn a bit."

4. Never begin any deliberate obstetric operation until you have all the instruments and equipment you are likely to need, within easy reach.

5. Never start any obstetric operation until you know what ought to be done and have formulated a plan as to how you are going to do it.

6. Never start anything you cannot finish. Be certain of your limitations.

7. If you are not certain that your act will result in success, be sure it will do no harm.

8. If you intend to send for a consultant, be fair with him and do not increase the complications before he arrives. Do not ask him to assume responsibility for a blunder that you have made.

9. On the other hand, when complications do arise the wise obstetrician will seek the assistance of a friend who will share both the burden and the risk.

10. If your time is worth anything get after your occipitoposterior cases early in the game, and let it be known that your prompt action is worth while.

The solution of this problem, as well as many others in obstetrics, is prophylaxis. Nearly every faulty presentation can be easily corrected if recognized early. We should keep our gravid women under our care during the latter months of pregnancy. We should advise them to notify us so soon as pains begin, or more important still, in premature rupture of the membranes, which is so frequently an accompaniment of malpresentations, as soon as the "water breaks." Then if on examination we find the presentation normal, we can go about some other business for a time and allow our patient to work out her own first stage, feeling confident in our prognosis. I believe most women will get along as well or better during a protracted first stage if the accoucheur is not within reach. I never could find any good reason why he should hang around a parturient for hours before he can be of any use.

For months I have been declining all obstetric calls coming from a patient who has not been under the care of some physician. I have a few pertinent questions I ask every stranger; if he does not answer them to my satisfaction I refuse to respond to his call. If he (the husband or whoever may call for him, as such a fellow often depends on the neighbors to get a doctor for him) admits his shiftlessness I simply inform him that I do not care for the patronage of any man who is so irresponsible as to allow his wife to approach the hour of confinement without engaging a physician. I am trying to do my part in educating the laity that childbirth is an important function; that good obstetrics is essential to the health and happiness of womankind, and that good obstetrics must include both antepartum and postpartum care; better care than she has been getting in the past.

I am fully aware that skillful antepartum service is often unrecognized and remains unappreciated by the average laymen, male and female. An obstetrician who is on the alert and by little or much dexterity can change a dystocia into a eutocia will get much less credit or praise than one who spends

twenty or thirty hours on the job, wearying the neighbors and fatiguing himself with misdirected effort, finally leaving his patient hovering between life and death, who, if she recovers, will be damaged for life—a monument to Dr. Blank's wonderful days work.

Good obstetrics requires skill, and should command a compensatory remuneration.

NOTE ON THE INJURIES TO THE SEMILUNAR CARTILAGE OF THE KNEE,

WITH SPECIAL REFERENCE TO INDUSTRIAL ACCIDENTS.

By JAMES EAVES, M.D.,

AND

PAUL CAMPICHE, M.D.,

SAN FRANCISCO, CAL.

SINCE Bruns in 1892 called attention to the injury of the semilunar cartilage of the knee joint, many excellent papers have appeared on this subject, most of them from the pen of British surgeons, who have had the greatest experience with this condition, owing to its frequent occurrence among sportsmen and coal miners. There is nothing to add to the papers of R. Jones, A. Martin, W. A. Lane, R. Morison, etc.

The mechanism, the pathological anatomy, the cause, treatment, and outcome of these injuries are well known, and there is little divergence of opinion among surgeons on the main issues of the problem.

In order to avoid repetition of what has been said by others we will confine ourselves to points of special interest. The questions foremost in our minds are: (1) When should we operate? (2) What character of operative procedure should be followed?

While the trend of opinion seems to be more and more in favor of surgery, we should not forget that there are many patients who get fairly well without operation. In the condition described by the French as a "pincement de menisque" (pinching of the meniscus) there is no rupture of the cartilage and no displacement of fragments, but simply a contusion with subsequent swelling of the semilunar. Such cases often get well after a few weeks' rest, and although they often have repeated attacks of "locking" these are so far apart that the patients do not desire an operation. There is no permanent exudation here and hardly any pain between the different attacks; so they are naturally willing to wait. This is the reason why all authorities advise against any intervention after a first locking, because in case of mild meniscitis, there is always a probability that the condition will improve by conservative measures and that the patient may be free from accidents for a considerable time. A delay of a few weeks is good in all cases in order to make a differential diagnosis and exclude all other knee conditions. The simplicity and safety of surgical interventions are, as a rule, proportionate to the timeliness in diagnosis.

However, in the majority of patients the injury has a more serious aspect, the patient is unable to fully extend the knee, and we speak here of a dislocation or a fracture of the semilunar cartilage. The proper treatment of the condition is *reduction* followed by immobilization in full extension for several weeks. This succeeds very often if done immediately, and many men treated in this way have gone back to most strenuous pursuits and have been free from recurrences.

It is an axiom of all authorities that no case should be operated after a first locking, and we certainly would like to remain orthodox in this matter. But everything depends on *when* and *how* the reduction has been done. Here is where we find ourselves in a peculiar position with our industrial accidents. We seldom see the men immediately after the injury, but often only weeks and months after the alleged "reduction"; even after a prolonged rest there is much pain and a stubborn effusion in the knee joint; the patient, feeling that the joint does not move smoothly, knows there is something wrong with his knee. It is evident that the reduction has been only apparent, that the meniscus has remained torn and dislocated, and that it is now too late to attempt a new reduction. It is a common occurrence to see patients treated six or eight months or more without the slightest improvement. And the question arises: Why should they remain incapacitated so long when they could be cured quickly by a simple intervention? If after six weeks' rest a man has still a swollen and painful knee, and if we have excluded other conditions, such as loose bodies, rupture of the crucial ligaments, incipient tuberculosis and the like, we know that the semilunar was not simply bruised but is most probably torn or ruptured, with its fragments hanging in the joint, and that nothing can be gained by waiting. Therefore, we insist that such interminable periods of disability as we now see should not be countenanced any more by the surgeons in charge of such cases. And if we bear in mind the frequency of this injury among the so-called industrial accident cases we can readily see what saving in weeks and months of disability could be effected by an early intervention. While we accept the dictum of the authorities that no patient should be operated after a first locking, with the reservation that the reduction has really been successful, we have been impressed frequently with the fact that no reduction has been attempted but simply a cast applied and no attention paid to atrophy of the quadriceps. This atrophy will add greatly to the disability. If the reduction has failed and the patient presents himself so late that reduction is no more possible, we think it is best to operate even if there has been only one locking. Just before finishing this paper we have read the last article of M. S. Henderson (Mayo Clinic) in the *Annals of Surgery*, 1920, and we are glad to see that he has come to the same conclusion.

Many cases of injured semilunars have no definite clinical symptoms, and the pathology is only recognized after exploration. Sometimes incisions over the internal reveal absence of pathology, but by opening the other side definite pathology is found.

Differential Diagnosis.—This subject is so important that we would like to recall briefly the points which R. Jones has so clearly outlined in his admirable paper on the subject: The locking due to a loose body is more transitory and as a rule the loose body can mostly be felt. Exostosis can be palpated and demonstrated by the *x*-rays. If synovial fringes are bruised the pain is more in front and the symptoms are less acute. In the rupture of the

crucial ligaments we have a gliding tibia which can be moved to and fro, and there are also lateral movements. Small bony separations of the tubercle of the tibia, the spine of the tibia, etc., can be seen with the *x*-ray. In a sprain the pain will be right on the internal (or external) ligament, etc.

The symptoms of displacement of the internal semilunar cartilage usually recognized as being characteristic are acute pain with or without the sensation of something having slipped or given way in the joint locking and loss of power to completely extend the leg, and effusion. Speaking generally, rotation of the leg outward upon the thigh with the knee flexed, followed by sudden extension, is the movement most likely to cause this condition.

Reduction.—No reduction is complete unless full extension of the leg can be maintained. To reduce such cases the knee must be put in acute flexion, with rotation inwards and full extension. The patient frequently will inform you whether the manipulation has been successful.

Operation.—We follow the technique of Robert Jones. The foot-end of the operating table being lowered, the patient has the bad knee flexed at a right angle, the thigh lying on the table and the lower leg hanging freely, so that the articular surfaces of the femur and tibia are well separated.

Incision.—Some European surgeons still use a longitudinal incision; this does not afford a sufficient exposure. We prefer the transverse incision of R. Jones, beginning at the inner border of the patella and extending about one and a half inches backwards, if possible, above or below the imaginary articular line of the knee. The meniscus is seized with a small hook and pulled; its anterior end is freed first, then the middle part and posterior end, and it is incised with a thin tenotomy knife and pulled out. This method seems adequate and respects the internal ligament (Lig. Collaterale Tibiale) of the knee.

However, in injuries to the posterior part of the meniscus when it is essential that this part should be completely excised, the incision of Herz may be found valuable; this is an incision of 6-8 cm. long, but interrupted in the middle so as to leave intact the internal ligament. (Lig. Collaterale Tibiale). It is made up of two incisions, the anterior part of the cartilage is first dissected and freed through the anterior incision, then the whole meniscus is pulled through the posterior incision which also allows the total removal of the posterior end of the cartilage. The capsule is then sutured with fine catgut.

Suture Versus Incision of the Meniscus.—Acting on the general principle that surgery should repair what is reparable and sacrifice only what is beyond repair, some surgeons (Katzenstein) have contended that the meniscus should, as far as possible, be sutured in its place when it is found that it has been torn off. We have witnessed such operations in former years. When the tear was not too long and was situated in the fibrous part of the meniscus, *i.e.* near the capsule, the suture was made with fine silk and the articular capsule closed also with silk. But as in the vast majority of cases the free (cartilaginous) border of the meniscus is the one to suffer it is clear that a suture will not succeed here.

Our conclusion is that in well-defined cases of rupture and dislocation of the semilunar cartilage, coming under our care several weeks after the original injury and where no reduction has been made or where it has obviously failed (as shown by the persistence of the symptoms of pain and effusion in spite of prolonged rest) the best plan will be (especially in industrial accidents) to perform the excision of the meniscus without further delay. This excision should always be as complete as possible.

The Senile Brain.—According to Marie, in the course of a clinical lecture on nervous affections, one should never confound old age, a physiological process, with senility, which is pathological. A senile brain, therefore, is a diseased brain (*Le Progrès Médical*, January 8, 1921, xlix, 2). The alterations are either parenchymatous or vascular. The former affect chiefly the cortical cells, the latter the central ganglia. Clinically there are three groups or stages—pseudobulbar, lacunar, and demential. In pseudobulbar paralysis so called there is no paralysis in the strict sense of the word, but an absence of function which amounts to the same thing. The lacunar state was described by Marie twenty years ago. Its symptomatology is characteristic—exaggeration of the reflexes in a subject over fifty years of age should suggest the possibility of the cerebral arteriosclerosis which is responsible for this condition. The subject walks with short steps and a tendency to retropulsion. If asked a question he is apt to show palilalia, repeating his answer several times. This phenomenon is usually erroneously termed echolalia in the United States, but in true echolalia the subject echoes the saying of his interrogator and not his own. There is often a history of so called "petty strokes," often attributed to "congestion," but there is no congestion present. The lacunæ of softening, as already implied, are usually seated in the central ganglia. The lecturer then considered briefly the parenchymatous alterations of the cortex which are signalized by intellectual disorders—dementia.

POST-BELLUM ACTIVITIES OF THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY.

How much of the post-bellum decrease in the size of the Annual Report of the Surgeon General of the United States Army for the fiscal year ending June 30, 1921, just issued, is due to peace-time relative inactivity on the part of the Medical Department, and how much may be attributed to the Harding-economy-Dawes-budget combination is not for the uninitiated to presume to know. That something has happened to reduce the size of the report is apparent when one glances back through the war period, for the report for 1921 is smaller than that for 1916.

As expressed in the number of pages, the activities of the Medical Department during the period of mobilization, active participation in the war, and demobilization, is interesting. In 1916 the story was told in 357 pages, including the index; in 1917, in 474 pages; in 1918, in 735 pages; in 1919, in two volumes totalling more than 2,000 pages; and now, in this report which covers actual peacetime activities, the story is told in 329 pages. It is none the less interesting, however, and, as one reads, appears not to connote any undue inactivity on the part of the department personnel. For in his letter of transmission the Surgeon General calls attention to the manifold duties which the situation for the year placed upon the regular medical service and the reserves who had remained on active duty. In addition to the large amount of work entailed by the rapid demobilization of the members of the medical profession who had accepted temporary commissions for service with the war Army, and to the routine work of the department, with the care of the sick of the Regular Army, professional care and treatment had to be provided for the sick and wounded of the war Army who were remaining in hospital at the beginning of the period covered by this report. The recruiting for the Army during 1920, with the expansion which followed the act of June 4, 1920, threw a further additional burden upon the department, not only in the way of making the necessary physical examinations, but in the care of an increased amount of sickness attributable to the enlistment of a considerable number of recruits of immature age and others with physical defects. The remaining personnel of the department was further taxed by the work connected with the distribution of the Army in this country and abroad, with the several changes made necessary by congressional acts, with training, and with the care of the beneficiaries of the Veterans' Bureau.

To the person in civil life, one of the most interesting items mentioned in this enumeration by the Surgeon General is headed "Unsatisfactory character of recruits." According to reports from corps area and department surgeons, the character of recruits enlisted during the year was very unsatisfactory. "Never in the history of the Army has its ranks been filled with such poor physical specimens and such young lads so susceptible to disease," reported one. "The heavy rate of discharge on certificate of disability, for disability existing prior to enlistment, suggests a reconsideration of the policy regarding the strict appliance of adherence to published and official standards," is another comment quoted. "Many of the enlisted personnel of this command," comes the report from another quarter, "should never have been enlisted, as they are poorly developed physically, mentally, and morally, which increases the difficulties encountered in controlling venereal disease."

To Medical Reserve men who never saw actual service, particularly, and to many other members of the medical profession of the country generally, who were none the less keenly interested because not on "active duty," all of whom are more or less familiar with war time physical examining boards, psychological tests, psychiatric examinations, development battalions, and other phases of the effort on the part of the Medical Department to have an army "fit to fight," the 1920 recruiting system, as portrayed in the quoted reports from men qualified to judge, must possess a decided element of shock. Whatever the "line" may have thought of much of the "tomfoolery" of the Medical Department efforts in these directions, the natural conclusion would be that out of these activities, plus actual war experiences, would have come a more up-to-the-minute system for increasing the standing army. It would seem that war experiences no less than labor pains and seasickness are soon forgotten.

LEUCOTHERAPY WITH CELLULOTOXIC SERA.

SINCE Metchnikoff's discovery of the part played by the leucocytes in organic defense many researches have been undertaken on anticellular serum with the result that at present alongside of antibacterial and antitoxic sera, an entire series of sera have been prepared which have a specific action on the cells of the body. Thus, we have the hemotoxic serum of Bordet, the spermotoxic of Landsteiner and Metchnikoff, the trichotoxic of Dungern,

nephrotoxic, leucotoxic, antipancreatic of Surmont, hepatotoxic, neurotoxic, and lastly suprarenotoxic. All these sera are obtained by similar procedures. The injection into the subcutaneous tissue of living cells from a given organ at various times imparts to the serum of the animal injected the specific property of destroying cells of the same kind as those injected, but only in the same animal species as that furnishing the substance injected. These sera, which produce necrosis and elimination of certain cells have, in common with certain drugs, the paradoxical property of acting differently according to the dose employed. Thus, if the normal dose—which must be determined for each animal and each organ—has a destructive action, much smaller doses will on the contrary exercise a stimulating action on the resistance and activity of the cells. A large dose of leucotoxic serum will destroy leucocytes, a small dose will produce a rather abundant and persistent leucocytosis. Now, to act on acute microbic infections the number of microphags and polynuclears must be increased, therefore a leucotoxic serum having a specific action on polynuclears is necessary.

But the practical difficulties of obtaining such a serum applicable to the treatment of disease in man has been the reason for rejecting this method. In fact, in order to obtain such a serum, it is impossible to inject polynuclears in a pure state so that tissues containing them in large number have been used and for this reason bone marrow has been most generally injected. But although it is easy to procure living bone marrow from animals, that of man is of course unobtainable. Consequently other methods have been resorted to with the result that cellulotoxic sera have been prepared. As far back as 1891, Lemière, in his work on aseptic suppuration, came to the conclusion that pyrogenous chemical substances were, in general, microbicidal and cellulotoxic as well. Suppuration occurred when the substance injected did not have sufficient power to cause extensive cell necrosis, but nevertheless it was essential that it should be capable of changing the cell vitality or even cause necrosis and destruction of some cells. In the state of science at this epoch, Lemière thought that this cell destruction was capable of setting free some new products to which he gave the name of defensive proteins. Under the influence of the toxic agent, these proteins set at liberty provoked a hyperleucocytosis, followed by diapedesis at the points menaced, all this being followed by phagocytosis.

Not long after this, Fochier, of Lyons, employed subcutaneous injections of aseptic pyogenic substances (turpentine), as a means of treatment, which soon took the name of fixation abscess, and this method was largely and successfully employed by Revilliod and the Geneva school. But it was shown that the procedure did not attract the pathogenic bacteria to the focus of suppuration and therefore they were not destroyed by phagocytosis. Why then was this method successful? It created locally a focus of cell destruction with the setting free of what Lemière called a protein, and as a result it gave rise to hyperleucocytosis, this being followed by diapedesis and phagocytosis. But the leucocytes are not content to exercise their defensive action only in the focus created by the injection. Quite to the contrary, they leave the vessels *en masse* everywhere in the organism, their united action being solicited by a focus containing substances endowed with chemotactic properties. Turpentine therefore provokes a hyperleucocytosis and while it is followed by diapedesis in the focus of the injection it is also certain that diapedesis and consequently phagocytosis will occur with renewed energy in the foci of infection in other parts of the body. This is the reason why loci of pneumonia disappear as well as the more diffuse lesions of general septicemia, especially the puerperal variety. The great objection to this unquestionably effective method is the pain caused and the creation of suppuration, although aseptic, which may assume considerable proportions in an already weakened organism.

Recently the properties of nucleinic acid have been studied and it is believed that the suppurative processes produced by the action of aseptic pyogenic substances must be related to the presence of this acid or at least the nuclein set free. All living cells contain a large amount of nuclein and the destruction of cells in the organism under the influence of certain conditions that are not clear, should result in setting free a certain quantity of nuclein. The method consisting of injecting nucleinic compounds to reinforce the organic resistance is simply a variation and progress in the method of fixation abscess and aseptic suppurations.

THE PROGNOSIS OF INJURIES DUE TO IMPALEMENT.

TAKING the various cases of injury resulting from impalement, they differ, from the viewpoint of violence of the traumatism, from a slight penetrating wound of the perineum, or erosion of the vagina to perforation of the abdomen or penetration of the thorax. Out of a total of 139 cases collected by Ponthieu there were 47 deaths, 82 recoveries, and in 10 the results were unknown. The 129 cases were: Impalement per rectum, 59 cases, with 24 deaths, 31 recoveries, and 4 doubtful; impalement per perineum, 49 cases, 18 deaths, 31 recoveries; impalement per vaginam, 15 cases, 3 deaths, 9 recoveries, and 3 doubtful; impalement per scrotum, 16 cases, 2 deaths, 11 recoveries, and 3 doubtful. Potel based his statistics on 108 cases and found a mortality of about 40 per cent, while Ponthieu found a total mortality of 36 per cent. These figures have only a relative value, because many of the case histories are not given, either because the resulting lesions were trifling, or because the results were disastrous, death having taken place before the arrival of the physician. Some deaths resulted simply from the extent of the lesion and are thus easily explained

Thus, in a case recorded by Villard, death resulted from penetration of an iron rod up to the pancreas, causing three perforations in the intestine, and at the time the patient was admitted to the hospital he offered all the symptoms of gangrenous peritonitis. In a case reported by Dubar, the shock produced by a fall from the fourth story of a building, besides the lesions produced by impalement, was enough to explain the rapidly fatal issue. Méhier reports a case of death in eighteen hours of a man who fell from the height of sixteen feet onto the handle of a pitchfork which penetrated about two feet, which was more than enough to produce serious irreparable lesions.

The great factor of gravity of these lesions is the tearing and infection of the peritoneum with peritonitis as the inevitable result. However, occasionally very serious damage may be recovered from, as in a patient of Aubert's in whom a fragment entered four inches into the rectum, but after development of very distinct peritoneal phenomena the man recovered and returned to work at the end of a fortnight. Recovery also took place in a patient of Woodbury's whose body was completely traversed by a stake which entered the anus and came out in the left side of the thorax, fracturing the ribs, while in a case of Abbe's the liver, diaphragm, and pleura were pierced, yet the patient got well. But these are most exceptional cases and need not be taken into consideration when making a prognosis.

Ponthieu studied the frequency of penetration of the peritoneum in cases of impalement and found that out of a total of 139 cases there was peritoneal penetration in 37 per cent.; of these the mortality was 87 per cent., and deducting the recoveries resulting from an immediate laparotomy he found the mortality to be 94 per cent. It should be recalled that peritoneal septicemia appears very rapidly in these cases and is quickly fatal, so that surgical interference should be resorted to at once when only a suspicion of peritoneal penetration exists in the mind of the surgeon. A useless surgical act is better than abstention which may end in the most serious consequences.

The immediate danger having been overcome, the patient is still exposed to certain complications, sequelæ of the traumatism. Vesicorectal fistulæ may develop, requiring operation later on, but these fistulæ have also been known to close of themselves in from twenty to thirty days following the accident. Rectovaginal fistulæ may have serious consequences; for example, in a case reported by Desmons a fistula of this type resulting from an impalement was the cause of puerperal septicemia nine years after the accident. The immediate symptoms following impalement are not always proportional to the gravity of the injury.

Does Mumps Ever Cause Male Sterility?

The laity sometimes manifest a fear that the "descent" of mumps to the testicle may entail a loss of manhood. The observation of physicians fails to show definitely that mumps orchitis leads to any interference with potency. The usual explanation is that this complication occurs chiefly in adolescent and adult years, and perhaps it is inferred that incidence in the earlier periods of childhood would be more dangerous by preventing the full development of the gonads. In rare cases where impotence, sterility, or loss of male secondary sexual characters has followed mumps or mumps orchitis it may have been a simple coincidence, for in any such event it would of course be necessary to exclude other causes of these conditions, to trace a proper relationship between the orchitis and atrophy or azoospermia, etc. During the late war regimental physicians had an excellent chance to investigate this subject, although naturally only in the case of adults. Bénard (*La Presse Médicale*, October 15, 1921, xxix, 83) states that during the past twenty-one years over 200,000 cases of mumps have been recorded in the French troops. The percentage of orchitis was 17, and the cases of double orchitis amounted to only 0.6 per cent. About one-half the orchitides were followed by atrophy which was usually incomplete, and not necessarily permanent. The author can find a record of but five proven cases of impotence, with five more of doubtful character, and but two in which there was loss of male secondary sexual characters. There is no recorded case of azoospermia. At the outside then the chance of any mischief developing after mumps orchitis in adults is extremely slight, and the patient with forebodings may therefore be confidently reassured.

Carbon Tetrachloride as a Possible Remedy for Intestinal Parasites.

It is a well known fact that many advances in medicine have been made possible by discoveries in the allied sciences. The results of a recent investigation conducted by the Bureau of Animal Industry of the United States Department of Agriculture may prove to be one of these in that it may open the way to a more effective treatment of hookworm disease. Experiments carried out by this Bureau show that carbon tetrachloride, once used in medicine as an anesthetic, and now used variously as a fire extinguisher, cloth cleaner, insecticide, and solvent for fats and gums, is very effective as a destroyer and expeller of intestinal worms. The effectiveness of this chemical agent against certain round worms has been announced by the Department, but what may be the most beneficial use has just been brought out by tests on animals infested with hookworms. In the case of sheep the minimum curative dose has not yet been determined, but all the doses used, from 12 cubic centimeters to 48, in each case given in 2 ounces of castor oil, removed all stomach worms and all hookworms. It has been equally efficacious for hookworm in dogs and foxes, and has been used with success against some of the various kinds of worms that infest the digestive tract of pigs. The Bureau of Animal Industry therefore considers that this drug will prove of special value in the removal of the various kinds of blood-sucking worms in domestic animals. Carbon tetrachloride is now being tried out in several places by medical men as a possible remedy for ancylostomiasis in man, and is said to give promise of success.

News of the Week.

Doctors Oppose Politics in Medical Appointments.—At its annual meeting on December 7 the Albany County Medical Society adopted a resolution requesting that politics be disregarded in the selection of medical officers for the city and county. Copies of the resolution will be sent to Mayor-elect Hackett.

Medical Examiner Requests Report Where Death Follows Doubtful Treatment.—Following closely upon the case of David Lebish, who died in St. Mark's Hospital, New York, recently as the result of a ruptured appendix following treatment by a chiropractor, comes the report of the death from bloodpoisoning of a man who had come under the observation of several chiropractors who had failed to recognize the nature of his malady. In inquiring into the cause of death, the Chief Medical Examiner states that one of the men subpoenaed, who were alleged to have given him treatment, refused to answer questions and the other said he did not attempt to diagnose cases or to take temperature; he was concerned only with any possible interference with the nerve supply that made its exit from the spinal cord. The postmortem examination showed that the man had died of blood poisoning. In view of these and similar cases that have come to the attention of Dr. Norris he has issued the following statement to physicians: "In all cases resulting in death where it appears in the history of the case that, shortly before admission to the hospital and while the patient was suffering from the disease causing death, such patient had been under treatment by an unlicensed practitioner and there is reasonable ground to believe that such treatment contributed to the condition causing death, you will forthwith notify the Medical Examiner of the city, in order that prompt and proper investigation of the case may be made."

Higher Requirements Advocated for Dental Schools.—In a report submitted to the Harvard Board of Overseers by Dr. William S. Thayer of Baltimore an increase in the requirements for entrance to dental schools is advocated. The report says: "The dentist and physician do not meet on the same common ground. This is unfortunate for physician, dentist, and patient. The circumstance that the requirements for admission to dental schools have been lower and the circumstance that the amount of general and medical education demanded of dentists has been less than that demanded of the physician and surgeon have worked to place the dentist at a disadvantage in the community. This has not only been of very real disadvantage to the dentist; it has been a very real disadvantage to the medical profession." New requirements for entrance to the Harvard Dental School and to some other dental schools now demand one year of college work in addition to a high school training.

Scarlet Fever in Flushing Schools.—More than fifty cases of scarlet fever have been reported to the New York Board of Health from the public and parochial schools of Flushing, in the Borough of Queens. The question as to the advisability of closing the schools came up before the Health Department authorities and it was decided that as there was not really an epidemic it was better for the children to attend school so that they could have the benefit of daily examinations by doctors and nurses of the Department, than to close the schools and have the children mingle in the streets without regular inspection.

New Hospital Plans Nursemaids' School.—A school for nursemaids, where they may learn to care intelligently for babies, will be a feature of the new Fifth Avenue Hospital when it is completed. The course will be of one year's duration. A diploma will be granted, and an employment bureau, to obtain positions for graduates, maintained in connection with the school. St. Christopher's Babies' Hospital, in Brooklyn, has a course of two years during which young women pupils are instructed in how to care for sick babies. They, however, graduate as baby-nurses.

New York City Has Nurse Militia.—Following the announcement by Dr. John Dill Robertson, Health Commissioner of Chicago, that he had developed at a small cost a force of home nurses available for use in epidemics and his recommendation that the plan be more generally adopted, the New York County Chapter of the American Red Cross has issued a statement describing its work in training emergency nurses that has been conducted for the last three years. During this time, 7,312 women in New York have received Red Cross home nursing certificates. At the present time 1235 women are under instruction. The names and addresses of all these women are on file in the office of the Red Cross Teaching center, at 24 Fifth Avenue, and are available for use in case of an epidemic such as the two epidemics of influenza in 1918 and 1919. The training of these women has cost the city nothing. At present a number of them are serving as nurses' aids in the municipal hospitals where the regular complement of nurses is not complete, some being volunteers giving full time.

The New York Association of Cardiac Clinics held a meeting at the New York Academy of Medicine on December 13, at which Dr. William Sidney Thayer of Baltimore delivered an address on "The Minimum Symptoms and Signs Necessary to Make a Diagnosis of Organic Heart Disease."

Violations of the Food and Drugs Law.—The United States Department of Agriculture has issued a report showing that violations of the Federal Food and Drugs law are not so frequent nor so flagrant as formerly. Only a small portion of the food and drugs in interstate or foreign commerce is either adulterated or misbranded. In the enforcement of the Food and Drugs Act during the last year, the Bureau of Chemistry recommended the seizure of 1,677 shipments and criminal prosecutions in 608 cases. The seizures and prosecutions recommended were based most frequently upon shipments of patent medicines including stock remedies, stock feeds, beverages, eggs, food colors, fish and shellfish, salad oils, vinegars, artificial sweeteners and tomato products, but included a considerable number of other foodstuffs. The activities of the year on patent medicines included 866 actions directed mainly toward the elimination of false and fraudulent claims on the labels regarding curative powers for a great variety of diseases. So-called lithia waters

containing only the merest traces of lithium, but alleged to be of the greatest therapeutic value because of their lithium content, have been virtually eliminated from the market. Interstate commerce in mineral waters and other drugs alleged to contain radium which were put on the market following the announcement that radium effected wonderful cures, threatened to develop to large proportions, but was stopped before it attained much momentum. Effective campaigns have been carried on to eliminate from interstate commerce shipments of milk and cream highly contaminated with bacteria. Some contaminated mineral springs have been closed, while in others the manner of handling the product and of purifying it have been revolutionized. Methods have been devised for the detection, by means of the microscope, of decomposed fruits and vegetables in prepared food products. Investigations have been made to establish as fully as possible the character of the practices necessary to protect consumers from food poisoning, and the information has been disseminated widely.

Positions for Surgeons' Assistants, Bacteriologists, and Roentgenologists.—The United States Civil Service Commission announces an open competitive examination for surgeon's assistant. Vacancies in the Public Health Service throughout the United States, at the compensation fixed by that service of $80 a month, without quarters, subsistence, or laundry will be filled from this examination. Applicants must have completed at least the sixth grade of common school. In addition, they must have had at least one year's private training in a physician's or dental office or one year's experience as a graduate or practical nurse. Open competitive examinations are also announced for the position of roentgenologist at $3,000 to $4,000 a year; vacancies in the Public Health Service in the position of roentgenologist at $200 to $250 a month, associate roentgenologist at $130 to $180 a month, assistant roentgenologist at $90 to $130 a month, junior roentgenologist at $70 to $90 a month; and vacancies in positions requiring similar qualifications. In addition there will be open competitive examinations for the position of bacteriologist at $130 to $180 a month, associate bacteriologist at $90 to $130 a month, assistant bacteriologist at $70 to $90 a month, and junior bacteriologist at $70 a month, and vacancies in positions requiring similar qualifications. To all salaries there is added the increase of $20 a month granted by Congress. Applicants should apply for Form 1213, stating the title of the examination desired, to the United States Civil Service Commission, Washington, D. C., or to the secretary of the local board of civil service examiners at the post office or custom house in any city.

Hospital Notes.—The Bronx Hospital, New York, has purchased a plot adjoining its present building as a site for a ten-story addition. The present hospital has only 110 beds and additional capacity is therefore urgent.

St. Elizabeth's Hospital, at Van Ness Avenue and Filbert Street, San Francisco, Cal., was formally opened on Nov. 19.

The contract for a county tuberculosis sanatorium at Fort Smith, Ark., has been let. The new building and equipment will cost $20,500.

The drive to raise $75,000 for a new nurses' home in connection with the Norwegian Hospital, Brooklyn, N. Y., has closed with a total of $57,421.46 contributed.

The Federated Women's clubs of Sterling, Colo., has just presented that city with an $85,000 hospital. When the hospital was opened early in December it was free from debt.

Dr. Thomas Gruber, formerly of Rochester, N. Y., has been appointed superintendent, and Dr. Donald Morrill of Ann Arbor, assistant superintendent, of the City Receiving Hospital of Detroit, Mich.

Dr. J. L. Freeland and Dr. R. V. Converse have been appointed special medical investigators of the Indianapolis Board of Health.

Dr. Henry Page has been appointed director of the medical staff of the Cincinnati General Hospital.

Dr. Harry S. Sweiwelt of Kankakee, Ill., has been appointed assistant superintendent of the Eastern State Hospital of Kentucky.

Dr. C. Floyd Haviland of Albany, N. Y., has been appointed State Hospital Commissioner by Governor Miller, to fill the vacancy caused by the resignation of Dr. Charles W. Pilgrim.

Gifts and Bequests.—The Presbyterian Hospital, Philadelphia, is the beneficiary to the extent of $50,000 to be used as a memorial to Joseph A. and Anna M. Tomlinson, by the will of the former, recently admitted to probate.

The will of Mary A. Burkhart makes a bequest of $250 to the Bancroft-Taylor Rest Home of Philadelphia.

The Journal of Orthopedic Surgery, published in Boston, Mass., announces that in January it will become a quarterly publication under the name of *The Journal of Bone and Joint Surgery.*

The New York Hospital announces that the Department of Urology, established with a bequest from James Buchanan Brady, will operate a clinic for women. The clinic will be open from 2 to 3 o'clock in the afternoon.

Physiotherapy Clinics for Physicians.—The American Electrotherapeutic Association and the New York Electrotherapeutic Society are arranging a joint midwinter clinical session to be held on Dec. 29 and 30, at the U. S. Public Health Service Hospital No. 61, at Fox Hills, Staten Island, N. Y. There will be explanation and demonstration of all physical modalities, and of the results obtained. A two days' demonstration of physical therapeutics, open to physicians generally, will be held during this meeting under the auspices of the U. S. Public Health Service. The opening meeting, with papers on "Physiotherapy in General," by Chris M. Sampson of Staten Island, and Frank B. Granger of Boston, will be held at the New York Academy of Medicine on Wednesday evening, Dec. 28, 8:30 P.M. All medical men are invited to attend, and programs and admission cards may be obtained from Dr. Richard Kovacs, 223 East 68th Street, New York City.

American-Jewish Physicians' Committee Incorporated.—This committee has been granted the privilege of incorporating as a membership corporation by the Supreme Court. The organization aims to collect and to expend and disburse for, or to pay over moneys to the trustees of the governing body of the Hebrew University in Palestine "for

the establishment, inauguration, maintenance and upkeep of a medical unit of the Hebrew University in Palestine."

Physicians Needed in Foreign Missions.—The Rev. Dr. R. F. Campbell, in a recent address before the foreign missionary board of the Southern Presbyterian Church, set forth detailed information as to the startling lack of doctors in African, Korean and Chinese missions. He pointed out that the band of missionary physicians was slowly dwindling, and that in the whole of the African Presbyterian mission there was but one doctor. Physicians willing to enlist in this service are asked to notify Dr. S. H. Chester, Foreign Secretary, 156 Fifth Avenue, North, Nashville, Tenn.

Medical Society Elections. — THE CALHOUN COUNTY (ALA.) MEDICAL SOCIETY, at its annual meeting held in Anniston, Dec. 7, 1921, elected the following officers for the ensuing year: *President*, Dr. J. F. Posey, Anniston; *Vice-President*, Dr. T. J. Patton, Oxford; *Censor*, Dr. W. H. Kinnebrew. The Secrtary and Treasurer are filling unexpired terms.

Obituary Notes. — Dr. THOMAS CANBY CRAIG, U. S. N., retired, died from heart disease at his home in Brooklyn, N. Y., on Dec. 13, at the age of sixty-eight years. He was graduated from the University of Pennsylvania School of Medicine in 1880. He served for eighteen years in the United States Navy, and after his retirement as medical inspector and diagnostician with the Brooklyn Board of Health. He was a Fellow of the American Medical Association and a member of the Medical Society of the State of New York.

Dr. EDWARD TORREY of Olean, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1869, died following an operation for cancer at a local hospital on Dec. 8, at the age of seventy-four years.

Dr. ROBERT MORRIS of Rome, N. Y., a graduate of Bowdoin Medical College, died following an operation for appendicitis on Dec. 4, at the age of fifty-three years.

Dr. EUGENE WOODBURY HILL of Sorrento, Idaho, died suddenly in Tacoma, Wash., on Dec. 13, at the age of fifty-six years. He was graduated from the University of Maryland School of Medicine, Baltimore, in 1886.

Dr. EUGENE T. HANCOCK of Philadelphia died on Dec. 5, at the age of fifty-two years. He was graduated from Jefferson Medical College in 1891, and was a veteran of the Spanish-American War.

Dr. GREENLY V. WOOLLEN, a graduate of Bellevue Hospital Medical College in 1865, died at his home in Indianapolis, on Nov. 30, at the age of eighty-one years. He was one of the founders and was the first Secretary of the Indiana State Medical Society.

Dr. J. MORTON BOICE, a graduate of the Medico-Chirurgical College, Philadelphia, died at his home in Philadelphia on Dec. 2, at the age of forty-five years. He was a member of St. Joseph's Hospital staff and formerly secretary of the Philadelphia Medical County Society.

Dr. TRUMAN H. COX of Lee Center, N. Y., a graduate of the Cincinnati College of Medicine and Surgery in the class of 1875, died on Dec. 2, at the age of sixty-eight years.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, December 1, 1921.

Report on the Financial Position of the Voluntary Hospitals of England and Wales.—Sir Napier Burnett, K.B.G., M.D., Director of Hospital Services of the British Red Cross, has issued recently a report on the financial position of the voluntary hospitals in England and Wales, those in London being excluded. This report is prefaced by an introductory note by the Hon. Sir Arthur Stanley, chairman of the Joint Council of the Order of St. John and British Red Cross Society. In the course of this note Sir Arthur Stanley makes the following pertinent remarks: "One important fact emerges from the report. It had always been known by those who made a special study of the matter that hospitals with which medical schools were associated were necessarily involved in greater expenditure than those hospitals to which no medical schools were attached. It will, however, come as a surprise to many that the thirteen training hospitals mentioned in the report are responsible for no less than 50 per cent. of the total deficit of £448,061 incurred by the 107 large hospitals. This seems to point to the possibility of obtaining financial assistance from the Government, not for the hospitals themselves, but in respect of the training work that is done in them. Without the hospitals it would be impossible to train the large army of doctors and nurses necessary for the public health service. If the voluntary hospitals did not exist and could not be used for this purpose the State itself would have to create hospitals and maintain them at a large expense. Moreover, the research work done in the training schools is of great value to the State and is an important factor in the health of the nation. For this work it seems clear that the hospitals have a claim upon the State which need in no way interfere with their voluntary nature nor with the fulfillment of their primary object, the provision of medical aid and nursing for the sick and suffering who are too poor themselves to pay for such treatment."

Sir Napier Burnett says in an introduction to his report that the present financial survey, for the year 1920, of the voluntary hospitals of England and Wales, is based upon data received, (a) from the secretary of the individual hospital, or (b) during personal visit to the hospital, or (c) from the figures published in the hospital annual report. The hospitals in the London area being under the supervision of King Edward's Hospital Fund, are not included in this report. The survey on this occasion not only deals with the figures for the year 1920, but also sets out, for the purpose of comparison, the financial data for the year 1919. In 1919, there were 600 hospitals surveyed out of a possible 668, which included a few convalescent hospitals, whereas on this occasion the figures of 572 hospitals are dealt with out of a possible 647. The following figures give some idea of the volume of work done by the hospitals during the year:

NUMBER OF IN-PATIENTS AND OUT-PATIENTS TREATED DURING 1920

	No. of Hospitals Giving Details	Available Beds	No. of In-Patients	No. of Out-Patients
Hospitals with				
100 or more beds	106	20,056	248,426	1,191,016
30 to 99 beds	160	8,202	97,619	388,707
Under 30 beds	289	4,122	50,363	130,851
Totals	555 = 97 per cent. of hospitals reviewed.	82,380 = 95 per cent. of beds in hospitals reviewed.	396,408	1,710,574

The total number of patients treated by 555 hospitals was 2,106,982. Included in these figures are those of the thirteen hospitals associated with medical schools, namely:

Number of Hospitals	Number of Available Beds	Number of In-Patients	Number of Out-Patients
13	4,388	68,966	457,635

In other words, these thirteen medical school hospitals with 13.5 per cent. of the available beds, treated altogether 526,601 patients, or 25 per cent. of the total. These hospitals treated 17.39 per cent. of the total in-patients and 26.75 per cent. of the total out-patients. The financial situation dealt with in the report indicates that considerable progress has been made by the hospitals in their efforts to adjust their finances to the post-war conditions. The author goes on to say that there is every indication that the high-water mark of hospital expenditure was reached in 1920, and that the present year will show considerable reduction in the cost of many hospital commodities; so that if the hospitals can maintain their present progress on the income side there is every prospect that the forecast outlined in the Cave report, that two years would be necessary for readjustment, will be realized. Valuable results are anticipated from the County Voluntary Hospital Committees now being established by the Voluntary Hospitals Commission.

The important work to be undertaken by these committees includes the gathering together of the voluntary hospitals in a county into a federated group, with the object of finding some uniform scheme for financing the hospitals within the area, and of establishing some system of coordination for the treatment of patients and of finding some common ground for the reduction of expenditure along the lines of cooperative buying, especially of non-perishable commodities, and of the standardization of many articles used in hospitals. Another reform urgently awaited, and which is likely to result in considerable benefit to the hospitals themselves, is the adoption of a simplified system of hospital accounts that will be uniformly adopted throughout the country.

The hospitals are graded into three groups according to the number of available beds, viz., (1) The large hospitals of over 100 beds. (2) The intermediate hospitals of from 30 to 99 beds. (3) The small hospitals of less than 30 beds. The figures show plainly that speaking generally, the pressure of the "waiting list" is most severely felt by the large hospitals, and further, the figures for the cottage hospital group bear out the statement emphasized previously: that these hospitals are not always fully occupied, and therefore there is urgent need for some system of coordination to be established by the new hospital committees, whereby these smaller hospitals with their empty beds may be linked up with the larger hospitals in order to relieve the pressure for beds at the latter.

Report on the London Hospitals.—The King Edward's Hospital Fund have reported recently to the Hospitals Commission in regard to the situation of the London hospitals. It is estimated that the aggregate deficit on the maintenance account for the year ending December 31, 1921, will amount to at least £360,000. Although this figure is less than that for 1920, the discouraging feature is that all the general hospitals, including all the medical schools will show heavy deficits. In addition, a considerable number of hospitals which have now exhausted their realizable assets will be compelled to close their beds. It is a condition of the Government grant of £500,000, which is not only for London, but for the whole of Great Britain, that a corresponding amount must be raised by the hospitals themselves. The total deficits for the year as estimated by Viscount Cave's committee is £1,000,000. The Hospitals Commission have provisionally appropriated £180,000 for London, which is half the total deficits for the year, so that to earn this grant the London hospitals must themselves raise a similar amount. Sir Robert Horne, the Chancellor of the Exchequer, made a statement the other day that the grant of £500,000 made by the Government to the voluntary hospitals was made only on the condition that a similar amount be raised by the hospitals themselves. The Chancellor also stated that having regard to the present financial position, he wished to make it clear beyond the possibility of a doubt that the £500,000 grant was the limit of Government assistance to the voluntary hospitals.

The "Lancet" and Wakley.—The account of the founding of the *Lancet* and the interesting sketch of its founder, Thomas Wakley, contributed to the MEDICAL RECORD October 9, by Dr. John Ruhräh, made very good reading. Incidentally, it may be mentioned that a full "Life of Wakley" was written by the present editor of the *Lancet*, Sir Squire Sprigge, for whom, by the way, Messrs. Hodder and Stoughton, have published recently a book entitled "Physic and Fiction." This book deals with various subjects of medical concern regarded from the sociological, scientific, and literary standpoints. Among the matters discussed are medicine in fiction, the medicine of Dickens, public developments of medicine, medicine in art, and poisoning. The chapter on poisoning is especially interesting and shows that "scientific development, where criminal poisoning is concerned, makes for security, for the law keeps ahead of the law-breaker." However, the book abounds in good things and is written in such a way that it provides amusement, interest, and sound information at one and the same time. The literary style is easy and distinguished, tinged with humor, and permeated with philosophy.

Post-Graduate Training in London.—A draft copy of the syllabus of the intensive post-graduate medical course in London and which will begin on January 9, has just been issued. The syllabus has been arranged to extend to six weeks, terminating on February 18. The hours of work are from ten to four on each day, with a short in-

terval between. As stated in a notice published in a previous letter, the subjects of the course will be "Diseases of the Chest, Pathology, Fevers, Diseases of the Heart, Gynecology, Infant Welfare, Lunacy, Cancer, Diseases of the Eye, Diseases of the Skin, of the Rectum, and of Children. The fee for the entire course has been fixed at £15.15. A notable feature of the new scheme is that it stabilizes a course of instruction which for six weeks will be in operation. As is pointed out in the Bulletin of the Fellowship of Medicine and Post-Graduate Medical Association of November 26, the advantage of this course is obvious. Instead of a post-graduate being required to draw up a program of work for himself, he is now provided with one, regularly arranged, and from the variety of the subjects included, so adapted to meet all ordinary requirements. A course in general surgery will commence on February 20 next and cover a period of six weeks to April 1. It will comprise all the various branches of surgical work, and as in the case of the medical course, the fee will be an inclusive one of £15.15 and the number attending it will be limited to twenty.

LETTER FROM SWITZERLAND.

(From Our Own Correspondent.)

GENEVA, November 10, 1921.

Seventh Centenary of the University of Montpellier.—The celebration of the seven hundredth anniversary of the Faculty of Medicine of Montpellier was perfect in every detail, the presence of the President of the French Republic and beautiful weather contributing not a little to the success. All the city was tastefully decorated with flowers and in the evening brilliantly illuminated. The proverbial hospitality of Montpellier was charming upon this occasion, the delegates from the French and foreign universities being lodged in the houses of the notables of the city.

The celebration took place on Nov. 5, in the courtyard of the anatomical theater of the Faculty. It was a spectacle never to be forgotten, unfolding itself as it did at the foot of the cathedral and the walls of the ancient college of St. Benoit, at present occupied by the Faculty of Medicine. On the right, on the roof of the cloister of the cathedral, were the students, several hundred in number. Opposite was the theatrum anatomicum, on the roof of which the flags of all the nations represented were floating.

On the stadium built up against the anatomical theater were seated Mr. Millerand, the rector of the university; the dean of the Faculty, the civil, military and ecclesiastical authorities and among the latter we noted the presence of the venerable cardinal-archbishop, Monseigneur de Cabrières, ninety-two years of age. The courtyard was filled by the delegations from the French and foreign universities, as well as the professors of the University of Montpellier, wearing their traditional gowns and caps.

The séance was given up to the glorification of the School of Montpellier, the oldest in the world after that of Salerno. Prof. Viret reviewed its history, referring to the vitalistic doctrine personified in the person of the celebrated Barthez who, in the XVIII. Century freed medicine from the grasp of the physiochemical sciences.

Prof. Forgues next delivered a discourse on the history of surgery at Montpellier, and vividly described the great XIV. Century surgeon, Guy de Chaubiac, and Lapeyroine (of Montpellier), surgeon to the King (XVIII. Century) and founder of the amphitheatre of St. Cosmos.

Prof. Widal, of Paris, spoke in the name of the universities of France, praising the rejuvenated vitalism taught by the late Prof. Grasset, its last representative at Montpellier, and confirmed by his (Widal's) researches, as well as by those of his collaborators.

Next came the turn of Prof. Bordet, of Brussels, to speak in the name of the foreign delegations. He paid a high tribute to French science and the high moral standard of its savants.

It is interesting to note that the great Swiss botanist, Pyramus de Candolle, was appointed professor and at the same time made doctor of medicine, by the Faculty of Montpellier, in 1808. The success of his lectures, which were attended by 400 to 500 students, was immense. De Candolle was at the same time appointed director of the Botanical Gardens, the oldest in the world, founded by Henry IV., and made famous before de Candolle by de Jussieu and Tournefort. The memory of de Candolle has been perpetuated at Montpellier by his bust in the Gardens and a path which bears his name, as well as fine portrait in the Chamber of Acts of the Faculty, painted while he was rector of the University in 1815.

Lastly, a few words about the beautiful ceremony which took place on Nov. 6, under the noble trees of the Botanical Gardens. I refer to the inauguration of Rabelais' statue, the work of the noted sculptor, Villeneuve. Around the pedestal stood students with their flags and banners while grouped in a semi-circle behind the monument was the chorus of the Normal School accompanied by that of St. Cecilia, who sang the National Hymn and the *Cantate au Drapeau*.

After a speech by the president of the students' societies, the Minister of Public Instruction delivered a wonderful word picture of François Rabelais and saluted the memory of the illustrious medical student of the school of Montpellier. Although Rabelais was in reality only a short time at Montpellier—about two and a half years all told, comprised in two separate visits—he played an important part by his teachings in the restoration of Hippocratic medicine.

"THE TREATMENT OF ORDINARY DISEASE."

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Having read Dr. Beverley Robinson's book, "The Treatment of Ordinary Disease," I cannot refrain from expressing my sincere admiration on the masterly presentation of his views regarding the treatment of disease, especially in surgical interference in gall bladder and appendicular involvement. Dr. Robinson is in accord with the views which I have expressed on many occasions.

I fully agree with Dr. Robinson that too much meddlesome surgery, with too great a destruction of organs is the rule and not the exception, and much may still be accomplished through medical means and leave the patient with his anatomy intact and in good working condition.

Dr. George L. Servoss, editor of the *Western Medical Times*, in a personal letter received some time ago, says: "To my mind there is too much slaughter of various organs, and the removal of this, that, or the other thing does not always bring about the results desired, and I sometimes think that something vital to the economy has been taken away."

Dr. Robinson's book gives the internist a proper place, for it is my belief that sooner or later the internist will come more nearly into his own. I am not saying that surgery is not warranted in many instances, but I do believe were proper diagnosis made and treatment instituted, there would be less lives jeopardized.

5. Forsyth Day.

1. Osteitis Fibrosa.—Charles F. Painter reports the case of a boy, eighteen years of age, who was admitted to the Carney Hospital in September, 1907, with the history that when about six years of age he had fractured the right thigh. The leg felt uncomfortable from that time until three years later, when he again fractured the thigh. Recovery seemed to be perfect and he had no further trouble until the latter part of July, 1907, when he commenced to have pain below the trochanter. When admitted to the hospital there was a hard firm tumor below the right great trochanter; it was apparently a part of the bone, irregular in outline and simulating a calculus. On account of the possibility of there being a neoplasm and because the *x*-ray showed an appearance not inconsistent with such a view, it was decided to explore the femur. The medullary cavity was found to be occupied by a dense, yellowish, homogeneous tissue, which was not at all vascular and could be readily peeled off, leaving hard, smooth, normal appearing bone beneath. This tissue seemed to be arranged in four cavities, each about 4 x 2.5 cm. These were thoroughly curetted to the cortical bone. There was no suggestion of a lining to the cavities. The patient made a good recovery and had no further trouble until the winter of 1912, when he commenced to have pain in the right lower leg at about the upper and middle thirds of the right tibia. At operation a condition similar to that found in the femur five years before was discovered. The case is unique in that the two foci developed in the same individual, separated by a long interval of time and without any determinable etiological factor. It would seem that some infective agency was operative in this case. If this is so why it should show a predilection for the medullary bone and produce changes which were so different from those commonly associated with bacillary processes does not appear. The history of some thirty cases of osteitis fibrosa is culled from the literature, a review of which brings out two theories worthy of consideration because of their agreement with fundamental pathological processes. The first is the theory of a low grade inflammation and the second of endogenous metaplasia. It does not seem to the writer that trauma can be considered as playing a rôle which is causative, and as for syphilis, osteomyelitis, osteogenesis imperfecta, tuberculosis, Paget's disease, osteomalacia, giant celled sarcoma or any other of the diseases cited as having close relationship to the lesions of osteitis fibrosa, it does not appear that there is any convincing evidence. Simple, free exposure of the lesion and curettage to solid bone offers a satisfactory solution of the problem of treatment.

3. Lateral Sinus Infection: Diagnosis, Treatment, and Complications.—G. L. Tobey, Jr., observes that in this condition the temperature cannot be considered a definite diagnostic symptom. Its presence indicates infection, but its absence or its atypical characteristics do not preclude an infection of the sinus. The temperature chart, however, must be taken into consideration in forming the conclusions as to diagnosis. Great stress has been laid on the presence of chills; chills occur in less than 50 per cent. of the cases. Occasional periods of perspiration (hot flashes) are often overlooked, but are most suggestive of infection. Subjective head symptoms are usually present. The leucocytosis is of value only when taken into consideration with other symptoms. Too much emphasis has been placed on the value of the blood culture as a diagnostic sign of the presence or absence of sinus infection. Edema or infiltration, with tenderness on deep pressure over the area drained by the mastoid emissary vein, was the most constant objective symptom which was found present in a large series of cases, and was present in practically every case of mural or complete thrombosis of the sigmoid sinus. Sufficient emphasis has not been placed on this symptom in the past. Enlargement of the external jugular on the same side is not infrequently observed. Tenderness over the jugular vein is a sign of no practical value. Since a large extradural or perisinus abscess will, in a certain number of cases, simulate symptomatically a lateral sinus infection, the mastoid operation should be performed, and in every case the sinus should be exposed before ligating the jugular. When a positive diagnosis of involvement of the sinus is present, direct communication of the sinus with the general blood stream should be cut off. Statistics show that simple ligation is the logical operation, bearing in mind that in a small percentage of cases it is necessary to proceed with complete excision of the vein. In favor of simple ligation are the very few cases requiring resection, the very short time required for the operation, with the consequent small amount of shock to the patient, nonexposure of the tissues of the neck to infection, and the very insignificant scar. The essayist takes exception to the statement that in simple ligation without removal of the jugular bulb and vein one is leaving a large sac of pus which does not have free drainage, the reason being that pus does not drain up hill. Those making this statement have neglected to consider the fact that their patients are in the recumbent position, and that the upper portion of the jugular bulb is the most dependent part. Among the complications likely to be met after operation in sinus infection are secondary metastases, localized central pneumonia, erysipelas, and occasional iodoform poisoning from the use of iodoform dressings. A very unusual and rare complication is the occurrence of a septic sinus thrombosis on the other side.

Interval Operations.—Virginius Dabney. (See MEDICAL RECORD, c, 17, p. 744.)

3. Treatment of Recurrent Pleurisy by the Injection of Oxygen.—Andrew MacFarlane reports this case, which occurred in a man sixty-seven years of age. The pleural cavity was aspirated four times; the amount of fluid remived varied from eight ounces at the first aspiration to two quarts at the fourth. After the withdrawal of this fluid at the fourth aspiration the rubber tubing from an oxygen tank was fitted over the aspirating needle and the oxygen was allowed slowly and carefully to enter the left pleural cavity, passing through the usual water bottle. From this time the patient gradually gained in strength and was practically well at the end of two weeks. Numerous examinations for the tubercle bacillus were negative, as were guinea-pig inoculations. In a second case of chronic pulmonary tuberculosis and tuberculous pleuritis the results were not so fortunate. The writer states that this method of oxygen injection is easily carried out and is without danger, especially if a manometer is used. It might be tried in cases of pneumococcus empyema where aspiration alone has at times been able to effect recovery. The fact that almost all cases of pleurisy with effusion are tuberculous would suggest that even temporary immobility of the lung which follows this procedure might be of some value in the pulmonary condition.

5. Aspergillosis and Pulmonary Pseudotuberculosis.—Vincent Anthony Lapenta asserts that diseases caused by parasitic and pathogenic phytomycetes have seldom received the attention they really deserve. The symptomatology caused by aspergillosis varies from an acute mucoid bronchopneumonia to that of chronic tuberculosis. In this chronic type the symptoms are a close parallel to tuberculosis. The necessity of early diagnosis of pulmonary aspergillosis is evident from the fact that, in the absence of complications from concomitant tuberculosis, the disease can be rapidly cured by appropriate treatment. In the routine examination for the tubercle bacillus the presence of the *Aspergillus fumigatus* will often escape detection. A separate examination should be made for it. In the presence of negative findings cultural examinations are advised, as sometimes the sputum will contain only the spores. Iodine seems to be specifically destructive to the life of the aspergillosis. The writer has employed it in the form of the iodides of potassium and sodium by mouth and by intravenous injection. For the intravenous injection he recommends one or two grams in 25 c.c. of saline solution. Under this treatment several cases have cleared up in the course of four or five weeks. In one patient who did not respond readily to the iodine therapy, a saline extract of aspergillosis culture was employed. With the use of this agent in addition to the iodides, the patient improved very rapidly.

12. Tonsil Thyroid Syndrome in the Female.—Joseph H. Barach bases this discussion upon two premises, the first being that in the present state of our knowledge we are not at all sure to what extent the constitutional or metabolic disturbance producing the clinical picture known as hypothyroidism is due to hyposecretion of the thyroid gland, and how much of it is brought about by disturbed function of the adrenals, pituitary body, and gonadal system. The second premises is that chronic tonsillar infection or chronic infection of their contiguous structures, as it existed in the cases studied, is disease producing, because of the local disturbance and the constitutional effects resulting therefrom. The chief symptoms presented by these cases in their order of frequency are: Chronic tonsillitis, hypertrophic; tonsillar node; thyroid gland enlarged; complexion pasty and sallow; skin and hair dry; breasts excessively developed; menstrual function disturbed; subcutaneous tissues thickened; obesity; tendency to sterility; ate no breakfast; hands, moist, cold, cyanotic; body hypersensitive to cold; blood pressure low; pulse rate slow; tongue thickened and tooth-marked; speech thick and voice coarse; early fatigue; dyspnea on exertion; alopecia; nails brittle; neuralgias. If the latest theory concerning the cause of colloid goiter is correct, namely, that colloid goiter is produced by a lack of iodine, it is quite possible that in the chronic tonsillar infection the system becomes impoverished in iodine and colloid goiter with hypothyroidism is the result.

14. Influenza as a Primary Edema of the Respiratory Mucous Membranes and Adnexa.—I. M. Brenner states that as a result of careful observation he has found that whenever the infecting organism of influenza implants itself upon the respiratory tract there will be a definite objective edema, such as is always evident on the uvula and fauces at the initial onset of the disease. Pathologically, it has been demonstrated that large amounts of fluid are present in the lungs and that they present an entirely different picture from that of bronchopneumonia. There is a congealed area of protoplasmic distended endothelial cells which the author calls congelatinous pneumonia. He goes on to show that osmosis is a definite accepted phenomenon and the response of the organism to changes in the osmotic pressure has been clinically demonstrated. Bleeding, the administration of immune or non-specific serum, glucose injections, colonic irrigations, diaphoresis, menstruation, all serve to remove fluids, that is, are agents of dehydration, thereby increasing intraarterial osmotic tension. Therefore, any treatment which brings about dehydration and causes blood concentration will, by osmosis, remove the fluid from the edematous protoplasmic cells of the lung tissue, brain, or gastrointestinal tract. Therapy directed to this end has and will prove a positive, if not almost a specific, means of treating this type of infection.

1. The Treatment of Brain Tumors.—Walter E. Dandy endeavors in this paper to present a more hopeful outlook in the treatment of brain tumors, which he summarizes as follows: Brain tumors are among the most frequent neoplastic lesions; their growth is always progressive and almost always leads to a train of terrible sequellæ and eventually to death. There is only one form of treatment for tumors of the brain—operative removal, and this must be complete. To obtain the best operative results, brain tumors must be diagnosed and localized in the earliest stages. It is now possible to do this. When all other signs and symptoms fail in the localization, cerebral pneumography will make the diagnosis and localization with precision and without equivocation. And when a tumor is not present, it can be excluded by the same method. After correct localization all brain tumors should be disclosed at operation. Every effort should be made to cure the patient by complete extirpation of the growth. There is less mortality from carefully performed tumor extirpations than from unsuccessful explorations for tumors. When, for any reason, it is impossible or unjustifiable to remove the tumor, the maximum palliative relief should be given at the same operation. Decompressions, routinely performed, are among the most harmful and indefensible operations in surgery. They should never be performed for unlocalizable tumors. They are the exact equivalent of giving morphine for abdominal pain; the symptoms are masked until it is too late. Decompression should be performed only as a last resort—when the tumor cannot be removed; and then only after the localization of the tumor is known, for in half the cases of brain tumor, no good can possibly be derived from a decompression. Exploratory craniotomies are now scarcely ever indicated. The tumor should be precisely located before any operative procedure is attempted. Early and accurate localization and thorough operative treatment will eliminate all unnecessary and harmful operations. The treatment

of brain tumors can only be a direct eradication of the cause.

2. **A Method for the Administration of Sodium Chloride for Headaches.**—Walter Hughson calls attention to the fact that intracranial pressure is a well recognized cause of headache. As demonstrated by Weed and McKibben, the pressure of the cerebrospinal fluid can be markedly reduced by intravenous injections of common sodium salts, and, further, as shown by Cushing and Foley, similar reductions of the fluid pressure can be accomplished by the simple alimentary ingestion of strongly hypertonic solutions. The difficulty in applying this information practically was that persons suffering from severe headaches were found to have considerable trouble in retaining the salt for a length of time sufficient for it to pass into the intestine, where its absorption into the blood stream could take place. This difficulty has now been obviated by the preparation of compressed tablets salol-coated, each containing 1 gm. (15½ grains) of sodium chloride. Such tablets pass unchanged through the stomach, yet liberate their salt when the alkaline secretions of the small intestine are reached. The clinical use of these tablets has been somewhat limited thus far, but at the same time sufficient observations have been made to show that they have a beneficial effect in practically all of the milder forms of headache. The treatment of headaches with these tablets possesses advantages over the employment of the various coal tar products.

4. **The Serotherapy of Bacillary Dysentery in Children.**—Hugh W. Josephs and Wilburt C. Davison find in a limited series of cases of proved bacillary dysentery in children in whom subcutaneous and intramuscular injections of from 20 to 50 c.c. of antidysenteric serum were used, serotherapy did not influence the mortality or the course of the disease. In the very ill, especially in young infants, the pain at the site of the injection is a contraindication to the use of intramuscular injections.

5. **Clinical Studies of Drugs of the "Digitalis Series." III. Apocynum and Convallaria.**—H. M. Marvin and Paul D. White have studied the action of the fluidextract of apocynum in twelve cases of heart disease complicated by auricular fibrillation and the action of convallaria in twelve similar cases, from which they conclude as follows: (1) The results of clinical studies on the fluidextract of apocynum cannadinum indicate that the drug has, in some degree, a digitalis-like action in cases of heart disease with auricular fibrillation. Its possible usefulness in the treatment of heart failure, however, is markedly limited by the discomfort, nausea, and vomiting which invariably follow its administration in doses sufficiently large to affect the heart. (2) In one case of auricular flutter, the administration of apocynum was followed within several hours by a change to auricular fibrillation. The drug was withdrawn, and normal rhythm was resumed two days later. So far as we are aware, this is the first case reported illustrating the action of apocynum in auricular flutter. (3) Similar clinical studies on the fluidextract of *Convallaria majalis* indicate that only in occasional cases does it have any favorable action on the heart in auricular fibrillation; even in these occasional cases its action does not resemble that of digitalis in all details. (4) It would seem from these results that neither apocynum nor convallaria can be used as substitutes for digitalis. Digitalis has been characterized by quicker action, more pronounced effects, less discomfort, and more prolonged improvement, than are seen following either of the other drugs. We are convinced that both of these members of the digitalis series have no place in the rational treatment of heart failure.

7. **Spirochetal Pulmonary Gangrene.**—B. S. Kline reports three cases of pulmonary gangrene observed in the course of 130 autopsies at the Montefiore Home, New York in which the presence in large numbers of fusiform bacilli and spirochetes in early gangrenous ulceration of the lung suggest their etiological relationship thereto. These spirochetes morphologically resemble *Spirochaeta* (or *Treponema*) *buccalis, vincenti, microdentium, mucosum,* and *macrodentium.* In all three cases marked dental caries and pyorrhea alveolaris were present. Smears from these lesions showed organisms morphologically indistinguishable from those mentioned above. These organisms, which are poorly colored by the usual laboratory stains, are readily demonstrated by the Fontana method in smears and by the Levaditi method in tissues. From a study of the pulmonary lesions in these three cases the impression is gained that they are extensive pneumonias, caused by organisms from the unclean mouth, in which gangrenous ulceration occurs because of activity of the aspirated fusiform bacilli and spirochetes. If this explanation is correct this type of spirochetal pulmonary gangrene may be prevented by proper oral hygiene.

1. **Permeability in Physiology and Pathology.**—H. J. Hamburger, in this discourse, reviews his investigations on the permeability of red corpuscles to electrolytes, permeability to non-electrolytes (organic substances), and the permeability of cells other than red blood corpuscles. He recalls that twenty years ago he pointed out that the permeability of one and the same kind of cell had no constant value, but was dependent upon the physiological condition of these cells. His experiments on permeability of the glomular membrane to glucose demonstrated the variable permeability to organic substances. Recently experiments have been performed in his laboratory with organic substances, especially with glucose and its isomers and stereoisomers. Experiments were made with the perfused kidney of frogs, using Ringer's solution, in which the sugar is exclusively free and not in the form of a colloid compound. These experiments show that the glomular membrane is normally impermeable to glucose. It is further shown that minute changes in the liquid flowing through the glomerular epithelium make a profound change in the permeability. While glucose is retained crystalline bodies like sodium chloride, sulphates, and phosphates pass through. It was thought that if the molecule of the monosaccharide glucose was so large that its passage through the glomular membrane was hindered, that disaccharides, like sucrose, maltose, and lactose, which have a still larger molecule, would certainly be retained as well. Experiments have shown that the glomerular membrane is highly permeable to these three disaccharides. It is even perfectly permeable to raffinose, which has a still larger molecule. Thus the size of the molecule is not the determining factor. For this reason sugars isomeric or stereo-isomeric with glucose were experimented with. It was found that fructose and mannose passed through completely. Glucose, therefore, occupies a peculiar place amongst the isomeric monosaccharides with regard to the glomular membrane in virtue of some peculiarity of configuration of its molecule. The mechanism of permeability is discussed and the reasons why one obtains different states of permeability on the addition of sodium or calcium, and attention is called to the fact that there is impermeability in the presence of a definite amount of Ca-ions which is replaced by permeability again when there is a superabundance of calcium in the liquid. In the therapeutic application of lime salts one may also notice opposite effects according to the amount used.

2. **Craniotabes of the Fetus and Infant.**—Edmund Hughes, in a previous paper, reached the position that the recognized craniotabes arising during the first month of infancy was in many, and probably in most, cases only a fresh manifestation of a state of craniatrophy already existing in later fetal life. This craniatrophy having no physical differences from the latter form, and occurring predominantly in the same individuals, was held, therefore, to deserve the same title. He now goes over his previous findings and incorporates new material, the total number of cases

studied being 134. The result of these observations makes it clear that the condition he calls craniotabes and the condition of the parietal due to immaturity are entirely distinct. In the first there is a discontinuity of the bone forming spicules—a true atrophy in some part of their course—together, sometimes, with attempts at repair; in the second, merely an evenly progressive ossifying process in an incomplete stage. It is shown that mistakes can rarely arise in palpating these bones. The normal parietal at the period in question is rigid, and the only spot where localized yielding due to immaturity is liable to occur is a small symmetrical area about the parietal foramina. Except for this, which is easily excluded, the parietal at about term presents no features due to absolute immaturity which could simulate craniotabes. The evidence obtained affords sufficient proof of the identity of the fetal and infantile forms of craniotabes. In craniotabes atrophy occurs as depressions found on the inner aspect of the bone. The atrophic areas show both lacunar and diffuse formations, both being frequently present in the same bone. While palpation is sufficient to settle the fact of atrophy and to determine the main features, in detail it is inaccurate and recourse should be had to the *x*-ray in order to fill in the detail. The difference in macroscopic detail is that in parietals at birth, showing normal ossification, the vascularity of the bone may appear uniformly distributed, or show a degree of irregularity in this respect, while in those showing craniotabes there is sometimes, not always, definite hyperemia, with an irregular distribution. The hyperemia is seen to be more pronounced in a broad zone around the atrophic parts. The writer has only found craniotabes in births by the vertex. Its occurrence in other than head presentations would indicate that the fetus had recently changed its position. It would seem probable that the organic causes of decalcification present in the fetal state are carried on into infancy. In 109 cases of infantile craniotabes intensively studied the occipital was rarely affected as compared with the parietal and, when affected, was a secondary involvement. The relation of syphilis to this condition is beyond doubt, but there are very good mechanical reasons quite apart from the activity of an accompanying syphilis. It is probable that the relation of syphilis to craniotabes is similar to its relation to rickets, the action in both conditions being to promote resorption of bone. In craniotabes there seems to be a seasonal curve; 51 per cent. of the fetal series, and 60 per cent. of the infantile, were born in the last four months of the year. The condition would seem to be dependent upon pressure on the cranium by its position in the lower uterine segment and possibly upon an ill-balanced maternal diet. The latter point needs further study.

2. Pyrogenic Therapy ("Protein Shock").—A. G. Auld recalls that in a paper published in the *British Medical Journal*, Vol. I, 1919, p. 195, he described a severe febrile reaction which he obtained in 1916-17 with certain colloidal metals used intravenously, a reaction identical with that produced by the intravenous use of suspensions of killed typhoid and coli bacilli vaccines and termed "protein shock." He found, however, that the full reactions following these particular metallic colloids could be produced by the protein used as the protective or coating to the metallic particles, and in the same dosage. He thinks the term "protein shock" is rather an unfortunate expression and suggests instead the term "pyrogenic therapy," chiefly in view of the fact that the reaction is produced by substances called pyrogens by Burden-Sanderson. Moreover, the fever which occurs is essential and no benefit accrues without it. The cases in which the reactions were produced by the protein-coated metals were chiefly those of delayed resolution in pneumonias and pleurisies, with rises of temperature of from 100° to 101° for some considerable time. Recovery seemed complete at the end of the reaction. More recently cases of arthritis of various kinds have mainly been treated, with on the whole very favorable results; also in skin affections and many infective disorders the response had been rapid and relief complete. This treatment is not to be lightly undertaken. Careful consideration must be given beforehand to the condition of the patient, the pyrogen to be used and the dosage. In suitable cases the full pyrogenic reaction may be necessary for a successful result, namely, a good rigor, high pyrexia, body pains, profuse sweating, and usually sickness and diarrhea. Some cases considered unfit to stand the maximal reaction may derive great benefit from submaximal doses more frequently repeated. As regards the pyrogen to be used that depends largely on the experience of the operator, but for those not especially acquainted with the various substances, typhoid vaccine or caseose (2 c.c. and upward of a 2 per cent. solution) may be employed. The writer has the caseose prepared by gentle hydrolysis. The particular pyrogen used is immaterial so far as the characteristic effects are concerned, and in the case of infections there is no added advantage in using the particular organism, since the reaction is entirely non-specific. The physiological and vital changes which occur following the use of pyrogens are very similar to those described as due to artificial heat. As a matter of fact, the conditions amenable to pyrogenic therapy are chiefly those which are benefited by thermal baths (water or air), such as arthritis (various), neuritis, or neuralgia, certain skin affections, and subacute or chronic inflammatory exudations; and, further, the results are so far comparable in view of the more intense and prolonged pyrexia produced by the pyrogen and the collateral effects of its autogeneration.

7. The Blood and the Nervous Diathesis.—Harry Campbell insists upon the important part played by the blood in the genesis of the neuro-psychoses. He discusses the influence of the plasmic enviroment upon the evolution of the neuron and shows that abnormal development of the nervous system induced through the plasma may be due to inborn or acquired defects of the plasma and that thus it influences both sensations and emotions. A person's temperament may be defined as the sum total of his emotional dispositions. What may be termed the habitual constitution of the blood is peculiar for each individual, and is largely responsible for the feeling note of each. There is little doubt that the difference of the feeling note of different persons is due to differences in blood constitution. On the same lines racial temperaments may be explained. The writer says he does not contend that psychic factors, factors making a direct appeal, take no part in their causation, nor that psychic means are wholly unavailing in their treatment, but he does contend that psychic treatment is important to alter the emotional state which is the essential etiological factor in the more malignant forms of these disorders—those that break out in a favorable environment, for no mental treatment is capable of rectifying the peculiar condition of the blood which is responsible for it. This can only be done by material means.

11. The Early Diagnosis and Treatment of Disseminated Sclerosis.—Douglas K. Adams, in conjunction with E. M. Dunlop and J. W. S. Blacklock, has attempted an investigation of disseminated sclerosis along clinical, serological, and experimental lines. It is imperative from the point of view of successful treatment that the disease be recognized in its earliest stages. On interrogating advanced cases in which the clinical diagnosis is beyond doubt, one almost invariably elicits a fairly definite symptomatology referable to the earliest stages of the patient's illness. There is derangement of bladder function, as evidenced by urinary frequency, precipitancy, slight retention, or in-

continence, in the male at this period frequent nocturnal seminal emissions, and usually a past history of temporary derangement of vision and diplopia. The colloidal gold reaction appears to be almost constantly positive in this disease. In a series of twenty cases of functional nervous diseases which the writer investigated the cerebrospinal fluid was negative to Lange's reaction, and should these facts be substantiated in a larger series of cases some help in the early diagnosis might be hoped for from the use of this method of examination. The test appears not to be specific in the sense in which the Wassermann reaction is specific, but it would seem to be of undoubted value to the clinician as indicating the first definite sign of involvement of the central nervous system in organic disease. The writer's experience supports the view that in the large proportion of cases presenting symptoms as described above the condition is not of syphilitic origin, and further, that they have their basis in infection by some other agent which is probably specific in character. From the experiments carried out it would appear that a disease showing nervous symptoms can be produced in rabbits inoculated with blood or spinal fluid from cases of disseminated sclerosis. This disease can be transferred to other rabbits by an injection of an emulsion of brain and cord of inoculated rabbits showing nervous symptoms before death. This would make it seem that in this disease we are dealing with an infective agent. In the treatment of disseminated sclerosis the best results have been obtained by intensive mercurization with the Aachen formula, combined with repeated intravenous injections of small amounts of novarsenobillon, extending up to twenty or more doses, intramuscular injections on intramine and oral administration of potassium iodide.

1. The Physiological Treatment of Cancer.—Albert C. Geyser argues that it is not the histological or anatomical formation of cancer which ultimately causes the death of the patient but the perverted physiology that is inimical to life. A number of investigators have shown that nearly all tumor growth is arrested by heat of a certain degree, yet sound tissue is in no way affected. It is also a well known fact that dry or moist heat applied to the living body can only penetrate three to five millimeters. All of the good effects observed from the application of moist or dry heat is due to the gradual heating of the blood volume and to the reflex effects of local heating. In the diathermic phase of a high frequency current we have an agent that heats the tissues through and through without practically exerting any influence on the outside. A malignant growth being firmer, of harder consistency, and with a lessened circulation than normal tissue, is especially adapted to the storing and retaining of heat, when this is artificially supplied. In fact, the malignant mass is always of a higher temperature after applying diathermy. Under these circumstances it is easy to maintain a tissue or an organ in a state of elevated temperature for hours. Practical experience has shown that when the entire malignant growth is subjected to an increase of three degrees of temperature for sixty minutes daily its physiology is markedly interfered with. Cachexia is prevented or removed; the tumor mass undergies a retrograde metamorphosis, individual nodules soften, become smaller, and finally disappear; pain ceases entirely, and discharges lessen and lose their offensive odor. The claim is not made that diathermy will necessarily remove the growth, but after diathermy has been used for a sufficient length of time and constitutional changes have been brought about, there is no reason why the growth should not be removed surgically, because practically all chances of recurrence have been removed. The treatments should be given daily or at least on alternate days for at least two months, then once a week for an indefinite time, from forty to sixty minutes being consumed with each treatment, with the current turned on to the point of tolerance.

3. Gonorrhea in Men: Further Observations in the Use of Acriflavine.—Gray Philips states that in a former communication he recommended normal salt solution with the dye, 1:4000 being used for irrigation and 1:1000 for injections. It has since been shown that solutions made of distilled water are equally efficacious and that for injections a strength greater than 1:4000 is not necessary. Men with a free discharge, whose first and second urines are clouded, are irrigated once daily, are instructed to use injections twice daily, are given bicarbonate of sodium, and in addition are given 1 c.c. of stock vaccines. Sitz baths at four hour intervals are ideal, but are not usually practicable more than twice daily. Progress in these cases is eminently satisfactory, especially when there is a strong local reaction at the site of the vaccination. When frequency, deep urethral pain, and nocturia indicate the presence of deep involvement of the urethra the irrigations are not used but the injections are continued. Observations on such patients show that this in no way interferes with resolution of the deeper structures, and men so treated recover more quickly than others treated expectantly. In patients seen early in the course of their disease when it is limited to the anterior urethra a cure may be brought about in six weeks. Acriflavine is more efficacious than the proteid silver compounds. It has, however, special indications and definite limitations. When brought *into contact* with gonococci its germicidal effect is absolute. It is manifestly no aid in epididymitis. Except that massage may be instituted earlier when the bladder is filled with the dye, it has no direct effect on prostato-vesiculitis.

Hydrocele Renis.—Krogius under this name reports a case of pararenal cyst in a woman of 67. The tumor of the right side was found on operation to be a hydronephrosis in association with a cystic formation, the wall of which was formed by the renal capsule. There was a large quantity of clear, brownish fluid in this cyst which contained albumin but only traces of urea. The kidney projected into the cyst exactly like a testicle into the sac of a hydrocele—hence the name given by the author. The kidney was the seat of a disseminated interstitial nephritis and the urine contained traces of albumin and was slightly turbid from blood cells and cocci. The hydronephrosis was due to pressure on the lower part of the ureter by a carcinoma. The renal lesion had been six months in growing. Nephrectomy cured the patient, nothing being said of the uterine cancer. A similar case was treated by Runeberg in a man of 55. In this, as in the above, a growth the size of a man's fist was present at the time of consultation. The cyst had formed beneath the capsule of the kidney and the latter projected into the cyst cavity. The contents of the cyst were clear and yellow. The kidney was extirpated. The urine was of the same type as in the first case. Other cases are in literature, reported by Malherbe, Minkowski, Kirmisson, Albarran, and others. Some authors might prefer the name perinephritis serosa.

Book Reviews.

SELF DEVELOPMENT. By A. ADDINGTON BRUCE. Author of "The Riddle of Personality," "Nerve Control and How to Gain It," etc. Price $1.50. New York and London: Funk & Wagnalls Company, 1921.

WRITING in his characteristic conversational style, the author develops his theory that all men of normal psychic constitution contain within themselves success-winning powers, utilized by the majority to nothing like their maximum possibilities. His endeavor is to show how to draw upon these powers and at the same time how to direct them to ends compatible with a wholesome philosophy of life. He aims to assist his readers not only to gain prosperity in a material sense, but also to gain the high prosperity which too many people today are taking into too little account. Titles of some of the chapters are: "Organize Your Life," "Making Oneself Interested," "Aids to Real Thinking," "To Develop Will-Power," "The Art of Forgetting," "Defense Reactions," "Moods and Their Control," "Face the Unpleasant," "Hints of Self-Study," etc. While there is nothing strikingly new in the book the advice proffered is of the kind that bears frequent repetition. Individuals who need "rebuilding" or at least refurbishing and mental readjustment may find in this book just the incentive and inspiration they need in order to gain a new and sane outlook on life.

THE EVOLUTION OF DISEASE with a Discussion of the Immune Reactions Occurring in Infectious and Non-Infectious Diseases. A Theory of Immunity, of Anaphylaxis and of Antianaphylaxis. By Prof. J. DANYSZ, Chef de Service, Institut Pasteur, Paris. Translated by FRANCIS M. RACKEMANN, M.D., Assistant in Medicine in the Harvard Medical School and in the Massachusetts General Hospital, Boston, Mass. Price $2.50. Philadelphia and New York: Lea & Febiger, 1921.

DR. RACKEMANN has given us an excellent and sympathetic translation of Danysz' interesting work. And the work is interesting even though it is difficult to accept many of the authors statements. At the outset he says that all antigens are colloids and then goes on to the statement that a number of synthetic colloids also may act as antigens. Among these colloids he mentions the substances of the arsenobenzene series. That arsphenamine may cause unfavorable symptoms is known but the present tendency is to ascribe these to hypersensitiveness rather than to anaphylaxis. These two types of reaction have been shown to be quite different in nature. His explanation of the progress of certain infectious diseases is that during the stage of incubation the body is developing immune substances to the infecting agent and that with the onset of the disease proper the body cells have been surcharged with specific antibodies. The symptoms of the disease then become merely an expression of an anaphylactic reaction. There are many good arguments that may be advanced against such an assumption. In order to produce anaphylaxis in animals it is necessary that the antigen be injected at rather long intervals while in disease in man we must assume that the antigen reaches the circulation practically continuously. We feel that his theory cannot find acceptance until he brings forward much more and better evidence than is presented in this book. The author states that an antigen will produce disease only when its reaction with its antibody results in an insoluble product (except in the purely toxic forms of disease as for example in diphtheria). In the later portion of the book he gives a number of case reports showing instances in which skin lesions, asthma, etc., have been cured by the administration of preparations of intestinal bacteria. But he admits that the action is not specific and one suspects that these are merely instances of the non-specific action of foreign proteins. As a whole the book makes interesting reading and will probably bring to the readers mind many arguments which tend to contradict the author's theories. It is therefore stimulating. But we feel that it will hardly furnish help to the average practitioner in the understanding of the nature of the infectious diseases unless he has been well trained in the literature and practice of immunology. A curious error is found on page 26 where ricin is derived from rice instead of from the castor oil bean.

LEHRBUCH DER SPEZIELLEN PATHOLOGIE UND THERAPIE DER INNEREN KRANKHEITEN. Für Studierende und Ärzte. Von Dr. ADOLF STRÜMPELL, o.ö. Professor und Direktor der Medizinischen Klinik a. d. Universität Leipzig. Zweiundzanzigste vollständig neu bearbeitete Auflage unter Mitwirkung von Dr. Med. et Phil. CARLY SEYFARTH, Privatdozent und erster Anat. Assistent am Pathologischen Institut d. Universität Leipzig. Zwei Bände. Price 125 marks. Leipzig: F. C. W. Vogel, 1920.

THIS work has been a standard of excellence ever since its first appearance thirty-eight years ago. During that time it has grown enormously in size and service to the profession and this, its latest edition, will be welcomed as furnishing a means whereby the younger members of the profession may become familiar with the book. Each volume contains well over eight hundred pages so that it is impossible to review it in detail. It should be sufficient to say that the original plan of the author has remained unchanged and in this edition he has added much that is new and has revised much of the former text in order to bring it into line with our present information. The work has grown so large that it has been necessary for him to procure as assistant for this edition. The work can be recommended without reserve.

LES NOUVELLES MÉTHODES D'EXAMEN DU CŒUR EN CLINIQUE. PAR R. LUTEMBACHER 136 Pages with 138 Original Illustrations. Price 20 francs. Paris: Masson et Cie., 1921.

THE modern graphic methods, together with radioscopy, have become an indispensable complement to the clinical examination in the study of diseases of the heart. The first part of the book contains a large number of graphic tracings showing every type of cardiac arrhythmia which the author carefully deciphers and explains. The second part is devoted to the radioscopy of the heart and to the interpretation of the fluoroscopic picture. Of the latter 24 are given in schematic outline, and facing each one is a photograph of the corresponding post-mortem specimen. This is a capital way of teaching one to visualize the actual condition indicated by the radioscopic outline. The pictures in the book are unusually good and illustrate all the principal cardiac lesions as expressed radioscopically and in graphic tracings.

THE HEART. Old and New Views. By H. L. FLINT, M.D., Late Captain R.A.M.C., Cardiological Center for the Northern Command; Physician to the Mansfield Hospital. 177 Pages, with Illustrations. Price $4. New York: Paul B. Hoeber, 1921.

THIS is really a history of medicine in relation to the heart, and a very interesting history it is and a very instructive one. The author begins with the earliest period of which we have any records, namely the early Sumerian, noting what references there are in the literature to the heart from those times down through the Indian, Egyptian, and Greek eras. The earliest notes were religious in character, the heart being referred to as the seat of the soul, the first medical reference being in the Ebers papyrus, about 1550 B.C. The real beginnings of cardiology as of all other branches of medicine are found in the teachings of Hippocrates. Then we come down through the Galenical period to the middle ages and to the latter half of the nineteenth century to the invention of modern instruments of precision which have made possible a scientific study of the venous and arterial pulses, blood pressure, and the mechanism of the cardiac rhythm in health and disease. By far the greater part of the book is concerned with the later instrumental period, for it is only in this period that our knowledge of the heart and its action has reached a utilizable stage where it can be applied practically to the recognition, prevention, and treatment of functional and organic disease. This is a capital little book and it is a pity that it was found necessary to list it at so high a price for this will keep it out of the hands of many who would profit by its contents.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 1, 1921.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

As this meeting was held under the auspices of the Public Health Committee of the New York Academy of Medicine, Dr. Stewart asked Dr. Charles L. Dana, chairman of that committee, to take the chair during the scientific session.

Dr. DANA stated that the survey of the hospital situation and problems in this city to be reported on this evening had been made possible by a grant of $25,000 from the commonwealth fund to the Public Health Committee of the Academy. This money was used in making a survey of the hospitals of the greater city. Their executive secretary, Dr. E. H. Lewinski-Corwin, had organized the staff, which was composed of four physicians, five or six nurses, one or two statisticians and social workers, and a hospital superintendent. This staff had accumulated information with reference to 180 hospitals. They had succeeded in assembling an immense amount of material which would be of interest to those concerned with hospital construction, to physicians and to the nursing sorority. In order to avoid the tediousness of statistics much of the data would be presented on charts. There had never been any investigation of hospital conditions, at least in this country, conducted as carefully and thoroughly as this one, only a part of which could be presented in the time allowed for the meeting. It was hoped that as a result of this work a permanent organization would be established to carry out the purposes and ideals which had been reached in the course of this study.

A Summary of the Findings of the Hospital Study of the Public Health Committee of the New York Academy of Medicine.—Dr. E. H. LEWINSKI-CORWIN made this sentation, which was illustrated by lantern slides. He stated that the study of the hospitals of this city was made possible by a grant from the Commonwealth Fund; the study covered a period of almost a year. The survey was both extensive and intensive. Some of the important facts brought out in the preliminary report were: (1) That 32,000 hospital beds in this city were sufficient to meet the present demands of the community because one hospital bed was available for every 200 of the population, and on the basis of the approximate number of sick one bed was available for every fourth sick person. The average utilization of available bed capacity did not exceed 70 per cent. There was a need to create a central hospital bureau through which the utilization of the beds in many hospitals could be increased. The study showed that in the general hospitals 8 per cent. of the cases were private patients and 9 per cent. semi-private, and this was for all the hospitals, including the municipal hospitals. He thought the private pavilion should not be looked upon as a milch cow to sustain the wards. The present need seemed to be for more of the inexpensive private and semi-private beds for the people of moderate means. The private pavilion of the hospital should, however, not be expected to earn money for the hospital beyond the cost of maintenance. (2) There was a distinct need for the expansion of facilities for the care of convalescent and chronic disease cases. (3) The immediate needs of the hospitals were ampler funds for maintenance purposes and for the employment of larger nursing and other professional staffs; also for the extension of laboratory and *x*-ray facilities. In most of the hospitals the provision for nursing care was utterly inadequate, and particularly so in the municipal hospitals. There was need of reorganization of the training schools to attract a larger number of pupils. At the present time only 57 per cent. of our nursing done in hospitals with training schools was done by pupil nurses. The need of the extension of the training of nurse attendants was likewise very great. In some of the hospitals, however, the percentage ran above 80 per cent. (4) Hospitals should be utilized to a greater extent for medical research and teaching than was being done at the present time. The scientific work of hospitals was hampered by the hostile attitude of the public toward post-mortem examinations. In the Kings County Hospital autopsy was performed in only one-half of 1 per cent. of deaths; in Bellevue in 15 per cent. Hospitals in which autopsy was done in 25 per cent. or more of deaths were the New York, St. Luke's, Greenpoint, and Beth Israel. At the Peter Bent Brigham Hospital post mortem examinations were made in 65 per cent. of deaths. (5) A change in policy was indicated which would admit larger numbers of physicians to the opportunities of hospital practice. At present only a little over 40 per cent. of the physicians in this city were associated with hospitals. (6) There was a distinct need for a more uniform method of statistical and financial accounting in hospitals. Likewise for more cooperative business arrangements on the part of hospitals to ensure greater savings in buying. The hospitals in this city expended annually for maintenance $35,000,000. Sixty-eight per cent. of the cost of maintenance came from pay patients and 19 per cent. from endowments. There was $78,000,000 invested in hospitals. Of this amount approximately 43 per cent. was invested in private hospitals, 33 in city hospitals, and 25 per cent. in private special hospitals. In 37 per cent. of the hospitals the land value was considerably in excess of the value of the buildings. In order that the manifold problems of the hospital should be kept continuously before the public, a Central Hospital Bureau should be established, which would act as an exchange of experience and a storehouse of information. Among the various ways in which such a bureau would be valuable were the following: It would contribute toward a better distribution of the patients among the hospitals; it would bring about the unification of hospital reporting; it would be a repository for information on morbidity; it would be an aid to the public in forming an opinion as to the needs of the institutions; it would supply information to benefactors, trustees, and architects, and it would stimulate efficiency of hospital work and organization.

Dr. GEORGE B. WALLACE said that in this extensive study of the New York hospitals, made by Dr. Corwin and his associates, one of the features looked into was the data concerning the immediate care of the individual patient. Inquiry was directed to the recorded facts brought out in establishing the diagnosis—that was, the history and the physical and laboratory examinations, the course of the disease or injury, the treatment, and the condition of the patient at the time of discharge from the hospital. It was assumed that such an inquiry would not give an absolute but still a fairly definite idea of the character of the medical work done in the hospital. Indeed, with those making the study personally acquainted with a very small percentage of hospital physicians, the patient's record was practically the only definite criterion of the medical work done in any particular instance. As might be expected, the inquiry showed the most marked variation in the matter of patients' records. At the one extreme the record consisted of a filling out of the printed headings on the record sheet and practically nothing else but the nurse's notes. At the other extreme, where certain types of cases were being intensively studied, the records contained the minute and detailed data that one associated with the accurate recording of facts in experimental research. The conclusion was properly drawn, Dr. Wallace thought, that the records of the first type were almost useless except for the purpose of compiling the annual hospital reports, and that those of the second type, admirable as they were, represented an amount of work not practical in the ordinary hospital with its limited staff. Obviously some mean between these two extremes should be selected as a working basis. In considering what was the general purpose in keeping an individual record, and what might be the value of such a record, two points especially presented themselves. The first had to do with the immediate welfare of the patient. Certain procedures, such as the obtaining of a proper history, a thorough physical examination, certain laboratory examinations were necessary for a diagnosis, using this term in the broadest sense. Subsequent examinations were equally necessary for a knowledge of the course of the disease. Yet in some hospitals such facts as were necessary for

an understanding of the case either were not recorded or were recorded only in part. For example, one record gave the diagnosis "typhoid fever," with no statement of the presence or absence of an enlarged spleen, or rose spots, no mention of a Widal test or of a blood or other culture. Another containing the diagnosis "chronic nephritis" had no urinary examination recorded. These omissions did not necessarily prove that the necessary examinations had not been made, but it was manifestly impossible for any one to carry accurately in his memory the history and the findings in each patient in a ward. Again, without a record, the following of the course of the disease and the recognition of complications became more difficult. Further, in many hospitals there were sudden shifts in the staffs, and the newcomers, with inadequate past records to guide them, were often quite at sea regarding any particular case. In order to avoid mistakes, therefore, and to be able quickly to refresh the memory on any question arising, a written record was indispensable. The acceptance of a hospital appointment carried with it the obligation on the part of the physician to do all he could for the welfare of the patients under his charge. Since the keeping of a proper record had a great deal to do with the patient's welfare, it became a duty to see that the proper record was kept. Failure to perform this duty rendered the hospital open to criticism that the medical work was not well done, and since so many hospitals were dependent upon private contributions for their maintenance it might well follow that discriminating donors would hesitate to make contributions to such a hospital. A second point brought out was the educational value of the record. There was no doubt that an accurate recording of clinical facts instilled a spirit of carefulness and thoroughness on the part of the recorder. Such a spirit was of great value in self-education. Another aspect was that the advance of clinical knowledge was not dependent solely on laboratory research work, as some seemed to think. Our knowledge of disease was based largely on the careful observation of patients. It was an obligation of hospitals, with their wealth of clinical material, to add to this knowledge. One way of doing this might be to render the ward more accessible to those who wished to study certain diseases. Certainly one way was to keep case records which were sufficiently comprehensive to have the desired facts clearly set forth. When it was considered to what use records of the large number of patients passing through the average hospital in the course of a year might be put in furthering medical knowledge, the failure to supply these records seemed inexcusable. In considering what constituted a proper record, Dr. Wallace said it was obvious that there could be no standard record for all hospitals and all patients. Generally speaking, there was this minimum requirement. First, every record should contain all the facts necessary for a diagnosis; this included a complete history and physical examination, the latter showing not only what was abnormal but what was normal, together with certain routine laboratory examinations, such as the urine and blood; second, besides notes describing the progress of the case, a full account of any complications or unusual features arising; third, an adequate statement of any therapeutic measures employed; fourth, the nurses' notes on pulse, temperature, etc., and finally, a statement of the patient's condition on discharge, based either on recorded facts or a final general examination. With this minimum established there was no limit to the additions which might be made in cases which were being especially studied. In concluding Dr. Wallace put forth the following suggestion: They frequently met in Bellevue with patients who showed scars of previous operations, who gave histories of definite illnesses or injuries, who told of having blood examinations or injections made. On inquiry they were ignorant of what the operation was for, or what was found, or what the illness was, or what the blood test showed. In a study of dispensaries made some years ago there was shown a small book, slipping easily into the vest pocket, which each patient in one of the dispensaries was given. This little book, which was kept by the patient, contained very brief statements, over a doctor's signature, concerning the complaint from which the patient suffered. It was worth considering whether it would not be advantageous for hospitals to see to it that each patient on discharge had some such similar book containing the proper entries. If this system became general it would result in time in a large number of patients having an accurate record of their past medical history.

Dr. S. S. Goldwater said he would be ungrateful if he did not express his profound appreciation of the splendid report which Dr. Corwin had presented. Before coming to the meeting he had felt that Dr. Corwin was facing an impossible task. Conditions existing in New York hospitals had never before been presented so graphically. He had been asked to say a few words about the private room and the ward; the professional and economic problems involved. One might start by defining what was meant by private room and ward. When one spoke of a ward it might be taken to mean the thing that formerly existed in some hospitals and still existed in some places, a large barrack, sometimes lighted, at others very poorly lighted, sometimes ventilated, sometimes not ventilated, with no facilities for classifying patients and no way of changing the environment of the patient. Sometimes there was no receiving department and an absence of special examining rooms. This was the type of hospital that lacked decency and where all the surroundings were what they should not be. So there were wards and wards. To-day one found, even in the municipal hospitals, 20, 30, 40, and even 50 per cent. of the ward capacity in the form of one, two or three room ward units and every facility for separating patients. Usually there was in addition a veranda which provided for outdoor treatment. The condemnation of the large ward had now led to the other extreme with a tendency to have many single rooms which meant a great increase in the cost of construction and maintenance. In this connection the experience of the Boston City Hospital was of interest. There was a great outcry against the absurdity of putting a pneumonia patient and a nephritis patient in the same ward under the same conditions. So a small hospital of 80 beds, each having a separate room, was built. A nurse, when asked how she liked the new arrangement, answered that it would be all right if she had some means of seeing what was happening to the patients. The same nursing force that could care for 40 patients in a ward could not take care of those same patients in separate rooms. The result of this experiment was disastrous. Then Boston City Hospital swung back when another addition was built, and there was not a single quiet room and even the service room was separated from the ward by a glass partition. Both of these extremes were wrong. Private rooms should be provided for ward patients only where it was an advantage to the patient to have a separate room outside the ward. The private room of course had the advantage of preventing contagion provided other measures directed to that end were also employed. However, if the doctor and nurse put on a gown and gloves and then passed from one room to another without changing or sterilizing them, as he had seen done on one occasion, this advantage was nullified. Other advantages of the single room were that the light could be adjusted, there was more quiet, and one could show more attention to the individual patient in the matter of contact with his family. Dr. Goldwater said one was shocked in Japan when he found males and females being treated in the same ward, but one had to consider their temperament and manner of living. When one found the female friends of the male patient spending a great deal of time in the ward one came to realize that classification into male and female did not mean anything anyway. In Pekin the average Chinaman wanted at least four or five of his family with him day and night. In Hong Kong the hospital was constructed with anterooms for the patients' servants. Coming to a consideration of the economic side of the question of private rooms and wards, the difference in the cost of construction of a good type of private room and good accommodations for a patient in a ward was about 100 per cent. The difference in the cost of maintenance was also very great; for instance, the cost of cleaning the same space was double in a private room what it would be in a ward, for there was not only the ceiling and floor but four walls and many more corners. When it came to

the nursing side a greatly increased nursing force was required for private rooms. There was an adequate number of private rooms in the hospitals of this city. If these private rooms were turned over to persons of moderate means for the small price they would be able to pay the hospitals would be unable to carry on unless they were provided with stiff endowments. There was at present a shortage of nurses and if more private rooms were operated this shortage would be still more acute. A larger force of domestics would also be required. All this would mean that the hospital would have to have larger funds. Dr. Corwin had spoken of a hospital having a surplus of $150,000. That was a most exceptional and fortunate hospital. He thought that if they looked into the affairs of that hospital they would find that it employed an overwhelming amount of pupil nursing, and that a large percentage of ward patients were paying their way. One also had to take into account the fact that the proportion of ward patients paying their way was influenced by different conditions as the rise and fall of wages, and changed conditions of living which made people go to a hospital because they did not have room in their homes to care for a sick person. He could not agree with Dr. Corwin that the ward patient should pay no more than merely the cost of his care. One ought to see that the private pavilion earned at least the interest on the capital invested and anything over and above that should be applied to the free wards. The report showed that only 17 per cent. of the total number of patients in the hospitals of the city were private or semi-private full pay patients. It was true that the vast majority of decent working people did not have the sort of incomes which permitted them to pay their way; when sickness came they needed help. The deficiency in the cost of maintaining free wards might be met by charitable gifts and such gifts ought to be far larger than they were. He did not see why givers should make a difference between municipal and private hospitals. The poor person in a municipal hospital was just as much entitled to help as when that same patient was in a private institution. Of course he thought the taxpayers should listen with more open ears to the needs of the city hospitals. He felt that Commissioner Coler had not had a fair deal. A much lower standard was permitted there than in other hospitals. Dr. Goldwater expressed the hope that the central hospital bureau which was proposed would be established.

Dr. W. GILMAN THOMPSON said, in part, that it had long seemed to him important that a city which had 182 hospitals and which was constantly erecting new ones or reconstructing older ones should have a central bureau of information where any and all practical facts concerning existing hospitals might be attainable for guidance, either in organization, construction or management. Had such a bureau existed a generation ago, we might have developed a much less heterogeneous assortment of hospitals than we had with these institutions as they now existed, founded many of them on a basis of religion, language, of sex, age, of some special organ of the body, or even of some one disease, like a recent hospital for cutting out tonsils. All this might be desirable in the individual case, but it had unquestionably led to an overlapping of interests, a poor economic situation, and a general lack of scientific cooperation. Meanwhile the cost of hospital construction and equipment had increased by leaps and bounds. There was a certain economic unit of size for a hospital. Much of the personnel, for instance, required for a hospital of 50 beds could equally well manage a service of 100 or more beds. Much of the equipment now regarded as essential for every well organized hospital for accurate diagnosis, like *x*-ray apparatus, or good clinical laboratories, might serve a hospital of any reasonable size without duplication. With this pioneer work accomplished and a bureau once established, it would be relatively easy to keep the information always timely, through a well organized active bureau. Municipal hospitals were dependent for maintenance upon a budget system which often suffered through reductions made by those in authority who might be poorly informed and quite inexperienced in modern hospital requirements. Comparison between the service rendered and the results obtained in the municipal and privately supported hospitals, respectively, which might readily be procurable from an impartial bureau might be utilized to great advantage in securing adequate appropriation from city funds. Dr. Thompson traced the development of the modern hospital from little more than a boarding house for the sick to the modern institutions like great hotels with elaborate engineering, laundry, kitchen and diet kitchen departments equipped with all modern machinery and economic devices, and with laboratories, physiotherapy facilities and all the elaborate paraphernalia of the operating department, and showed that the modern hospital building must be studied architecturally as a factor in treatment. It was a very serious problem to construct a modern hospital, or even to devise an addition to an existing one. The first thing to do was to collect all the composite information possible from the experience of others. A hospital bureau would be prepared to furnish all this information. It would be prepared to answer questions on a large variety of subjects as, for instance, "Do you pay your internes? Do you continue to pay your nurses when on prolonged sick leave? How much did your complete *x*-ray department cost? Are your visiting staff permitted to retain fees paid by accident insurance companies for operation? Do you have an elevator man at night? What is your per capita meat bill? Have you occupational therapy? Have you a special workshop? What is the salary of your teacher? What is the relation of your social service department to the medical staff?" Scores of questions like these were constantly arising which a central hospital bureau could be prepared to answer. The organization of such a bureau need be neither elaborate nor expensive. The personnel that would be needed would consist in a competent director and possibly an assistant, two investigators to visit hospitals and obtain information, a stenographer and two clerks to file and keep records, compile statistics, tabulate data, and answer correspondence under dictation. In summing up, Dr. Thompson outlined the functions of the proposed Hospital Information Bureau as follows: (1) To collect information of all kinds regarding the details of hospital construction, organization, maintenance, and administration. (2) To tabulate and report this information on request. (3) To publish from time to time information regarding important facts concerning the general hospital situation in the city as, for instance, whether the hospital beds were adequate and properly distributed in reference to the population, etc. (4) To collect architect's plans of existing new hospitals, and also the general literature on the subject. (5) To furnish information especially for those who were contemplating new hospital construction. (6) To aid in equalizing and balancing hospital service in many ways as, for example, in securing uniformity on hospital record forms and preventing overcrowding in some institutions while others were practically empty. In order to illustrate the principles of economy of service which should be an important function of the bureau to bring about, it should preferably be inaugurated under the direction or patronage of some existing organization concerned with general hospital affairs.

Mr. BIRD S. COLER, Commissioner of Public Welfare, spoke briefly for the municipal hospitals. He said they knew the weak points in these institutions. One of these was a shortage of nurses and there were other defects but on the whole they were doing fairly well. It had been said that propaganda stood in the way of progress, and we had had an illustration of this in educational lines. For a time every fad that came along was introduced into the educational system until these fads became such a burden on the budget that when the question of medical education came along, they said "take it off." So the facts in reference to hospitals must be properly presented to the heads of the city government if the hospitals were to receive sufficiently large appropriations. It must be remembered that private hospitals were receiving appropriations from the city to aid them in the care of charity patients. Dr. Thompson, in the course of his address, had spoken of obtaining money from foundations. Mr. Coler expressed the hope that they would not accept money from a foundation because the foundations were going to have full time teachers in the medical schools who would do nothing but teach. The medical schools being

closely related with the hospitals this was a question that would affect the hospitals. He believed that a teacher should be able to *do* the thing he was *teaching*. Again the refinements of standardization might be carried to extremes and sometimes that was worse than having no standardization. They might, for instance, carry the standardization of nurses to the point where only a post-graduate collegian could qualify for a nurses' training school. Commissioner Coler strongly emphasized that the city was working intensively in cooperation with the Academy of Medicine and the Public Health Committee and was interested in this study of hospitals. The place to have this proposed bureau was here in the Academy of Medicine. Those interested in the medical school work in public hospitals knew what tremendous advances could be made where there was a proper cooperation between these institutions. If they could have this cooperation between great public hospitals, the Academy of Medicine, the private institutions, and the medical schools, it would be possible to develop a post-graduate medical work which would make New York City the great medical center in this country, but foundations must be kept away so that they would not standardize things—so that they would be ineffective before they were fairly under way. He assured the Public Health Committee that in establishing a Hospital Information Bureau they would have the cooperation of the city hospitals.

SECTION ON SURGERY.

Stated Meeting, Held October 7, 1921.

DR SEWARD ERDMAN IN THE CHAIR.

Recurrent Carcinoma of the Tongue, Treated by Radium and Roentgen Therapy.—Dr. M. J. SITTENFIELD presented this patient, a man 54 year sof age, referred to him by Dr. Lewisohn, in December, 1920, for recurrent carcinoma of the tongue. Two months previously excision had been performed and the growth found to be a squamous cell sarcoma. Rather than submit the patient to the very radical surgical procedure that would have been necessary, Dr. Lewisohn suggested a trial of intensive radiation. At the time the patient came under observation there was an ulcer extending along the right lateral border of the posterior part of the tongue about ¾ of an inch in width, and ¼ of an inch in depth, necrotic looking with indurated borders, causing him great pain. Aside from this the patient was suffering excruciating pain from the side of the face upward along the temporal region, necessitating the constant us of narcotics. Having just returned from abroad where he had observed the more gratifying results in radiotherapy through the use of the newer technique and modern apparatus, Dr. Sittenfield said he decided to institute intensive radiation. The man received five hours of deep roentgen radiation, one hour on each of five consecutive days, over both submaxillary and cervical glands. The local lesion on the tongue was treated by small repeated doses of radium element, 100 to 150 milligram hours, applied directly over the ulcer. Within sixteen days after the beginning of treatment, the ulcer began to heal, pain was diminished, and the patient reported that his tongue felt lumpy. After five weeks his pain had almost entirely disappeared, so that he left off all narcotics, and was able to pursue his usual activities. Since February 8, 1921, two months after beginning treatment, he has been entirely free from clinical manifestations of the disease. Since the advent of the newer intensive radiation technique, the speaker had treated two other cases, but not sufficient time had elapsed to report a clinical arrest.

Dr. RICHARD LEWISOHN, after congratulating Dr. Sittenfield on his brilliant result in this case, stated that the primary operation had been performed in October last year, and consisted in cleaning out the sub-maxillary glands, ligating the lingual artery, and local excision of the tumor. The pathologist's report stated that the growth was carcinoma. They had been very much chagrined to see the man come back with a large recurrence which was causing terrific headaches and difficulty in swallowing. They thought at first of doing a resection of the jaw and removing the greater part of the tongue. This would have been a very formidable operation, so he thought it would be best to give the man a chance to be treated with radiation, as it was doubtful whether he would survive the extensive operation that would be necessary. No specimen of the secondary growth was excised, but clinically it was a very extensive and rapidly recurrent carcinoma. The result, as shown by Dr. Sittenfield, was certainly excellent.

Dr. E. G. RAMSDELL said it might be of some interest in connection with this case to report some observations made at Sir Berkeley Moynihan's Clinic this summer. Sir Berkeley Moynihan said he had given up the use of radium and that he was using fulguration and diathermy in superficial carcinomatus. He had treated tumors of the bladder in this way and with that type of treatment had had very good results. He stated that he hoped he would never do another excision of the tongue, that he cleaned out the submaxillary glands and treated the local lesion with fulguration and diathermy. These cases had been followed for a two-year period and remained free from recurrence. With radium one could not control the reaction and some patients had a great deal of pain, swelling and trouble, whereas with this treatment the reaction was very much less severe and the results very good.

Dr. BURTON JAMES LEE said Dr. Sittenfeld should be congratulated on his immediate results. Every case of this sort he thought should be reported by saying that one had suggestive results to date. Too often the radiologist had been unduly enthusiastic and later had seen untoward results. He thought the primary lesion could properly be treated by radioactive means. It was fairly well proven that the disease was embolic in its metastasis into the nodes of the neck. He had seen the neck nodes successfully treated by dissection and insertion of radium, at the point of severance of lymphatics. In these cases one should say the result was a very suggestive one, to date. The case further demonstrated the usefulness of *x*-ray therapy in such a condition.

Dr. SEWARD ERDMAN said that Dr. Sittenfield had certainly obtained a very satisfactory result for this period. He could not help feeling that since surgery for cancer of the tongue had been so disappointing in results and so mutilating to the patient that *x*-ray and radium should be given a trial if they were going to help even in a palliative way and did not give a final cure. If they helped to heal the local ulceration that would be welcome, for all surgeons were familiar with the excruciating suffering caused by carcinoma of the tongue and the distressing foulness of the mouth. Last year he had referred a case of ulcerating carcinoma of the tongue for radium treatment. The patient had a very foul ulcer, which healed and cicatrized. The man went on and died with metastases in the neck, but at least he had been saved a great deal of suffering and discomfort by the healing of the horrible ulceration.

Dr. SITTENFIELD, in reply to a question as to the length of the spark gap, the number of milliampères he had used, and the thickness of the filter used with the *x*-ray, stated that he had used a 15-inch spark gap, 2 milliampères, and a zinc filter 0.5 mm. in thickness. The radiation was administered at a focal distance of 50 cm. A dose under these conditions required about 2½ hours in order to get an erythema dose. With the new technique and a more accurate dosage it would be possible to accomplish much more than heretofore. They were now beginning to see a little more daylight, and an effort was being made to arrive at a correct and proper dosage for these conditions. Dr. Sittenfield said he quite agreed with Dr. Lee that they ought not to be too enthusiastic about the ultimate outcome, he was presenting this case as one in which the disease had been clinically arrested for one year. He had two other cases treated by this method with apparent success, but he did not feel that enough time had elapsed to report them. If they remained clinically arrested for a year he would be very glad to present them before the society.

Bilateral Congenital Dislocation of the Hip: Result of Treatment.—Dr. WALTER M. BRICKNER said he presented this case, not because the cure of congenital dislocation of the hip was remarkable, but because such a case was usually presented before orthopedic surgeons, and also because it illustrated what might be

accomplished under favorable conditions without open operation and without Lorenz muscle rupturing procedure. The child was now between four and five years of age. When she first came under observatiin, in June, 1919, she was two years 8 months old. At that time she walked with the waddle typical of dislocation of the hip, and had an extreme lordosis and characteristic elevation of the trochanters. She suffered pain and stumbled a great deal in walking. She had been treated by an orthopedist by a brace on the knees without recognition of the hip dislocations. The *x*-ray plates showed this characteristic upward dislocation. At the Park Hospital both hips were reduced by manipulation under ether without any particular difficulty. A plaster cast was applied extending to the knees, with the hips abducted to a right angle and rotated in. An *x*-ray picture the next day showed that one of the hips had again become dislocated during the fixation in plaster. The cast was removed and the hips replaced; this time the thighs were rotated out instead of in, and this time they remained in place. On September 9, a little over two months after the reduction, the child was admitted to Mt. Sinai Hospital. The cast was removed and a second cast was applied with the hips flexed to less than a right angle. A month later this cast was removed and the hips found in place without any tendency to luxate. A few days later, however, it was found that both joints were again luxated. They were again reduced with both thighs at full right angles but the knees free. On November 2 the child was sent home, but the cast was not removed until nearly four months later, March, 1920. At this time the hips were in place and remained so. Daily massage was instituted to overcome the shortened flexors, especially of the sartorius, and by May the lordosis had disappeared. On May 25 the child walked freely, though there was still a tendency to waddle. At the present time, over two years later, the child walked and ran normally without any waddle or lordosis or pain. *X*-ray pictures showed the heads of the femora in the acetabula and the bones enlarging at the normal rate of growth.

Dr. REGINALD H. SAYRE said that Dr. Brickner had obtained a beautiful result. The first picture showed a great deal of twist in the neck of the femur. In these cases it was not always necessary to do an osteotomy to correct the twist so as to get the toe joints to the front when the femoral head was in place. There was not much overhang to the upper edge of the acetabula, so it was not a very favorable case, and one would not have expected it to do so well.

Dr. ERDMAN asked what length of time the orthopedists usually kept the leg in complete abduction and flexion in order to prevent recurrence of the dislocation.

Dr. SAYRE, replying to Dr. Erdman's question, said they generally left the first cast on for three months, and then tried to bring the legs down toward a normal position, pulling them down as far as they could and at the same time leaving them solid. Dr. Lovett had told him that he sometimes left the first cast on for nine months. Dr. Sayre said that if he got one of these cases that was well in the course of a year's time that was about as fast as he expected to correct the deformity, though occasionally he had seen dislocations in very young children corrected in a shorter time. In a few cases he had been much surprised to see how much more promptly he could remove all supports in young children and have them well in eight or nine months, but generally one could count on eighteen months' treatment.

Dr. Brickner, in closing the discussion, said the child was 2 years 8 months old when the first cast was applied. The whole period of treatment was about 11 months. The child walked unaided during the eleventh month. The first cast was left on a little less than three months, the second cast about a month more. After its removal the dislocations recurred. He would not again remove the casts so early; he felt that it was wiser to continue the fixation for a longer period.

Fracture of the Second Cervical Vertebra with Anterior Dislocation.—Dr. WALTER M. BRICKNER presented this patient. He said that from the therapeutic standpoint those familiar with the active traumatic hospital services would agree that in such a service the serious injuries fell into three classes. The first class included those who died promptly either while being carried to the hospital or within a few hours. In the second class were included compound fractures of the skull and certain abdominal injuries in which prompt operation might save life. The third group comprised injuries which, while extremely serious, did best by being left alone. He had treated cases of crushing fractures of the pelvis which made perfect recoveries by being left alone.

The case presented was that of a man 32 years of age, junior ship engineer, admitted to the speaker's service at the Broad Street Hospital on March 25, 1921, after having been caught in a dynamo and sustaining a fracture of the body of the second cervical vertebra with great forward dislocation. He had also sustained a compound fracture of the left tibia and fibula just above the ankle, and a superficial laceration of the scalp. The neck was held rigidly in position and the man complained of exquisite pain on motion. He had the following signs and symptoms of spinal cord disturbance: There was a burning sensation in the back and sides of the neck, extending downward onto the shoulders; marked hyperesthesia of both anterior triangles of the neck, lateral to the thyroid cartilages, in the general area supplied by the third cervical nerve. Subjectively also, he complained of numbness of the tip of the right thumb, on the chest there was slight hyperesthesia and diminished temperature sensibility from the third to the eighth ribs on the left side, and in the areas supplied by the nerves from these segments. There was also some hyperesthesia and diminution of the thermal sense of the left upper and lower extremities. The dislocated axis could be felt prominently in the pharynx and there was a corresponding depression in the back of the neck. There was no dysphagia. There was no disturbed motility. The upper and lower left abdominal reflexes were absent; others were normal. The roentgenogram showed fracture of the second cervical vertebra and forward dislocation of the axis (and with it of the atlas and cranium). In view of the mildness of the cord symptoms it was felt that reduction by operation was not indicated. In a case of this kind one might feel tempted to make an effort at reduction of the dislocation to bring the head and first two cervical vertebræ in line with the rest of the spinal column where they belonged. Such an attempt might easily have produced hemorrhage in or on the cord and might even have been fatal immediately, so the patient was merely kept quiet in bed. Examination on May 5 showed that the neck was not held as rigidly as before, rotation was possible within an arc of 15 degrees on either side; flexion and extension were also limited, and there was some hyperesthesia of the areas supplied by the second and third cervical nerves. The cord symptoms were diminished and some had disappeared. On May 10 the man walked without support, and on the following day was discharged from the hospital at his own request. On July 6 the man's status was as follows: Rotation was possible within a radius of between 30 and 35 degrees to either side. About 20 degrees of both flexion and extension were also possible. The depression at the site of the injury was still palpable; also the projection in the pharynx. The cord symptoms had practically disappeared, except that paresthesia of the right thumb still remained. It involved, also, the terminal phalanges of the right hand and occasionally the tip of the right shoulder. The abdominal reflexes were as before. There was hyperalgesia of the skin of the middle of the left thigh, with occasional paresthesia here. The man was examined again a month later, when rotation of the neck was possible to 40° on either side. Wide flexion and extension were possible, but flexion of more than 20° caused tingling of the finger tips and arms. The deep muscle reflexes were livelier on the right side than on the left side. The paresthesia was still present in the left thigh. The patient's gait was improved, and he had gained five pounds in the month. Examination on September 5 showed the man to be normal with the exception of a slight limitation of rotation of and lateral flexion of the neck. The depression at the back was still palpable, as was the projection of the body of the vertebra in the pharynx. He was now free of the paresthesia and numbness once noted in the

right hand, shoulder and left thigh, had no pains and was, in the speaker's opinion, in very good health.

Dr. REGINALD H. SAYRE mentioned that it was his experience that fractures in the spine were very much slower to heal than in other parts of the body. He had had a number of cases of fracture of the neck in which the patients were allowed up and about after the subsidence of the early symptoms and the symptoms had returned, and it was necessary to protect the neck later. He had had two cases of dislocation of the neck sent him by colleagues. One had fallen doubling his head under his body and his arms were paralyzed. On stretching the neck the arms lost their paralysis. He kept this patient protected for about six months, and recovery resulted. The other patient had fallen from a tree and had broken his neck. He lost the power of his bladder. He got over the paralysis and after six weeks went about his business. Two weeks later he had to go back to bed in the hospital. He then came on from Atlanta and was referred by Dr. Fisher. After protecting the neck for eight or nine months he recovered. He had seen several cases that made him feel that injuries of the spine had to be protected longer than other parts of the body.

Traumatic Fat Necrosis of the Female Breast.—Dr. FRANK E. ADAIR presented these patients in connection with the paper of the evening. The first patient was a woman who had been struck on the breast by another woman carrying a baby. A tumor developed just where the blow was struck. In this case the muscles had been dissected off and the axilla cleaned out. The second patient had had an operation for an ectopic pregnancy and was given a hypodermoclysis under the breast? The tumor was diagnosed as carcinoma, and due to a difference of opinion as to the diagnosis, it was finally decided to do a simple mastectomy, leaving the muscles. The third patient had fallen down thirteen steps, striking the right breast on a sharp-cornered post. In this case the diagnosis was benign tumor. These cases illustrated the different types of trauma that might cause fat necrosis and the various types of operation that were performed.

A Further Report upon Traumatic Fat Necrosis of the Female Breast (with lantern slides and presentation of post-operative cases.)—Drs. BURTON J. LEE and FRANK E. ADAIR made this presentation, in which they recalled that they had reported two cases of traumatic fat necrosis encountered at the Memorial Hospital before the American Surgical Association in 1920, which were published in the *Annals of Surgery*, August, 1920, Vol. 2, page 188. Since making that report they had encountered the three additional cases which Dr. Adair had presented this evening, which afforded additional evidence as to the clinical behavior of this lesion, and pointed to it as a distinct clinical entity. In one of the cases presented the condition was diagnosed as carcinoma of the breast and a radical operation was performed. In the other two cases all the evidence pointed to the condition as being benign and conservative surgical procedures were employed. In their former report they had stated that the greatest emphasis should be placed on this disease because of its resemblance to carcinoma, and the fact that it might be mistaken for carcinoma and a radical operation performed when such a procedure was not necessary. Some of these cases of traumatic fat necrosis presented characteristics quite suggestive of malignancy, while in other instances the evidence was not so marked. They did not hesitate to say that the differential diagnosis between carcinoma and traumatic fat necrosis might be difficult. A history of the appearance of a mammary tumor with no preceding definite trauma would practically eliminate fat necrosis as a possible diagnosis. Traumatic fat necrosis was not accompanied by pain. Deep adhesions and dimpling of the skin were nearly always present in traumatic fat necrosis. Axillary nodes, if present, had not the hard consistency of those associated with carcinoma. In connecting the appearance of the tumor with a history of trauma one should bear in mind the four medicolegal points usually required: 1. The history of trauma must be sufficiently definite and of a severity adequate to produce tissue damage. 2. The site of the trauma and the location of the lesion must be identical. 3. A proper time relationship must exist from the receipt of the trauma to the appearance of the tissue changes. 4. Proof should be at hand that the tissue was normal before the receipt of the trauma. They were indebted to Dr. Ewing for a description of the outline of the gross and microscopical appearance of the disease. This description was published in the *Annals of Surgery* of last year. Grossly the lesions did not present the smooth, opaque texture of carcinoma nor the chalky points or streaks. There was opaque discolored fat tissue well demarcated from the normal fat tissue. Microscopically areas of necrosis in fat tissues were to be seen with new connective tissue cells, growing in and about these areas of necrosis. The growth of new tissue was very abundant. With the giant cells that one saw scattered through the tissue a luetic granuloma might be superficially suggested, but the lesion seemed to have no connection with syphilis. The giant cells were of the so-called foreign body type. Certain portions of the sections showed proliferation of the nuclei of fat cells probably representing certain changes in fat saponification. The blood vessels showed an obliterating endarteritis. The ages of the five patients in this series were 52, 36, 40, 47, and 54, all within the cancer age. All were fat, corpulent women with a large amount of subcutaneous fat. All gave a history of trauma; in three instances hypodermoclysis had been given. Skin fixation was present in all but one of the cases, a feature that would lead one to believe he was dealing with a malignant condition. Two of the cases had shown marked ecchymosis following the injury. The time intervening between the receipt of the injury and the appearance of the tumor varied in these cases from three weeks to ten years. The diagnosis in two cases was carcinoma, in the third benign tumor, in the fourth traumatic fat necrosis, and in the fifth fibroadenoma. The incidence of the lesion varied from 1.8 per cent. of the cases diagnosed as carcinoma to 7 per cent. of those diagnosed as benign tumor. The three points especially to be emphasized were: (1) The present study furnishes important additional evidence that traumatic fat necrosis is a disease not infrequently encountered and one that must be carefully differentiated from carcinoma. (2) They hoped the study would stimulate the pathologist and the surgeon to study the gross and microscopical characteristics of this lesion and believed that such study would reveal many cases of this disease hitherto unrecognized. 3. It is possible that some cases diagnosed as carcinoma by the gross appearance may not have been carcinoma but traumatic fat necrosis.

Dr. EDWARD WALLACE LEE asked Dr. Burton Lee whether he had had the opportunity to observe the termination of the cases that he said he had had under observation, and that were not operated upon. It would be interesting to know what the history of those cases would be.

Dr. SEWARD ERDMAN stated that this was a subject of great interest that Dr. Lee and Dr. Adair had brought to the notice of the profession. He wondered if they had at the present time any possible explanation of the determining etiology. It seemed strange that one never encountered such tumors involving the abdominal wall which was so often adipose and frequently the site of trauma. The question arose as to why the breast should seem to be particularly predisposed to develop this lesion. He suggested the question as to whether lactation might possibly be a factor and asked whether the lesion occurred in the virgin breast as well as in the breast that had lactated.

Dr. CHARLES EVERETT FARR said he had been working on traumatic fat necrosis for 10 years. He had not encountered a case involving the breast, but had some 10 or 12 cases involving other parts of the body. He had one case in a new-born infant. The cases with two exceptions were in males, and one was of 30 years' duration. He thought he could answer Dr. Lee's question as to the end results. It was a calcareous cyst filled with fat and products. There seemed to be no cause but trauma. The disease was common. He had seen a large number of cases of fat necrosis where he was not allowed to investigate. The one of thirty years' duration was on the thigh and was due to a blow. Most of the lesions were on the arm or shoulder, or in the groin.

Dr. BURTON JAMES LEE, in closing the discussion, said he thought Dr. E. W. Lee's question had been answered. The cases referred to as under observation were very recent cases, one having been seen only a few weeks ago and the others a few months ago. They had not been followed long enough to warrant one in drawing any conclusions. As to the reasons for the lesion he did not understand them completely. Following the injury to the fat, a production of new connective tissue appeared, which was probably an effort at protection. Further than that he could not explain the pathology. All the instances he had reported were in breasts which had lactated. He felt that the disease was not bizarre, and the fact that Dr. Bloodgood had seen two cases confirmed that opinion. Many patients were treated for breast tumors by radium and the *x*-ray or had a breast removed and no microscopic diagnosis was rendered, and there was no pathological report. It was quite possible that some of these remarkable cures without microscopical examination might well have been instances of this disease.

Synergistic Analgesia.—Dr. JAMES TALOE GWATHMEY and Dr. J. GREENOUGH. (See MEDICAL RECORD, October 1, 1921, c. 14. p. 583.)

Dr. ALLEN O. WHIPPLE stated that when this method was first introduced, in this series of cases which Dr. Gwathmey had reported, and he first heard of it, he thought it was rather complicated, that it was a gunshot technique compounded of many different agents and he was free to confess that he was prejudiced against it. He did not use it himself for several months, but in watching the results during and after operation he was, rather slowly perhaps, converted to the method, and when he began using it on patients his attitude entirely changed from one of prejudice to one of enthusiasm. Three things had much impressed him. First, the marked difference in the muscle relaxation when patients were having morphine and magnesium sulphate and nitrous oxide oxygen anesthesia. He had been greatly impressed by this fact and all the men using this type of anesthesia said the same thing. Second, there was a markedly lower pulse rate and absence of the usual symptoms of so-called postoperative surgical shock as compared with ordinary ether or nitrous oxide oxygen anesthesia. Third, the comfort of the patient; there was seldom nausea and vomiting, and the patient seldom complained of pain and the next morning did not have the washed-out look of persons who had gone through the experience of ordinary ether anesthesia.

Dr. JOSEPH MANUEL RECTOR of Jersey City said it was a pleasure to add from his clinical experience to Dr. Gwathmey's presentation. He had had the opportunity of being with Dr. Gwathmey, and operation with this method was quite feasible. He was about to report 100 cases in which this method was employed. He began with morphine and magnesium sulphate, and later added chloratone, paraldehyde, cannabis indica, and deodorized tincture of opium. Giving hypodermoclysis, drugs by mouth and by rectum, he found rather complicated, and the nurses and internes found it added considerably to their work where he was operating on ten or twelve cases a day, so finally he evolved a simpler technique. He gave one hypodermic of morphine 2½ hours before operation, and 2 hours before he gave a sigmoid instillation. The patient gradually passed into a condition of sleep. Analgesia began about one hour after the administration of the instillation. The patient first lost sensation in his legs and at the end of about two hours the patient was completely analgesic. The pulse usually dropped after operation from 120 to 80, and respiration from 26 to 24 to normal. The blood pressure usually fell 10 to 20 millimeters of mercury. After operation there was practically no shock. The cases operated on by this method were abdominal, abdomino-pelvic, and vaginal, perineorrhaphies, trachelorrhaphies, etc. In some of these cases he had talked to the patient while operating, and the patient did not know the operation was going on. There was no stage of excitation before or during the operation. Gas pains seldom annoyed the patient. He had been so impressed by the advantages of this method that he had made it a routine procedure with the exception of some cases that did not come in time. Inhalation was used entirely for cutting the skin and abdominal walls, but seldom after opening the peritoneal cavity. He used in some cases a dram of chloroform and 3 ounces of ether. In others he combined ether, chloroform, and ethyl chloride, not exceeding 1 or 1½ ounces of inhalation.

Dr. EDWARD WALLACE LEE recalled the time when Dr. Gwathmey gave an anesthetic in a very simple way and questioned whether the technique of anesthesia was not becoming rather too complicated.

Dr. ARTHUR LEIGHTON SHERMAN said he had a leaning toward this method, the development of which he had watched from a distance. It seemed important to him, however, to ask the question as regards its safety, inasmuch as at any time the hypodermoclysis might become an intravenous injection, and this latter Dr. Meltzer had distinctly warned against as very dangerous to the lower animals. In passing these 2-inch needles under the skin nobody could be sure that he would not puncture and therefore infuse a vein. With this possibility in mind he felt that careful experiment should be carried out, giving intravenous injections of various strength solutions of magnesium sulphate to test its toxicity, when thus given to the lower aminals, and careful deduction formed as to what would be a safe strength to inject into the human, with the thought always in mind that it might, in whole or in part, find its way into the vein.

Dr. GWATHMEY, in reply to Dr. Sherman, said they had begun in the laboratory and had studied the action of magnesium sulphate while they were developing the method. Calcium chloride, 2½ per cent., was in the physiogical antidote to counteract the depression in hypernea of magnesium sulphate; 10 to 15 c.c. injected intravenously (slowly) was the amount used. Out of all this work, contrary to Dr. Lee's idea, they had developed a method that was very simple, three hypodermics and then nitrous oxide-oxygen. It was not at all a complicated arrangement. As Dr. Whipple had said, the comfort of the surgeon and the comfort of the patient fully compensated for the trouble that one took. It was new work and the idea was different from that of the third stage anesthesia we were now using. The condition was one of analgesia plus unconsciousness. The patient did not go into third stage inhalation anesthesia.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

LES NOUVELLES MÉTHODES D'EXAMEN DU CŒUR EN CLINIQUE. By R. LUTEMBACHER. 183 pages with 36 figures. Price, 20 francs. Published by Masson & Cie., Paris.

SURGICAL ANATOMY. By WM. F. CAMPBELL, M.D. 681 pages with 325 original illustrations. Price, $6.00 net. Published by W. B. Saunders Company, Philadelphia.

DIAGNOSTISCHE UND THERAPEUTISCHE IRRTUMER UND DEREN VERHÜTUNG By PROF. DR. J. SCHWALBE. Augenheilkunde 1 Vol., Frauenheilkunde 5 Vols. Published by Georg Thieme, Leipzig.

THE ANATOMY OF THE HUMAN ORBIT. By S. ERNEST WHITNALL. 428 pages with illustrations. Published by Oxford University Press, American Branch, New York.

HEART DISEASE AND PREGNANCY. By SIR JAMES MACKENZIE. 138 pages with diagrams. Published by Oxford University Press, American Branch, New York.

THE EARLY DIAGNOSIS OF THE ACUTE ABDOMEN. By ZACHARY COPE. 223 pages with illustrations. Published by Oxford University Press, American Branch, New York.

THE CARE OF EYE CASES. By ROBERT H. ELLIOT. 172 pages with 135 illustrations. Published by Oxford University Press, American Branch, New York.

THE LIFE OF JACOB HENLE. By VICTOR ROBINSON. 117 pages with illustrations. Price, $3. Published by Medical Life Company, New York.

Medical History.

Cleora Augusta Seaman, One of the Pioneer Women in Medicine.—In connection with a recent article on Dr. Elizabeth Blackwell (MEDICAL RECORD, Nov. 19, 1921, c. 21, p. 922), the history of Cleora Augusta Seaman, written by her daughter, Lucy Seaman Bainbridge, and published in the *Medical Woman's Journal* of March, 1921, is of added interest. She followed, ten years later, the trail blazed by Elizabeth and Emily Blackwell. Her history is particularly striking because of the unusual handicaps and difficulties which she surmounted in order to carry out an irrepressible desire to relieve human suffering. In spite of a frail body, an early marriage, and the care of seven children, Mrs. Seaman found time to study medicine, but it was not until she was well along in life that she received the degree of Doctor of Medicine from the Western Homeopathic Medical College in Cleveland (her home) in 1860. At this time this was the only college in Cleveland that would admit a woman. Being in poor health, Mrs. Seaman each day was driven to the college. In a tiny gallery were placed a comfortable armchair and footstool, with drapery at the sides. The male students would look up and smile and joke about their "guardian angel." However, they were still happier when they were invited to her home to quiz in anatomy or other branches and then stay to one of her bountiful suppers.

Before receiving her degree Dr. Seaman had become much interested in the study of hydrotherapy and medical electricity and had read practically everything written on those subjects at that time. After her graduation she added a wing to her home and installed a bathtub for the use of electricity in water, the first of its kind in the State of Ohio, so far as can be learned. She was most successful in relieving pain and reducing inflammation of swollen joints by this means. Her record for doing good warded off attempts to ridicule this venture. She was always actuated by a deep and lofty altruism, and worked for souls as well as bodies. Her house bore no sign, no card, and there was no advertising, but a host of ailing women, realizing not only her sympathy but her ability, came to her for relief in the troubles peculiar to their sex. At first no charge was made, but later it was deemed wise to have those patients who were able to pay carry with Dr. Seaman the expense of the work for the poor. Dr. Seaman kept in her home one chamber called the "Lord's Room," which was always occupied by a poor student studying for the ministry or someone sick or in sorrow.

In the late '60s women were excluded from the classes of the medical college and, as a result, largely through Dr. Seaman's untiring zeal, a woman's college was organized and chartered in 1868. She was made its first president and professor of theory and practice and delivered lectures on the Therapeutic Uses of Electricity. In connection with the college she was instrumental in establishing the Seaman Free Dispensary, which was largely attended and gave the students ample opportunity for practical study.

Dr. Seaman was born in Middlebury, Vt., in 1814, and died in 1869. The outstanding features in the record of her life are her strong character, her indomitable will, and her instinctive sympathy with human suffering. She exerted a wide influence in her community because of her altruistic work, an influence which spread abroad to ease the path of the long line of medical women that have followed her. From the vantage point of the present, when the World War has demonstrated the ability of women physicians to do constructive work, to surmount difficulties, and to win respect and confidence, when women physicians have done a work in the relief of war-ridden countries that can never be forgotten, it is difficult to realize the attitude of Dr. Seaman's time toward the woman physician, as illustrated by the following experience: In the early spring of 1860 Dr. Seaman visited an Eastern city and called at the home of a clergyman whose home had previously been in her own city and who had left a smaller charge for a large and influential church. She handed the maid a card which read "C. A. Seaman, M.D., 65 Seneca Street, Cleveland." She waited patiently. Forgetting all the hospitality he had received from her, the narrow-visioned reverend gentleman penciled on the back of the card, "I refuse to see any woman who has so unsexed herself as to study medicine." Cleora Augusta Seaman will be long remembered as a woman who studied medicine solely that she might relieve human suffering and who helped make it possible for other women to secure larger opportunities to serve humanity.

The Search for John Hunter's Coffin.—In referring to the celebration of the two hundredth anniversary of the present church edifice of St. Martin-in-the-Fields, a writer in *The Morning Post* of London, of November 5, says that, like many other churches in old London, St. Martin's has suffered most of the misfortunes which come under the head of "vicissitudes," and some of these have affected the worthies committed to its care by confiding relations and friends. The church records refer to the burials of Robert Boyle, Nell Gwyn, and John Hunter, of whom the greatest for our purpose today is the great high priest of Nature, founder of scientific surgery.

When Benjamin Latchford and Charles H. Petter, worthy church wardens of sixty years ago, announced that any person having relatives buried in the vaults of St. Martin's had better remove them quickly, or agree to their being built in forever, it occurred to Frank Buckland to search for the body of the famous surgeon. In the sexton's old register book he found the following entry:

Leister Squar, Oct. 22, 1793.

M. "John Hunter, Esq., ¼ past 4 o'clock. 6l. 10s. 2d. No Candles. N-3-V. Duty 3d.—C. 4 ij. yrs. Aperplexy."

M. meant male; the letters and figure indicated the vault, and C. meant that the "searchers" had given a certificate that Hunter had died from natural causes.

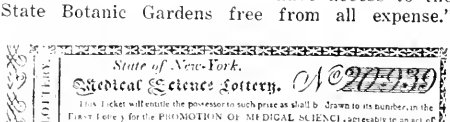
Day after day Frank Buckland rummaged about in the vaults, examining each coffin by the light of a bull's-eye lantern as it was removed. As

the coffins decreased in number he was beset with fears, especially as somebody had whispered that, after all, John Hunter shared with "Old Q" the shelter of St. James's, Piccadilly. He was encouraged to continue by one of the laborers declaring that he had seen the surgeon's coffin in 1832, and he remembered it well, because "John Hunter invented vaccination." In all, 3,258 coffins had been removed; two only remained; they were Buckland's last chance. If either was not that of John Hunter, his labor had been in vain. "As one of them moved slowly off I discerned first the letter J, then the O, and at last the whole word, John. My anxiety was now at its height, and quickly running to one end, Mr. Burstall at the other, we moved the coffin away. At last I got it completely off, and to my intense delight read upon the brass plate the following inscription:

"'JOHN HUNTER.
Esq.,
DIED 16th OCTR.,
1793.
AGED 64 YEARS.'"

Two important events arose from the discovery—the reinterment of John Hunter in Westminster Abbey, and the erection of a marble statue to his memory in the Museum of the Royal College of Surgeons. Buckland's father was Dean of the Abbey at the time, and he used all his influence to insure that the famous surgeon should lie in the great temple of silence and reconciliation. On the north side of the nave you will find him, between Wilkie and Ben Jonson.

A Medical Lottery.—On March 12, 1810, an act was passed by the New York Legislature to establish a lottery to raise money to purchase the Botanic Gardens established by Dr. Hosack at Elgin, three miles outside New York City. The request for this lottery had come from the New York Hospital and the Medical Society of the State of New York. The act suggests that the Botanic Gardens "may become a great public benefit by being able to promote medical science in this State." A committee was formed by the act "to treat with the State and attend Hosack for the purchase," etc.; and a commission was formed who had "the power to raise the consideration money by a lottery." The act also stated that "physicians and students of medicine throughout the State shall at all times have access to the State Botanic Gardens free from all expense."



Five members of the lottery were named. The act was published in the Public Laws of the State of New York, Thirty-third Session of the Legislature, Albany, 1810, Chapter 50, page 17. The lottery ticket reproduced is a photograph of the original ticket in the collection of Mr. Frank L. Reuss of Albany, to whom I am indebted for the loan of this ticket for photographic purposes.—HENRY VIETS, in *The Albany Medical Annals.*

Early History of the Use of Male Fern as a Vermifuge.—In *La Presse Médicale* for July 16, 1921, xxix, 57, Leclerc states that this remedy goes back to Theophrastus, who recommends it for both "broad" and slender worms (the original distinction between tapeworms and round worms). Only two other writers up to the time of the XVIII century are known to have mentioned this drug, which seems to have fallen into obscurity. These are Marco Gatinaria and Simon Paulli. The resurrection of this remedy is due to the charlatanism of the XVIII century. A Swiss surgeon named Nouffer hit upon a novel way to provide for his widow by bequeathing her the secret of a wonderful remedy for tenia. This was marketed under the name of Widow Nouffer's Remedy, this lady becoming, as it were, a prototype of Mrs. Winslow and Lydia Pinkham. It had considerable vogue toward the end of the reign of Louis XV and the widow became well-to-do. In 1773 Louis XVI paid her or her heirs 18,000 livres for the secret and had his minister Turgot proclaim the formula. This consisted of powdered rhizome of filix mas in infusion of lime-tree flowers—about 6 parts to 100. There was a technique in its administration, in which the usual fasting and emptying the bowels was taught. Once no longer a secret, the remedy was quickly forgotten, but a quarter century later male fern was formally introduced into practice by leading therapeutists of the day, including Hufeland. The ethereal extract was not manufactured until long afterward—about 1825.

Death of Schmiedeberg.—The death of this pioneer in scientific therapeutics took place last July. He was born in 1838 and his career corresponds very closely with that of the German dominion of the University of Strasbourg, for he joined that faculty in 1872 and was in control of the chair of experimental pharmacology up to the time of the French occupation in 1918. The chair and laboratory were not established until after Schmiedeberg had been brought on from Dorpat for the purpose. He was born in Courland, and after his graduation from Dorpat he became assistant to Büchlein, who was at the head of the Institute of Experimental Pharmacy of the local medical school. When he moved to Strasbourg he, in association with Klebs and Naunyn, began to publish the *Archiv für experimentelle Pathologie und Pharmakologie*, which has issued over 90 volumes. The number of papers published from the laboratory is 220. Schmiedeberg's "Treatise on Pharmacology" has gone through seven editions. His example led to the establishment of similar chairs in most of the world's universities. While sharply differentiated from other chairs because of its exclusively experimental study of drugs in their action on living beings, experimental pharmacology shades into biochemistry, ordinary pharmacology, physiology, and pathology and serves as a connecting link between other branches, as, for example, between physiology and pathology. It was 38 years ago that the deceased attacked the belief that alcohol stimulates the brain cells. In 1895 he showed that ions have a special pharmacological action.—*La Riforma Medica.*

POLYNEURITIS OF INFECTIOUS ORIGIN.

DISCUSSION OF THE PATHOGENESIS OF NEURITIS DURING INFECTION, WITH SPECIAL REFERENCE TO DISORDER OF HEPATIC FUNCTION; DISTINCTION FROM RADICULITIS; TREATMENT.

BY TOM A. WILLIAMS, M.B., C.M.,

WASHINGTON, D. C.

CORRESPONDING MEMBER OF THE NEUROLOGICAL SOCIETY OF PARIS, OF THE NATIONAL ACADEMY OF MEDICINE OF RIO DE JANEIRO, ETC.

Pathogenic Consideration. That toxin is the most frequent cause of polyneuritis is assumed because of the etiological rôle of such poisons as alcohol and arsenic, and because of the diffusion of the action of these so widely throughout the nervous system. When polyneuritis occurs during infections, it is again assumed that the pathogen is a toxin. However, that toxins so different in their manifestations as those from the microorganisms of diphtheria, scarlatina, typhoid fever, and sepsis should give rise to the same syndrome has not been explained. Further, no explanation is offered of the comparative rarity of polyneuritis in the course of zymotic disease. The polyneuritic syndrome found in diabetics has been given another interpretation, *i.e.*, that of a degenerative process in the spinal cord; while the polyneuritis reported as due to malaria is not necessarily toxic, for capillary emboli by destroyed erythrocytes are capable of explaining its symptomatology.

While alcohol causes polyneuritis only after prolonged ingestion, a very few doses of a mineral poison will produce a long standing multiple neuritis; and an acute infection, especially diphtheria, of apparently only a short duration sometimes leads to a prolonged attack of neuritis more or less multiple. The polyneuritic nerve is in a very different state from that of the nerve infiltrated by a local infection, for in the former exudation of connective tissue elements is absent. All that we find is a hyaline swelling and later disintegration of the myeline sheath, and still later degeneration of the neurofibrils, scarcely then an inflammatory process at all in the full sense. It is not likely that alcohol in itself produces this hydration effect, for it dehydrates colloids. French pathologists have regarded its effect as secondary to its action upon metabolism chiefly incurred by damage to hepatic function. They support this belief by the damaged hepatic function shown morphologically by a cloudy swelling followed by a disintegration of the hepatic cellules which is seen in acute poisoning by heavy metals such as arsenic, and also in the acute yellow atrophy produced by chloroform, and they point to the cloudy swelling of the noble elements of the liver in the course of prolonged or severe infections.

Many clinicians, especially the French, have remarked that polyneuritis is often the product of two or more pathogens, as for example a severe infection in an alcoholic. The explicability of this relatively frequent duplex agency is simple on the assumption that a single pathogen is a common product of each of the two noxæ acting simultaneously.

Pyrexia *per se* can have nothing to do with polyneuritis; for it may be absent after prolonged high fever, and may occur when the fever is of short duration and low degree. The comparative rarity of polyneuritis in fevers is, however, dependent upon multiple factors which we have not yet learned to analyse. It is no more remarkable than the variable incidence of delirium, of herpes, of albuminuria, of cardiac insufficiency, of achylia, of bronchial catarrah, of asthenia, of stomatic discomfort, and of cutaneous eruptions in different patients having acute generalized infections. The polyneuritis, like these, must be a function of the ratio between tissue resistance and pathogenetic potency, modified by wise or unwise interference with the physiology of the patient by himself or by attendants.

When the functions of that great biological filter, the liver, are impaired, the nocuous proteins from the food fail of elaboration into the pabulum required by the tissues; and furthermore are highly detrimental to them. When cloudy swelling of the renal epithelium is only slight, these substances are quickly excreted, but when the kidney is sufficiently impaired, then there is retention of products highly toxic to the tissues. One of these, pyridine, has been shown experimentally to produce a high degree of cloudy swelling. Both protein and nervous tissue in a weak bath of this substance will swell up to more than twice their bulk because of hydration. Now hydration is a function of variation from isotonicity. The acid ions are particularly damaging to the delicate adjustment of tissue interchange regulated by the alkaline plasma of the blood with its exquisitely balanced safety vent in the alveoli of the lung. Whether or not the noxious action of these substances is qualitative, specific, or merely a function of their hydrogen-ion content *qua* acidity is yet to be determined. However, so far it has been assumed that the former is the case because of the minuteness of the dose of such alkaloids as morphine, atropine, etc., which will disturb cellular function even to a lethal degree.

However, smallness of dose is equally true of cyanogen, where the chemical reaction of the tissue is simple, far from specific, quantitative, and is definitively neutralizable in a known chemical way by nitrites, which form an immediate antidote to this poison. The solution of this problem of specificity should not be beyond the ingenuity of biological chemists.

Clinically there are no specific differences in the polyneuritic syndrome induced by the different agencies, the peculiarities described concerning different types not being invariable and in some cases being inexplicable by local action upon the nerves by direct absorption. For instance, diphtheria toxin affects the palate far more frequently than it induces a polyneuritis, which leads one to believe that it is a specific toxin acting upon the nerves by direct absorption.

It is, however, to be considered whether or not the pathogen of multiple neuritis in the course of infections may be the same in them all and not different from that induced by alcohol, and perhaps even in some degrees assimilable to the process induced by the heavy metals themselves.

The lecithin, in which nerve tissue is so rich, contains within itself the seeds of its own disintegration, for from choline, one of its derivatives, with a formula $(CH_3)_3 = \overset{N}{O^1H} - CH_2 - CH_2\,OH$, oxidation quickly produces an isomer of the highly toxic muscarine, or by losing H_2O the still more toxic neurine $(CH_3)_3 = \overset{N}{O^1H} - CH - CH_2$. This substance can be produced in large amounts by feeding eggs or brains to an animal of which the intestine is occluded. It is not difficult to imagine the clinical significance of this fact in patients in whom an infection, such as typhoid, has led to an inertia of the intestine.

On the other hand, indol, another product of intestinal stasis, is shown experimentally to possess an antineuritic property which is equally decided with its derivative alpha-keto-beta-propyl-indol. Also antineuritic is N-meythel-beta-ethyl-indolinon. In spite of this, not all the derivatives of indol are antineuritic N-methyl-beta-ethyl-indolinon is negative, as is also alpha-phenyl-beta-methyl-indol. The antineuritic properties of thyroid secretions are attributed by some to their indol-forming property.

Albuminuria, indicating an attack upon the renal epithelium, is not infrequent in polyneuritis. In addition in the series reported by Klippel[1] there were urobilin, indican, and alteration of the urinary pigments, all indicative of hepatic disturbance. He insisted too upon the significance of tachycardia in these cases, which showed hepatic cirrhosis in the hypertrophic stage. In Gordon's[2] case there was reported a variation of the symptoms corresponding to the amount of urinary sugar.

It is right to say that this interpretation is opposed by such cases as that of Poljakoff and Chroschko, where they incriminate directly the *Bacillus coli* in the bladder, which it had reached from an intestine with thinned walls; but it is significant that a post-mortem examination of the case which confirmed the diagnosis of polyneuritis showed also the changes in the liver described by Claude,[3] consisting of cloudy swilling, etc.

The changes reported in the blood vessels along the nerves by Paulian[4] are to be expected both in toxic and infectious processes and do not help us to a decision regarding a pathogen.

It is doubtful if polyneuritis is ever syphilitic in cause, although, of course, it may occur in syphilitics. Very significant is the case of H. Oppenheim in a syphilitic which was not benefited by specific treatment but soon responded to the usual measures.

In support of the directly infectious nature of polyneuritis are cited a number of cases occurring in trench warfare in which the motor fibers are chiefly affected and in which the cranial nerves and sphinctors also share. These cases are of benign course as a rule; but before adjudication they require consideration from the point of view of toxin of hepatic origin. Others have reported epidemica of polyneuritis and not only in the Orient, which have given rise to the opinion that a specific organism may be in question, but these reports are in need of a critique in that the question of dietetic privation has to be considered, and the clinical diagnosis must be clearly affirmed to the exclusion of the radicular type of encephalitis and of poliomyelitis, while the matter of coincidence has to be considered. For the report of a few cases usually attracts increased attention to a condition which leads to the detection and report of many more, which would otherwise remain unnoticed, or at least unpublished.

That the pathogen affects not only the peripheral nerves but in some cases the central nervous system is indicated by the changes in Korsakoff's syndrome, where there is reported very definite neurolysis of the centrum ovale. It is clinically manifested by the delirium which accompanies the polyneuritis in these patients.

The meninges too show a reaction in some cases of polyneuritis. This consists first of hypertension, later of hyperalbuminosis, and last of all sometimes of a mild lymphocytosis plus a few leucocytes. These signs may last for six weeks after onset and have been reported in cases of infectious polyneuritis.

We are not considering the epidemically occurring "neuronitis" which has been described by recent observers, for this is thought now to be merely a clinical form of a virus resembling that of poliomyelitis, possibly the same as epidemic encephalitis.*

If these conclusions are warranted, it can be assumed that on account of a failure of hepatic function† from other causes, polyneuritis might ensue. This, however, I must leave for future consideration in order to cite some instances of polyneuritis from different infections, the occurrence of three of which within a short period impressed me with the desirability of presenting this subject for your consideration.

†The numerous attempts to test hepatic function in considered in this communication.

*The numerous attempts to test hepatic function in the laboratory are not regarded as satisfactory by clinical pathologists. Hence, none of these tests have been used in any of the cases reported here and the foregoing considerations are presented as a basis for future study by others, as organized means for investigation of this kind have not been at my hand.

CASE I.—Thus a woman of 53, wife of a well-known Government official, referred by Dr. Gill because during convalescence from diphtheria, which she had contracted two months before, there had ensued weakness of voice, numbness of feet and thighs, and more recently a progressive weakness of the limbs. She was very nervous and was suffering also from osteopathic treatment.

Examination revealed absence of the triceps, radial, and biceps reflexes as well as a reduction of the patellar, achilles, and plantar, while there persisted the deltoid, masseter, and abdominal reflexes. There were subjective tinglings in the extremities, and tenderness both to prick and pressure was increased; the vibration sense was diminished in the legs, arms, and trunk; the nerve trunks were tender. The spacing sense was diminished in the left hand, where she could not distinguish two points nine millimeters apart. The localization of touch was almost lost in the toes and ankle, and scarcely perceptible in the hands. The walk was unsteady, the hands unskilful, and the motor power much diminished, yet there was no perceptible atrophy. Both optic disks were slightly pale. There was a slight tachycardia. She was seen several times, during which the symptoms rapidly regressed after the administration of antitoxin which was recommended, so that she was able to go to her new home about six weeks later.

The diagnosis, of which there was no question, was post-diphtheretic polyneuritis, and the recovery was gratifyingly rapid.

CASE II.—A fellow psychiatrist, of bilious type, aged 35, consulted me because of a numbness and tenderness which had recurred after the subsidence of an attack two weeks before which he had attributed to a septic state derived from tonsillitis. The chief symptom was an intolerable itching in the right foot, and considerable tenderness on walking, along with tingling of the fingers, and pain in the hand when he clasped tightly.

Examination revealed tenderness of the nerve trunks in the upper arms, and the popliteal region, and slight tenderness on deep pressure of the muscles. There were no sensory losses, even spacing being intact, vibrations being felt everywhere, and the attitude sense was unimpaired. The reflexes were all present and the motility was unimpaired.

He was sent to a laryngologist, who cleaned out the tonsils, which were full of purulent foci chiefly staphylococcic, after which he made a rapid recovery, not even returning for a second examination.

This is an example of infectious polyneuritis in its incipiency, that is to say before the noxa had sufficiently affected the neurofibrils to interfere with their conductivity, although it had done so sufficiently to augment their tenderness.

The role of faulty hepatic metabolism is pointed to in such an instance as that of a much prolonged posttyphoid polyneuritis in a man who had jaundice at 18, hepatic colic at 26, and in whom there was decided tenderness over the liver before the attack of typhoid fever.

CASE III.—Mild polyneuritis in the course of typhoid is not so rare, but a severe attack occurring after the cessation of the fever is an unusual occurrence. Such a case in a Federal judge I saw with Dr. Claytor six years ago, and which he published soon after. The recovery of this case was slow, six months being required before he could walk satisfactorily, and nearly two years elapsing before he could do so in comfort, while paresthesiæ did not altogether disappear even then. It might be significant that this patient was treated on the principle of full feeding by a diet in which eggs, as custard, played a large part.

CASE IV.—A corporation official of 56 was seen with Dr. Mason, because six months before there had been recurrent paresthesiæ, the soles feeling like a soft pad, itching of the hands, and a muscle-bound and rheumatic feeling in the legs after walking. Eight years before there had been a dilatation of veins in abdomen and thigh, with successive painful ruptures which lasted for about a year. A rupture had occurred six weeks before I saw him. He had had lumbago about two years ago, while two days before there had been a hemorrhage from the throat.

Examination showed a pretty well-preserved man of feminine type, except that the breasts were masculine. The reflexes were sluggish, the cremastor and abdominal were scarcely present. Vibration sense and that of attitudes were diminished in the toes. The deep pain sense was accentuated, especially in the legs and wrists, and the nerve trunks were slightly painful.

A diagnosis of very mild polyneuritis was made. The possible etiological factors were increased. He had acidity, a blood pressure of 156-98, a slow pulse of 66, but without cardiac hypertrophy, normal urine, and a history of gonorrhea fifteen years before, with the presence of a 2-plus positive serum reaction to the gonococcus, which was already under treatment by vaccines, which had produced a severe reaction, comprising twitchings and cramp in the back and general malaise.

It was recommended that vaccine be continued, that thyroid gland, ½ grain per day, be administered, and that meat extracts, of which he had been taking a great many, should be eliminated from the diet. Dr. Mason informs me he made a rapid and uninterrupted recovery, returning to business the following week.

Influenza is frequently followed by mild neuritic pains lasting for several weeks. In a few cases there is a definite, severe polyneuritis.

CASE V.—An instance of a milder type is that of a nurse, aged 41, who had not been well since an attack of measles one year before. Two months before examination she had influenza and a temperature of 103°, since when she had not been free from sciatica and neuralgic pain in the face.

Examination showed dulled reflexes and increased deep pain sense in the left arm and leg, while a blood pressure of 132 and 110 indicated a heightened peripheral resistance, with a weakly acting heart. Her dietary was defective. She was recommended to cease the cold baths she was taking in the belief that they were tonic, to be massaged thrice weekly, and to take a modified model diet which I prescribeed. In three days the blood pressure had decreased to 124-90, and she felt much better, while one month later she was quite well.

The *diagnosis* of polyneuritis presents no difficulty to a well trained neurologist, the syndrome being so distinctive; but by those who are not versed in the refinements of the technique many mistakes are made. Diagnosing as neuritic, conditions entirely different is commoner than to fail to diagnose polyneuritis.

I need not go into the *differential diagnosis* of well-known syndromes clearly described in all modern text books. This is particularly so as regards poliomyeletis, meningitis, encephalitis, myositis, and arthritis. The diagnosis from radiculitis* is a particularly thorny one for the inexperienced; and as knowledge of the latter condition is not generally diffused I have elaborated a table to include the chief differentia from neuritis.

Treatment.—Neuritis must be treated in accordance with its cause, *i. e.* the detection and elimination of mineral or other poison, when the nerves will regenerate spontaneously. Local sepsis must be sought for and eliminated.

Local application of heat, radiant energy, electrical ionization, is sometimes highly beneficial. Massage is nearly always an advantage if properly given.

*In a recent edition of a well known neurological text-book even the name radiculitis is unmentioned in the index, and there can be found no allusion to the syndrome even where the dorsalis is described.

SYNDROME.	*NEURITIS.*	*RADICULITIS.*
Definition.	Irritation of peripheral nerves.	Irritation of spinal root.
Etiology:		
Toxin.	The usual cause.	Doubtful.
Chemical poisons: Alcohol or metals, especially arsenic or lead.	Frequent.	Doubtful.
Diffuse bacterial poisons aside from local exudation, especially diphtheria and influenza.	Occasional.	Doubtful.
Metabolic poisons: lithemia, arthritism.	Occasional.	Doubtful.
Endocrine imbalance.	Possible.	Doubtful.
Focal infection.	Occasional.	Doubtful.
Tuberculosis.	Scarcely.	Frequent.
Syphilis.	Doubtful.	Commonest cause.
Neoplasm.	Occasional.	To be suspected.
Physical agencies: Cold, trauma, etc.	Occasional.	Especially trauma.
Concomitant of arthritis.	Of the neighborhood.	In the spine.
Pathology:	Usually degenerative from toxicosis, or by strangulation by neurodocitis.*	Often inflammatory; by strangulation, by inflammatory or neoplastic compression.
Onset:	Often abrupt.	Insidious.
Symptoms:		
Pain.	Except in plumbism or pure motor neuritis.	Usual when posterior root is implicated.
Tenderness.	Characteristic, especially of deep tissues.	Absent or minimal.
Conductivity.	Impaired.	Impaired.
Hypesthesia.	Except in early stages, irregularly progressive.	Except in early stages, irregularly progressive.
Sensory dissociation.	Not usual; sometimes pseudotabetic, but never truly of tabetic type.	Occasionally of syringomyelic type in tuberculous radiculitis; of tabetic type in syphilitic radiculitis.
Motor weakness.	Usual.	When anterior root is affected, best marked in tuberculous radiculitis.
Atrophy.	Severe and of long duration except in mild cases.	Less evident except in tuberculous radiculitis.
Deformity.	Contracture and stretching of tendons and ligaments.	Contracture and stretching of tendon and ligaments less marked.
Reflexes.	Impaired except at first.	Impaired.
Trophic changes.	Early and evident.	Scarcely.
Extent.	According to distribution of nerve affected. In polyneuritis more marked peripherally.	In the segmental distribution of the roots affected.
Diagnosis:	Increased deep tenderness with or without hypesthesia. Syndrome conforms to distribution of peripheral nerves.	Hypesthesia both cutaneous and deep. Syndrome conforms to distribution of roots.
Differential Diagnosis:	From trauma, osteitis, arthritis, myositis, meningitis, poliomyelitis, encephalitis, myelitis.	From the same.
Prognosis:	Highly favorable upon removal of cause.	Unfavorable in proportion to destruction of sensory fibers. Favorable as regards motor fibers except when dense cicatrices have occurred.
Treatment:	Elimination of the pathogen; metabolic regulations; physical agencies to stimulate local nutrition.	Removal of the pathogen; rest of the regions affected.

*A term to denote inflammation of the fibrous sheath or bony canal through which a peripheral nerve passes; *e g.* the fascia lata for the n. femorocutaneus or the aqueduct of Fallopius for the n. facialis.

The *metabolic* condition I look upon as of supreme importance in many cases. Even the most obstinate sciaticas may yield in a week or two to carefully considered metabolic regulation, such as the following:

In the morning upon waking 5 ounces of hot water containing 10 grains of sodium bicarbonate. Half an hour later, after a rest, a large plate of raw or cooked fruit and milk or cream, followed by abundant cereal and milk with bread and butter. No meat, eggs or fish.

Wait four hours or more before the next meal, which should be preceded by ten minutes' recumbency on the right side, and consist of a small portion of hot vegetable soup if desired, not more than four ounces of meat or fish, which must be quite fresh, a very large plate of succulent green vegetables, potatoes sparingly, and nothing more than a taste of sweets; no custard, ice cream, or junket.

The third meal should be taken at least five hours later and may be a repetition of breakfast, but salad or succulent vegetables may replace the fruit, and macaroni or a similar dish may be substituted for the cereal.

Thirst and hunger between meals may be satisfied by water, lemonade, or fruit about one hour before a meal or during the night. Gelatin, coffee, meat juices (gravy and soup), tea, cocoa, salt and strong condiments, alcohol, pastry should be abstained from. All starches and meats must be well cooked. Fresh vegetables must not be over boiled,

e. g. a cabbage divided into four to eight pieces to be put separately into *boiling* water for only eight minutes *without meat or salt*. Fine milled grain should not be taken even in bread.

Where there is evident endocrine abnormality, internal secretions may have to be administered also.

The *mental* disturbance due to pain and lack of sleep must be dealt with also; but one cannot protest too strongly against the indiscriminate giving of anodynes and narcotics, for these disturb metabolism, and interfere with repair, and in a long continued case they produce addiction, which is a most troublesome tendency to get rid of. For restlessness and insomnia the best measures are physiotherapeutic, especially hydrotherapy.

If hepatic inadequacy is a considerable factor in polyneuritis, then in the treatment of polyneuritis of infectious origin, a dilemma is presented because an abundance of protein is needed to build immunity against infections, while an abundance of protein cannot be dealt with by a disordered liver.

Fortunately, however, the dilemma is more theoretical than real, for hepatic potency has large reserves, while a temporary diminution of protein intake is not in practice serious, as it leads to better metabolism after a short interval of diet. Besides, when neuritis occurs, the infection has usually subsided and immunity has already been effected. Hence in practice a low protein diet, rich in saline, is given at once as above.

THE RELATIONSHIP OF ALASTRIM TO SMALLPOX.

BY V. E. WATKINS, M.D.,

LA ROMANA, SANTO DOMINGO.

PHYSICIAN AND SURGEON, CENTRAL ROMANA, INC.

DURING the past year there has been prevailing in the West Indies, in epidemic form, an eruptive disease closely akin to smallpox, but presenting certain distinctive characteristics which have led some observers to consider it a separate disease entity. The condition has been described by various writers under the names alastrim, Kaffir milk-pox, modified West Indian smallpox, varioloid-varicella, and amaas. The negroes from the British West Indies speak of it as "glass-pox." The disease prevailed in epidemic form during 1920 in Jamaica, Panama, Cuba, and Haiti. It is supposed to have entered Jamaica from Cuba. During the early fall of 1920 it gained entrance into Santo Domingo from Haiti, through Barahona Province and has gradually spread eastward until at the present time it exists in epidemic form throughout this Republic.

The disease has been the subject of discussion among medical writers for some time, but there has been no uniformity of opinion as to its character. Osler[1] refers to a mild smallpox in the West Indies and Brazil as "alastrin amas." Castellani and Chalmers[2] discuss the disease under the name alastrim and give the differential diagnosis between it and varicella and variola vera. Their historical sketch is interesting, showing that the disease was recognized by Anderson in Jamaica as early as 1865. They conclude provisionally that the condition "is probably a slightly different form of disease from true variola." Chapin,[3] and MacCullum, quoted by Dr. Deeks of the United Fruit Co.[4] give lucid and interesting descriptions of the recent epidemic in Jamaica.

In reviewing the available literature on the subject one is impressed with the great diversity of opinion as to the nature and character of the disease. Upon one characteristic only do all observers agree, viz., the general innocuousness of the condition. This confusion is confirmed by the varying nomenclature given to the disease, and is due to a great extent to the attempt of recent writers to perpetuate the belief of the earlier observers that the condition is a separate disease, distinct from smallpox.

The first case occurring on our plantation was discovered on June 13, in a Guadeloupian negro, who wandered into one of our country bateys from an adjoining sugar estate near the city of San Pedro de Macoris. From this and from other foci of infection which have been introduced by ambulatory cases, the disease has gradually spread throughout our plantation, covering an area of nearly one hundred square miles. We have had to date (Oct. 29) eighty-five cases, all of which have been isolated in our pest house established at a remote point on the plantation to take care of this epidemic. It is from a study of these cases that the following observations on the disease are presented.

Age.—Children appear to have a relative immunity. Many unvaccinated children have been exposed to the infection during the four months the disease has prevailed here, we finding them on numerous occasions living in the same room with a person sick with the disease. In a few instances we have been compelled by force of circumstances to put children in the quarantine camp with the mother. But we have had only three cases in young children.

Sex.—Males appear to be more prone to contract the disease than females, but five of our patients being women.

Race.—All of our patients have been negroes. Whether the white race is susceptible is a question difficult to answer, for all the whites who come to the tropics are, as a rule, thoroughly and successfully vaccinated.

Incubation.—Our second case developed in the barracone where the first case presented himself just three weeks to the day after exposure. In all cases where we have been able to fix the time of exposure the incubation period has been twenty-one days, rather longer than that given by other observers. It was not until the second week in July, four weeks after the introduction of the first case, that the disease assumed epidemic proportions.

Symptoms.—The disease begins with general malaise, moderate fever, and headache. We have not seen any case presenting the severe bodily pains mentioned by some writers. No initial rash has been detected on the dark skins of our patients. The eruption begins invariably on the third

day in the form of more or less numerous papules on the forehead, face, arms, and hands, which rapidly spread, but less profusely, over the entire body. These papules have the hard, shotty feel characteristic of the smallpox papule. On the third day of the eruption, or the sixth day of the disease, these papules become distinct vesicles, with umbilicated centers. By the eighth day the vesicles have developed into pustules. On the lighter-skinned patients an area of inflammation can be detected about the pustules. The eruption matures in the order of its appearance, first on the head and face and then on the body. In other words, it follows the course of a typical smallpox eruption. In a number of cases the pocks have appeared on the buccal mucous membrane, the hard and soft palate, tongue, tonsils, and pharynx, causing the patient considerable discomfort in swallowing.

Recent writers have emphasized the statement that there is little or no secondary rise in temperature. This has not been our experience. The secondary fever has depended entirely upon the severity of the case. In our confluent cases, of which we have had several, the fever reached 104°, and one patient developed a mild delirium. As a rule, however, the disease has run a very mild course, and in none of our cases has there been the profound toxemia and prostration seen ordinarily in smallpox. In fact, most of our patients were never confined to the bed, and it is interesting to see them walking about, smoking cigarettes, and taking a general interest in their surroundings, although presenting the usual appearance of well-marked smallpox. All of our patients developed the pocks on the palms of the hands and the soles of the feet, which, when profuse, resulted in considerable pain and discomfort, due to the tension on the skin. Itching and burning of the skin at the site of the eruption have not been complained of at all by our patients. In a few of the more severe cases there has been some swelling of the cervical lymph glands, but in all except two very mild cases there has been a marked and rapid enlargement of the epitrochlears, the glands attaining the size of a large hazel nut and occasionally being multiple. No complications have developed in any of our patients. Desiccation is rapid. Considerable stress is laid by some observers upon the lack of pitting or scarring, as a distinguishing point of the disease. Our experience has been that the pitting is entirely dependent upon the severity of the attack, our bad cases all showing considerable pitting about the nose and cheeks. In all cases, however, no matter how mild, the site of each skin lesion is marked by a deeply pigmented spot still apparent on those patients remaining under observation for weeks after their discharge.

Prognosis.—Up to the present time we have had no mortality. The disease has run a remarkably mild course, and, with possibly one exception, there has not been the profound toxemia ordinarily to be expected in a disease with such pronounced local manifestations.

Diagnosis.—The only disease for which the condition under discussion could be mistaken is varicella, and this error would only be possible in a mild case at the beginning of an epidemic. As to the statements that this condition is a strange and rare disease to be differentiated from smallpox, our experience leads to the belief that we are dealing with an epidemic of mild smallpox. The experience of the past few years in the United States has shown that very mild epidemics of true smallpox may occur, and there is every reason, as will be shown later, why such epidemics should occur in the tropics. Brown[5] gives a very graphic description of the disease as it occurred in Haiti, and he has no doubt as to its being true smallpox.

Vaccination.—Upon receipt of the information that smallpox was prevalent in Haiti we instituted throughout our plantation a vigorous and thorough campaign of vaccination, and during December and January vaccinated nearly 7,000 of our people and their families, about 80 per cent. of which were successful. Since the appearance of the first case in June the disease has spread over the entire plantation, and there is not a batey that has not had at least one case. Considering the highly infectious nature of the disease, and the crowded conditions under which these people choose to live, it is a reasonable assumption that the protection afforded by vaccination has been the controlling factor in keeping our morbidity to 85 cases* among a population of some 7,000 people. A number of our patients stated that they had been vaccinated at some time during their lives, *but not one of them presented evidence of a successful vaccination.* I have been unable to confirm the observations of MacCallum (*loc. cit.*) to the effect that it is possible to obtain positive results from vaccination among convalescents. Twenty-two of our more recent patients have been carefully vaccinated with absolutely fresh virus with invariably negative results. Leake and Force[6] conducted a series of experimental inoculations in monkeys and rabbits with material derived from Jamaican and Haitian patients to determine the immunological relationship of the disease, and give the following summary of results: "The fact that definite immunity to vaccinia is produced by previous inoculation with alastrim is additional evidence of the essential identity of alastrim with smallpox."

Conclusions.—The clinical evidence presented by this disease does not warrant any other diagnosis than smallpox. It is submitted that recent writers on the disease have failed to take into consideration a very important factor which is apparent to every observing man experienced in the practice of medicine in the tropics. The people with whom we have largely to deal have lived for generations under climatic conditions and in an environment so diametrically opposite to conditions as they exist in temperate climates that they do not always respond to acute infections in just the same way as do their white or black brethren in the North, and when they become affected with acute diseases the clinical picture as we know it in temperate climates becomes at times so modified as to deceive an inexperienced or casual observer. For instance, our lobar pneumonias do not always present the classical symptoms seen in more northern latitudes, and the late influenza epidemic here differed in many particulars from the descriptions given of the disease in the United States.

*A number of mild cases have undoubtedly concealed themselves and escaped detection.

Excluding those diseases which are recognized as essentially tropical, it may be stated as an aphorism that no infectious or contagious disease runs true to form in the tropics except pulmonary tuberculosis.

It is not strange, therefore, that smallpox here should present clinical differences from the disease as known in colder climates, and the attempt to describe it as a separate and distinct disease under another name only leads to confusion and creates a false sense of security. He would indeed be a bold sanitary official who, in the face of our present knowledge, would relax his sanitary measures because he believed the disease to be alastrim or Kaffir-pox and not smallpox.

EUGENICS AND EUTHENICS IN THEIR RELATIONS TO THE TUBERCULOSIS PROBLEM.*

BY S. ADOLPHUS KNOPF, M.D. (New York and Paris).

NEW YORK.

THE modern conception of tuberculosis as a non-hereditary disease, while not absolutely correct from a strictly scientific viewpoint, may be considered to be accepted by the vast majority of students of the tuberculosis problem in its social as well as medical aspect. Direct bacillary transmission—that is to say, cases in which the bacilli of tuberculosis are found in the placenta — do occur, but are exceedingly rare. Prior to writing my article on tuberculosis for the "Twentieth Century Practice of Medicine" I looked up the literature on the subject and could only find that about 60 cases had been reported during the preceding 40 years. Both medical and social workers have a right to consider this a negligible quantity, and it is of incalculable advantage that the former strong belief that pulmonary tuberculosis, popularly known under the name of consumption, was an hereditary disease is gradually disappearing. The assurance which may be given to the patient whose father, mother, or ancestry have been tuberculous, that he has not inherited the disease, and that the fact that some of his near relatives may have died of it is by no means an indication that he, too, must fall a victim, gives him the peace of mind and the hopeful outlook so essential to recovery from the disease.

If, however, direct bacillary transmission occurs, as just stated, only in the rarest instances, it behooves us as students of eugenics to find out how we can account for the prevalence of the disease in general and the frequency with which it occurs in children of tuberculous parents. Of course, we know there are many post-natal causes of infection. When the tuberculous mother nurses the child she may infect the intestinal tract of the infant by her own milk, which may contain the bacilli; or the child may be fed on milk from tuberculous cows. In some sections of our country statistics have shown that in no less than 10 per cent of the children infected with tuberculosis the causative factor was the bovine type of the bacillus. Contact infection results when the mother kisses the infant on the mouth, or if she carelessly coughs in its face and droplet infection ensues, or if the infant is fed artificially she may insert the rubber nipple of the milk bottle in her mouth to test the temperature and sweetness of the milk, or in feeding the child some cereal, she may taste it from the same spoon with which she feeds the baby.

Aside from such well-known sources of post-natal infection and the infection in adult life arising from the careless disposal of the sputum of the tuberculous invalid, recent investigations have shown that there exists also a source of infection which, because it is so rarely recognized, is all the more dangerous. Prof. A. Calmette of the Pasteur Institute of Paris spoke of this source of infection at the recent tuberculosis conference in London as "healthy carriers of tuberculosis."[1] In other words, there are seemingly perfectly healthy individuals who, unknown to themselves, carry countless virulent tubercle bacilli in their system, and if they come in contact with a predisposed individual, particularly an infant or child, an infection is almost inevitable.

At the same congress, Gerald B. Webb, ex-president of the American National Tuberculosis Association, made the following statement concerning this dangerous source of infection: "The question upon which we must be alert is that of the tuberculosis carrier. In so many cases a parent before becoming a manifest consumptive had been a carrier of disease and had disseminated millions of bacilli in his immediate neighborhood."

During the past 25 years antituberculosis workers have done their best to combat all the known sources of post-natal infection in child life and of communication of the disease in adults, and these efforts have not been in vain. These workers claim that it is owing to their labors that there has been a marked decrease in the tuberculosis death rate in our country. Some statisticians, however, claim that this lower mortality rate is due to the improvement in general sanitation and better nutrition of the masses, which have reduced the death rate in general and also that of tuberculosis. Be this as it may, to the tuberculosis worker must be given credit for having had a great share in this improvement in individual and general hygiene.

Educating the masses as to the prevention of post-natal infection in children, as well as contact infection in adults, has done and is doing incalculable good, and in the few existing preventoria quite a percentage of the inmates who had been much exposed to tuberculosis and strongly predisposed by inheritance are apparently made

*Read before the Second International Congress of Eugenics, held in New York, Sept. 22-28, 1921.

strong and vigorous enough to resist the development of the disease. In almost every State of the Union there are numerous sanatoria and special hospitals, although as yet not enough to treat, cure, and isolate tuberculous disease in its various stages. Yet thousands of tuberculous individuals still die annually, in spite of popular education, in spite of preventoria, in spite of numerous institutions for the treatment of the disease, and in spite of apparent advance in phthisiotherapy.

It cannot be said that our studies in immunity have advanced sufficiently to count in the reduction of morbidity and mortality of tuberculosis. These studies have made only one thing sure—namely, that tuberculosis, in the vast majority of cases, was contracted during childhood, and that the tuberculous infection which remains latent becomes tuberculous disease most frequently between the ages of 18 and 35. It is then that an inherited predisposition, a "habitus phthisious," or an acquired predisposition make themselves manifest and the morbidity and mortality from tuberculosis is highest. Unfortunately, these are also the ages in which the procreative functions in man and woman are perhaps at the highest point, where marriages are most frequently contracted and children most frequently conceived. It is thus, in my humble opinion, at this period when we should consider the importance of eugenics in its relation to the tuberculosis problem.

I stated at the beginning of my paper that the bacillus of tuberculosis is very rarely found in the fetal organs. What, then, is responsible for this predisposition to the disease? We know that the child is more often found tuberculous when the mother is the tuberculous parent. This is not only to be accounted for by the fact that the mother is in closer contact with the child, but I am convinced that the primary cause of the tuberculous predisposition is a mingling of the blood in the maternal and fetal circulation. The bacilli lodged in countless quantities in the tuberculous lung of the mother are constantly secreting toxins of varied virulence which enter the circulary system of the mother and cause fever, anorexia, and emaciation. The maternal blood, reaching the placenta and fetus, impregnated with toxins, affects all the cells of the future child and thus the foundation for the predisposition or the habitus phthisicus is laid (a constitution below par, a cylindrical or flat chest, long body, deficient muscular development and little adipose tissue, a tendency to contracting infectious diseases and a particularly suitable field for the invasion and spread of the tubercle bacillus). The presence of alcohol has been demonstrated in the newborn child when the mother has been addicted to chronic alcoholism throughout pregnancy, or if shortly before the time of delivery she had imbibed frequently of strong alcoholic drinks. This alone would justify the conclusion that the toxins of Koch's bacillus in a consumptive mother may mingle with the circulatory fluid of the fetus.

In the assumption that something is inherited from the tuberculous parent, with the exact nature of which we are not as yet familiar but which we know is very rarely bacillary, I do not stand alone. The greatest living authority on tuberculosis statistics, Karl Pearson of London, quoted in Baldwin and Gardner's recent contribution on the subject,[2] "considers that heredity plays a large part in transforming infection into disease." This means that in many cases where there has been a slight bacillary infection from without, which should have been sufficient to render the individual immune, the hereditary factor overcomes this and the infection becomes actual disease. This endogenous development of the disease without direct bacillary transmission is perhaps much more frequent than heretofore thought. To quote again from the just-mentioned work: "The British epidemiologist and statistician, Brownlee, mentions his acceptance of the theory of immunity conferred by childhood infection, which, however, breaks down and causes two-fifths of adult phthisis from endogenous spreading. The inference is that three-fifths must be from exogenous sources."

Our recent war experience has shown us how many young people are physically below the standard health and unfit for military service, and that thousands of them are unfit for the duties of parenthood. For the following statistics I am indebted to the courtesy of Major General Ireland, the present Surgeon-General:

REJECTIONS, SELECTIVE SERVICE MEN, LOCAL AND CAMP EXAMINING BOARDS.

	Local Boards	Camp Boards
Total	549,099	207,617
Pulmonary tuberculosis	44,305	14,612
Suspected tuberculosis	16,899	156
Tuberculosis of other organs	8,731	679
Mental deficiency	33,636	7,963
Defective physical development	5,604	1,756
Deficient chest measurement	2,105	194
Underweight	59,022	11,586
Underheight	6,556	2,060
Malnutrition	676	93
Bones and organs of locomotion	113,287	58,536
Arthritis	3,934	2,539
Syphilis	8,802	...
Tabes	578	...
Paresis	252	...

The actual number of selective service men, first, and second registration, examined by the local boards was 3,764,101.

The actual number of selective service men, first and second registration, examined by the camp boards was 2,745,073.

The statistics for 1,961,692 selective service men as published in "Defects Found in Drafted Men" have been raised proportionately to cover the complete number 2,745,073.

We are at this moment mainly concerned with tuberculosis, its predisposing causes, and their relation to eugenics. Among the just-mentioned 3,764,101 men examined, there were 58,917 found actually suffering from pulmonary tuberculosis, 17,055 with suspected tuberculosis, 9,410 afflicted with tuberculosis of other organs; 7,360 were rejected because of defective physical development. 2,299 for deficient chest measurement, 70,608 because of underweight, and 769 for malnutrition. These four latter conditions are well known to be factors predisposing to tuberculosis. But I go even further by saying that bone and joint defects, for which 171,823 were rejected, were probably also in the majority of tuberculous

origin, which would mean 338,241 either actually tuberculous, suspected of tuberculosis, or by reason of their physical defects predisposed to the disease. If we add to this figure 9,632, afflicted with syhpilis and its sequelæ, which also predisposes to tuberculosis, we have a total of 347,873.

It is not unreasonable to suppose that the same defects found in men at draft age would be found in women at about the same age.

What can, should, and must be done to remedy this appalling condition of our nation's health? From our studies thus far we have learned that in order to reduce the morbidity and mortality of tuberculosis we must have, besides a rigorous individual and popular prophylaxis, a better physique, a stronger physical make-up. Against an inherited weak physique and physiological poverty in children and adults we must provide recreation centers where the masses can congregate and have plenty of fresh, pure air in winter and summer, particularly for prospective mothers, more maternity sanatoria, more open-air and sanitarily supervised kindergartens, more parks and playgrounds, more open-air schools, more outdoor school instruction, and more calisthenics and breathing exercises outdoors or with open windows at recreation time. Singing, recitation, botany, and geology should be taught outdoors whenever possible. Our municipal and school boards and public welfare commissions should combine to bring these improvements about. Compulsory military or physical training for boys and girls, encouragement for outdoor sports for old and young, and the utilization of roofs in cities where sufficient space for playgrounds is not available should also demand the attention of our authorities and philanthropists.

The social causes of a weak physique arise from underfeeding, intemperance, bad housing, bad factory, bad mine and workshop sanitation, child labor, woman labor, the social evil, etc. These are matters for the statesmen to attend to. These causes must be removed, and without their removal eugenists will be powerless to achieve success in their endeavor to help in the solution of the tuberculosis problem.

The diseases which predispose to tuberculosis are numerous, particularly measles, diphtheria, typhoid, smallpox, syphilis, grippe, etc. Many of these diseases are preventable either by detecting the carrier as in typhoid and diphtheria, or by vaccination or serum injections against the disease. Others are usually curable if discovered in time and properly treated. Medical science knows how to stop many epidemic diseases predisposing to tuberculosis, if the public would only trust it and if Federal, State, and municipal authorities will aid. All these environmental causes come under the heading of "euthenics."

What suggestions can we make to remove that strange and insidious source of infection which I have referred to as the healthy tuberculosis carrier, whose existence has been heretofore almost totally ignored? How many might not have been discovered had time and opportunity permitted to examine every man or woman drafted for service so as to be sure that he or she was not a tuberculosis carrier? What should be done now, and how may many still be discovered? Obligatory examination for tuberculosis of all individuals wishing to enter wedlock, so that if he or she happens to be a tuberculosis carrier, transmission of the predisposition to his or her child or causing post-natal infection may be avoided by careful instruction and guidance. There should be at least one annual examination for tuberculosis, typhoid, diphtheria, venereal diseases, etc., of all individuals desiring to pursue such occupations as nurses, dairy employees, dealers in milk, meat, or other food substances. This would be helpful in doing away with the danger arising from contact infection by many healthy tuberculosis carriers who are not aware that they are capable of transmitting the disease. The masses should be educated to the fact that a tuberculosis carrier, instructed and conscientious and careful with the disposal of his secretions, particularly of mouth and nose, is perfectly safe to associate with, and even marriage may be permitted.

There are also a number of useful citizens, men and women, who are slightly affected with tuberculosis, knowingly or unknowingly, and whose tuberculous condition can only be detected by a most careful examination. They, too, may marry after their recovery, which is reasonably sure to take place if timely and properly treated. A single pregnancy in the woman predisposed to tuberculosis does not necessarily mean a development or aggravation of her condition, or a tuberculous infant, providing she has the proper hygienic and dietetic care for a sufficient time prior, during, and after confinement. On the other hand, frequent pregnancies following each other in rapid succession, will surely undermine the mother's health, aggravate a predisposition or an existing slightly tuberculous condition, and will most likely bring into the world feeble and strongly predisposed children.

All this means that the solution of the tuberculosis problem is not possible without judicious, humane, and scientific birth control. Only healthy parents can procreate healthy children. When the children are too numerous so that most of them, and particularly the latter born, had no chance to develop into mentally and physically strong men and women, they, in turn, will have children frail and subject to disease.

In an admirable address entitled "The True Aristocracy," contributed to this congress, my esteemed friend, the distinguished vice-chancellor of the University of Liverpool, Prof. J. George Adami, very justly says that under modern conditions, through the larger families of the unfit, the race is deteriorating and not improving. He suggests a selective mating among the physically, mentally, and morally sound.[2] I have taken a careful history of many cases of tuberculosis covering a period of 25 years, and this has revealed to me that with surprising regularity the tuberculous individual, when he or she comes from a large family, is one of the latter-born children—the fifth, sixth, seventh, eighth, ninth, etc. The healthiest children, as a rule, are those of young people who married at a comparatively

early age. Eugenics has amply proved this, and here again birth control enters as a factor. Young people, strong and vigorous, would gladly enter wedlock if they could know that it was within their power to have only as many children as they could well provide for.

At the time of the marriage, the minister or magistrate who conducts this sacred act, or better yet, the official who issues the license, should hand to the couple a carefully prepared pamphlet containing instructions in parenthood and the duties and obligations this involves. Of course, no license for marriage should be issued except to such as have been found physically and mentally fit to become the fathers and mothers of the future generations. Individuals physically below par should be advised to delay marriage, and if that seems not feasible, they should be advised to delay having children until both husband and wife are physically in fit condition.

It is not necessary here to go into the details of the many moral advantages of early marriages, such as the diminution of prostitution and venereal diseases. Even in our well-to-do and healthy families, considered our best American stock, and where larger families would be no burden, early marriages are unfortunately not encouraged. The opponents of birth control love to dwell on the theme of so-called race suicide. If this is applicable it should only be spoken of in such instances where health, wealth, and culture abound and still family limitation is practised to a very appreciable and deplorable degree. Birth control in cases of a distinctly tuberculous father or mother, among the poor and underfed, is not race suicide but race preservation.

We lose in this country about 50,000 children annually from tuberculosis. What heartache and suffering the birth and the death of these 50,000 little ones, in many instances even unwelcome, have caused to the parents is difficult to conceive. There are overwhelming statistics to be found everywhere, showing conclusively that the larger the family, and particularly among those in moderate or poor circumstances, the greater is the death rate among the children. As to the economic loss which the commonwealth sustains from bringing into this world thousands of children mentally and physically crippled, I will confine myself to tuberculosis alone where we have been able to calculate, at least approximately, what this unthinking procreation costs. I stated above that 50,000 children die annually from tuberculosis in the United States. Figuring the average length of life of these children to be seven and one-half years and their cost to the community as only $200 per annum, represents a loss of $75,000,000. Such children have died without having been able to give any return to their parents or to the community. Who will dare to calculate in dollars and cents the loss which has accrued to the community because so many mothers died of tuberculosis when an avoidable pregnancy was added to a slight tuberculous ailment in a curable stage?

As eugenists we are interested in the possible results of birth control. Should our laws become more tolerant in this respect? Should birth control clinics become a general feature, as they have been in Holland and are now in England? Should these clinics function not only to help the poor and sick woman to prevent too frequent pregnancies, but also to help the healthy, childless wife who longs for offspring, but hesitates to seek or cannot afford to pay for private expert advice, to have her often curable sterility overcome? If our Government should be willing to spend as much money, or even a good deal less, for the study of the best possible and most careful means of preventing conception and encourage the study of the causes of sterility and their cure and allied subjects to improve the human race in general, as it is willing to spend to improve our animal industry, what would be the result?

In answer to this question and in defense of my advocacy of a judicious birth control, I should like to quote just a few statistics from Holland: "What is the physiological effect of voluntary artificial restriction of the birth rate, or "voluntary parenthood"? In Holland, where the medical and legal professions have openly approved and helped to extend artificial restriction of the birth rate, the health of the people is shown by its death rate, which has been lowered faster than in any other country. At the eugenics congress in London in 1912, it was stated that the stature of the Dutch people was increasing more rapidly than that of any other country—the increase being no less than four inches within the last 50 years. According to the Official Statistical Year Book of The Netherlands, the proportion of young men drawn for the army over 5 ft. 7 in. in height has increased from 24½ to 47½ per cent. since 1865, while the proportion below 5 ft. 2½ in. in height has fallen from 25 per cent. to under 8 per cent."

I do not believe that before an audience of eugenists further arguments on my part are necessary to substantiate the bold assertion that without birth control we will not control tuberculosis. In a statement issued a few years ago by Dr. Haven Emerson, then Health Commissioner of the City of New York, and one of the best-known authorities on hygiene and social welfare work, he said that any physician who does not give advice to his patient which will, if followed effectively, save her from any surgical risk is not living up to his responsibilities. He further said: "The patients of the tuberculosis clinics are, to all intents and purposes, under the personal care of the clinic physician. Wherever the patient's health might be jeopardized by the unavoidable risks and strains of pregnancy, such patients may, according to my understanding of the law, be informed as to how to avoid conception."

I have said that without birth control we will not prevent tuberculosis. I go further and say that without birth control the number of insane, mentally deficient, syphilitics, and criminals will not decrease. The support of these defectives costs the State of Massachusetts 35 per cent. of its income, and the cost of maintaining such institutions in the United States in 1915 was no less than $81,000,000 (Fisher). Yet our institutional care for this class of dependents in asylums, prisons, reformatories, hospitals, etc., is only sometimes curative, more often only palliative, and

rarely preventive. Birth control scientifically studied, judicially imparted, and carefully supervised would, in addition, prevent such social and economic catastrophes as wars and famines, would decrease underfeeding and insanitary and insufficient housing, all of which are the precursors not only of tuberculosis, but of typhus, cholera, etc., and last, but not least, of that social discontent undermining the very foundation of our civilization.

Even as great and conservative an authority on the subject of birth control as Irving Fisher, professor of political economy of Yale, admits this. In his recent article, "Impending Problems of Eugenics" (*The Scientific Monthly*, September, 1921), he has this to say: "If birth control exercised by individual parents could itself be controlled by a eugenics committee it could undoubtedly become the surest and most supremely important means of improving the human race. We could breed out the unfit and breed in the fit. We could in a few generations and, to some extent, even in the lifetime of us of today conquer degeneracy, dependence, and delinquency, and develop a race far surpassing not only our own but the ancient Greeks."

Dr. Marie Stopes, one of the most distinguished of English advocates of birth control, very justly said at a recent mass meeting held in Queen's Hall in London: "Constructive birth control is the key of all racial progress. It should be one of the planks of the League of Nations' platform. It is the only true safeguard of international peace."

In conclusion let me repeat what I said recently in the preface to the new edition of a lecture on "Birth Control in Its Medical, Social, Economic and Moral Aspects," which I had delivered some time ago before the American Public Health Association: "To any unbiased mind it must be evident that our very experience before, during, and after the recent world war answers all objections to judicious birth control in its medical, social, economic, moral and even spiritual aspects. What this world needs now—after the fearful catastrophe which was started by a nation in which unlimited procreation among rich and poor, the educated and the uneducated, the well and the sick, was not only encouraged, but officially rewarded—is not a greater but a better population. The empire which sought world dominion and the enslavement of other nations had the highest birth rate and the most rapid growth of population, and yet it was France, which had by its birth control produced not as many but better soldiers, which withstood the most terrific onslaughts of the enemy's hordes. The generals of the German army sacrificed their soldiers *en masse* in close columns; it would seem that these military leaders felt that the empire had produced such great masses of men that they did not need to be so sparing and economical with human life.

"The world needs now and for all the future the very best kind of men and women, not servile masses blindly obeying war-drunk monarchs and militaristic rulers, not a mass of weaklings, bound to succumb before reaching manhood or womanhood, unable to serve or produce. We need children, but only such as are welcome to the home which physically, mentally, and morally sound parents have provided. The parents being economically situated so as to be able to give enough food, enough clothing, enough playtime to their children and live in comfort and enjoy life themselves. The State will then be able to provide enough educational facilities for children, and child labor will be done away with. Parents and children of the present generation should receive a physical and moral training and practical education that, with the help of a wise Government and enlightened statesmen, should be instrumental to create a future race of true men and women, physically, mentally, and morally sound, spiritually high-minded, images of their creator."

The true aristocracy dreamt of by Professor Adami will then dominate the world.

Let this great Congress of Eugenists strive to attain this end.

THE AGES OF PARENTS OF GENIUS.

BY CASPER L. REDFIELD,

CHICAGO, ILL.

IN my writings on intellectual eminence I have studiously avoided the term "genius" for several reasons. One of these is that I do not believe in genii any more than I do in witches and fairies. Another is that the word has a vague and uncertain meaning, and means different things to different persons.

Originally, a genius was a guardian deity which accompanied a person throughout life and guarded and directed him. Later it came to mean a person possessed of an intellect which was independent of and superior to all of the processes of nature. With many persons, genius is half-brother to insanity. It is common to designate as a genius some child who is particularly skilled in playing the violin, writing limericks, or drawing pictures, but who is otherwise intellectually mediocre if not actually stupid. On the other hand, it is not common to designate as geniuses men of such robust intellects as Aristotle, Franklin, and Humboldt.

In the present case I find myself compelled to use the word, but shall intend it to mean great intellectual power. The reason for my present use of this word is that I wish to have something to say about "Hereditary Genius" by Galton, "A Study of British Genius" (1904) by Havelock Ellis, "The Trend of the Race" (1921) by Prof. Samuel J. Holmes of the University of California, and some work by other men cited by those writers. Additional references will be my "Control of Heredity" (1903), my "Dynamic Evolution" (1914), and my "Great Men" (1915).

In his recent book Holmes gives some space to the influence of the order of births, and to the ages of parents at the birth of offspring, in relationship to size, weight, vitality, longevity, and intelligence of the offspring. In this he quotes all of the persons mentioned and purports to give a review of all of the information on the subject. Here I will confine my remarks to that part which involves the age of parents in years and the intellectual powers of the offspring.

In writing about British men of science, Galton gave the ages of the fathers in 100 cases. These men were prominent and a few were eminent, but the average was not high because the investigation was confined to a single group of men in a single country.

Ellis investigated a variety of things about 1,030 persons of British genius. As one part of his work he gave the ages of the fathers in 299 cases. These men were of a higher grade than those recorded by Galton because they included all kinds of intellectual excellence, whereas Galton's was restricted to one small group.

A. H. Yoder, in investigating the "Boyhood of Great Men" of the eighteenth and nineteenth centuries, gave the ages of the fathers in 39 cases. These men averaged higher than those investigated by either Galton or Ellis, but the number was small and the grade not the highest because restricted to a small period of the world's history.

In all of these cases, finding the ages of parents at birth of superior children was merely incidental to other work, and in no case did any of these men establish a standard of the normal distribution of births by which their work could be measured. As a consequence, these statistics by Galton, Ellis, and Yoder are mere curiosities having no scientific merit because not properly calibrated.

In my work I picked out about one thousand of the most eminent men of the world's history, as indicated by encyclopedias, and went deliberately at the job of getting the ages of the parents when their children were born, and the ages of the grandparents and earlier progenitors at the births of the next persons in succession in the lines leading to the eminent men. By this means I put the matter definitely and positively in the domain of heredity, because, if a person is affected by the age of his grandparent when his parent was born, it can be only through heredity. This is something which does not appear in the work of Galton, Ellis, Yoder, or any other person who has touched on the ages of parents.

In this work I succeeded in getting definite information in 1,028 cases in the pedigrees of 571 eminent men. These 1,028 make my work on this point alone more than twice as comprehensive as those of Galton, Ellis, and Yoder put together. Furthermore, the average grade of the men in my investigation is far above the average of the others, because it is not restricted to some small group but is the cream of the entire history of the entire world.

In addition to determining what happened in the production of the most eminent men of the world, I established a standard of the normal distribution of births so as to provide a scale which would indicate to what extent the production of great men differed from the production of ordinary men. This scale was made by tabulating 1,800 births as they are found in the genealogies of New England families. New England stock is considered to have been good stock, and those parts of that stock which got into published genealogies are rather above the average of New England. That standard was checked against 3,600 births registered in Chicago, 16,385 births registered in Dublin, 16,301 births registered in Edinburgh and Glasgow, and 100,057 births registered in Finland and Sweden.

In establishing this standard for comparison, I put this matter of age of parents on a scientific foundation, and I am the only man who ever did put it on a scientific foundation.

I published the names of the 571 eminent men and the 1,028 birthranks in their pedigrees so as to give others an opportunity to check over my work. I also published the details of the standard, tables in which I put the standard and pedigrees of eminent men in parallel columns, and a diagram showing the results of the comparison.

In referring to this matter Professor Holmes says: "The evidence compiled by Redfield, however, may be offset by the data gathered by Ellis in the Study of British Genius." He then gives the table compiled by Ellis, but omits the comment made by Ellis on this particular matter, which comment is that "the fathers of our eminent persons have been predominantly middle-aged and to a marked extent elderly at the time of the distinguished child's birth."

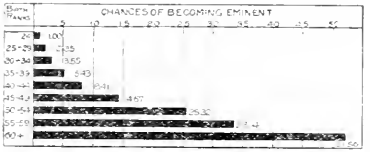
That statement by Ellis was a good guess, but it was nothing but a guess because he did not have any standard by which he could prove his statement. Let us put the results found by Ellis, and my results, alongside of the standard of normal distribution of births and see what we shall see.

Percentages of Births to Fathers of Different Ages

Ages of Fathers	Normal Pedigrees	Pedigrees of Eminent Men	
		(Ellis)	(Redfield)
— 24	9.06	3.68	1.63
25–29	23.05	15.05	9.77
30–34	26.00	27.09	16.63
35–39	19.67	19.73	19.19
40–44	13.39	14.72	20.23
45–49	5.50	10.03	14.53
50–54	2.22	4.35	10.12
55–59	0.72	2.68	4.30
60 +	0.39	2.67	3.60
	100.00	100.00	100.00

That table shows that Ellis and I get identical results, and that one does not offset the other, as intimated by Holmes. In the pedigrees of eminent men, both of us find a shortage of fathers at all ages under 30, and a surplus of fathers at all ages over 40. The differences between us are that my table departs further from the normal than does that of Ellis. When it is remembered that both of us are investigating eminent men, and that the men in my list are of a much higher grade than those in Ellis' list, it will be seen that the two investigations confirm each other. They show that the older the parents the greater is the intellectual power of the offspring. This is made clear by the diagram on the next page.

But let us carry this thing a step further. Let us bring into one table the statistics of Galton, Yoder, Ellis, and myself against the normal distribution of births. This table shows that we all get the same result. Each one of the four



investigators who tabulates the ages of the fathers of prominent or eminent men finds that men of this character come principally from elderly parents.

PERCENTAGES OF BIRTHS TO FATHERS OF DIFFERENT AGES

Ages of Fathers	Normal Pedigrees	Pedigrees of Eminent Men			
		(Galton)	(Yoder)	(Ellis	Redfield
— 24	9 06	1 00	2 56	3 68	1 63
25–29	23 05	15 00	5 14	15 05	9 77
30–34	26 00	34 00	25.64	27 09	16 63
35–39	19 67	22 00	33.33	19 73	19 19
40–44	13 39	17 00	17.95	14 72	20 23
45–49	5 50	7 00	7 69	10 03	14 53
50 +	3 33	4 00	7.69	9 70	18 02
	100.00	100 00	100 00	100.00	100 00

I object to Ellis' statement that my results may be offset by the results found by some other person when a comparison of the two shows that they confirm each other instead of offsetting each other. I also object to the assumption that a small, fragmentary investigation, not on a scientific basis because not calibrated, can be used to offset another investigation more than three times as comprehensive and fully calibrated.

But my principal objection to what Holmes has to say is that he classes my work with those of Galton, Yoder, and Ellis, whereas my work stands upon an entirely different foundation and is aimed at an entirely different thing. With those men, as far as this matter is concerned, the age of the parent at the birth of the child was the sole thing. They did not see or consider anything beyond. With me the age of the parent is simply the coefficient of a variable, and it was so written in my "Control of Heredity," from which Holmes quotes. That variable is the active agent, and the coefficient simply represents the extent to which the agent acts. Hence, the real thing I am presenting is a product, that product being the extent to which an organism modifies its own protoplasm by its own activities before reproducing. This is something totally different from mere age, which, standing by itself, is mere duration, and that is nothing at all, as far as producing an effect is concerned.

My investigations into the ages of progenitors of eminent men is more than twice as comprehensive and thorough as those of all the other men put together. My investigations into thousands of normal cases for the purpose of establishing a standard of comparison stands alone, no other person having done anything of the kind. And all of these things are merely preliminary steps in obtaining coefficients and establishing their value.

Comparing the ages of parents with the quality of offspring is one step in my proceeding. The utmost produced by Galton, Yoder, and Ellis combined amounts to only a fragment of that first step.

Comparing the activity of parents with the quality of offspring is a second step in my proceeding. This second step also involves the establishment of a standard which will indicate what is the normal activity of parents up to the time of reproducing. Neither of these factors of the second step has ever been touched by any other person, and my work on this matter is the only one of the kind in existence.

Combining the first and second steps into a product and comparing that product in parents with the quality of offspring is the third step in my proceeding. No other person has done anything of this kind.

Carrying the product back step by step, through preceding generations of animals of remarkable powers, or animals remarkable for lack of powers, is the fourth and final step in the proceeding, but does not represent all that was done for the purpose of determining the accuracy of the results.

So far herein I have been referring to investigations into the origins of men of great intellectual powers, men commonly referred to as geniuses. In addition, I directed special investigations into the Jukes, the Ishmaels, and the Kallikaks; into parts of royalty and the nobility of various countries, and into the marriage customs and activities of various tribes and races of men both living and dead. Going further, I carried my investigations down through the lower animals, plants, bacteria, and protozoa. As an illustration of the age end of the investigation, the following table will serve:

APPROXIMATE AVERAGE AGE OF REPRODUCTION

Rabbits	1 year
Cattle	4 years
Horses	10 years
Apes	16 years
Digger Indians	21 years
Eskimos	23 years
Polynesians	26 years
Chinese	29 years
Chicago in 1913	31 years
New England in 18th Century	33 years
Galton's Men of Science	36 years
Ellis' Men of Genius	37 years
Yoder's Great Men	38 years
Redfield's Eminent Men	40 years

Let us return to Holmes' book. He quotes my statement that "children of young parents are lacking in physical stamina and mental power," and calls it "an exaggeration." He says "there is no adequate reason for concluding that youth of parents *per se* is responsible for the degenerate heredity of the offspring."

That statement by Holmes represents dogma for which he has no scientific foundation. If he had said the "youth of parents *per se* is not responsible for the degenerate heredity of the offspring" he would have been on sound scientific ground. "Youth of parents *per se*" refers to mere duration, and mere duration is not responsible for anything. But inserting that "*per se*" into either form of statement misrepresents what I presented. Age of parents means time, and I have repeatedly pointed out that time is a factor

in measuring work performed, and is not a factor in measuring anything else. "Youth of parents" means a small coefficient, and that in turn means a small product in the development of powers by exercise. The fact that Holmes uses the term "youth of parents *per se*" when referring to my work is evidence that he is either juggling the facts or else he does not have the slightest idea what it is he is criticising. Also, when a biological work issued 18 years after my "Control of Heredity" was published contains comments of the kind I have quoted from Holmes, it is good evidence that none of those biologists who have hurled their thunderbolts at my head have taken the trouble to learn what it is they are condemning. What I originally presented remains to this day untouched by any criticism.

527 Monadnock Block.

WHY IS THE WASSERMANN?

By CHESTER TILTON STONE, M.D.,

Brooklyn, N. Y.

How many of us are relying too strongly upon the Wassermann test in determining the proper treatment for our patients? Do we realize the stress and faith we have taught the lay public, as well as ourselves, to place in this reaction which no one can say is absolutely correct? If this is a false teaching we are inspiring, and if too we are stimulating and fostering an incorrect standard, it is high time that we at least modified our beliefs and teachings. I am not an iconoclast. I am merely trying to bring up a subject which has been smouldering in my mind since I did my first test. If others care to fan the sparks and produce a flame which will give us more light, my efforts are well rewarded.

A patient comes with a definite chain of symptome which point to, or at least makes us suspicious of syphilis. The Wassermann test is made. It is reported negative. We at once look for other causes and forever rule out further thought of lues. A patient is sent for a routine Wassermann in the course of his general examination. His blood is reported negative. Straightway we exempt him from the luetic draft. A patient is under treatment for syphilis. He is sent to the laboratory that we may learn whether he is cured. The report is negative. He is discharged supposedly recovered. A man wishes to marry. He comes for a clean bill of health. His Wassermann is found positive. He denies all infection. We either call him a liar or tell him that it is hereditary and forbid his marriage, until well. Let us for a moment follow these set cases which all of us see daily. The first enters our office.

If we are in general practice we will either treat the patient symptomatically, search deeply for some mysterious disease which is causing his symptoms, or send him to one or more specialists. In the latter case we will carefully underscore Wassermann negative in his report and the patient will tell the specialist several times that his blood has been found all right. In my mind the real specialist will in most cases recognize the symptoms and, if he is a descendant of Thomas, institute specific treatment despite the findings of the laboratory. 'Tis true many cases in this class are very obscure. However, we still have our therapeutic tests. Many overlook that which is plainest and the patient starts drifting from office to office, condemning the profession as he goes, until he finally quits in disgust.

The second patient is called in. It is perhaps years later that after receiving a negative report, he reaches one doing special work. His symptoms are now real and his suffering intense. Despite his protests that he is free from infection, he is put on specific treatment. He may clear, or it may be too late, and the chain of symptoms be aggravated by treatment.

Patient number three, after receiving his negative report, has married. Some years have elapsed. He develops "stomach trouble" for which he seeks relief. His "stomach doctor," in questioning him, learns that he has been discharged as cured by Dr. X, prominent in his line. After a year of unsuccessful treatment the patient returns to Dr. X. Another Wassermann is made and found negative. Despite the fact, he is given further treatment. The stomach responds. He is then advised to bring in his wife and children.

Now the man who wishes to marry comes in. He has just proposed and expects to wed within a month. He is sent to a busy laboratory. A girl takes his blood in test tube No. 2. She has just taken another specimen in tube No. 1. Her attention is diverted. Tube No. 2 is placed in No. 1 hole in the rack. The marriage is postponed.

Are we being fair to our patients, to the profession, to ourselves by such methods? We most certainly are not. We are by far too easily satisfied. Consider if you please for a moment where and how our tests are made. There is the high class serologist. Does he always do our tests or are they done by assistants? How are these chosen, trained, and supervised? Is he careful, conscientious, masterful at his art? Are his reagents carefully standardized? What tests and methods does he employ? What is his standard scale? Does he run tests individually or *en masse?* This last point is the big stumbling block in many instances. Here is a vital question to be settled for each patient. Who of us would think of treating one hundred patients at one operation? Still, in the laboratory one hundred innocent patients may be doomed by one error in technique.

All of the above questions apply to the fair, the mediocre, and the commercial laboratories. As we go down the scale the awful truth confronts us that the search is more for the feathers of the eagle than the antigenic properties of the blood. Many laboratory workers are incompetent and many ignorant, merely doing the best they know how. Still we persist in honoring equally reports from any source whatsoever. Recently, as I have done in several instances of special cases, I split a specimen of blood, sending a sample to each of four reputable serologists. Four different reports came back on the same blood. Now who was right and what is the meaning of right?

The faults are numerous. They seem to lie in improperly performed tests due to carelessness, ignorance, and in trying to do too many tests at one run. Instead of (as I suggested in "Sources of

Error in the Wassermann Technic," *New York Medical Journal*, June 20, 1914) concentrating on one method and perfecting it, every one is trying to think of a new one to be called by his name. Then too, the scale varies. A 1+ with one worker is a doubtful with another, etc. There seems to be a growing doubt with many whether this is a test for syphilis. Other diseases give a positive Wassermann, and 10 per cent. of syphilitics do not react. It remains to be proven.

From my series of cases the following are picked at random: A. R. B. and B. E. had hemorrhoids (?) removed, Wassermann negative, later proved to be condylomata which cleared under specific treatment; no history of infection. W. W., no history of infection, Wasermann negative, vague pains throughout the body; cleared under specific treatment. C. S., history of infection, treated twenty years before, Wasermann negative, showing symptoms of beginning paresis when first seen. H. D. came with diagnosis of carcinoma of penis, Wassermann negative; failed to respond to radium, cleared under specific treatment. D. J., history of five miscarriages, no history of infection, Wassermann negative. After course of treatment gave birth to two healthy children. E. L., treated for years for tuberculosis, spent some time in Saranac, Wassermann negative. Now being treated for syphilis of lungs. Clearing.

It is useless to attempt a reform without suggesting the alternative. First of all we need more careful research along these lines, followed by clinical demonstrations of the results. We must have a standard test. This test to be used in identically the same way by every worker. If need be, there should be a laboratory inspector to see that no variations are introduced. Reports should be based on a standard scale. One plus should mean the same wherever seen. A better checking system should be installed to avoid mistakes in specimen tubes. Until this time arrives we should not place too much reliance on the absolute meaning of a negative or a 4+ Wassermann reaction.

Do not forget that common sense plus therapeutic tests did much before the Wassermann was ever used.

62 PIERREPONT STREET.

Medicolegal Notes.

Hypothetical Question Held Too Broad.—In an action for death alleged to have been the result of a fall in alighting from a train, counsel for the plaintiff asked several physicians, experts, substantially the following question: "If she received an injury to her left side and a shock to her knee and body by falling on the ground, and she was at that time suffering from tuberculosis, and afterwards was continuously confined to her bed until she died, what is your opinion as to whether or not that injury hastened her death?" There was no testimony that the deceased's side was injured by the fall, and no testimony that any part of her body was injured except her knee and ankle. It was therefore held that the hypothetical question was too broad, because it assumed the existence of facts the evidence did not tend to prove. The question was defective. There was, however, evidence tending to establish some of the facts assumed in the hypothetical question; and it was held that counsel for the defendant, if he desired to have eliminated the particular fact which he claimed on appeal there was no evidence to sustain, should have called the trial court's attention to it by specific objection to such fact, and it was too late to make the specific objection for the first time on appeal.—Payne v. Thurston, Arkansas Supreme Court, 230 S. W. 561.

Medical Testimony as to Powder Burns and Shock.—In an action on an insurance certificate, where the insurer pleaded suicide as a defense, it was held that the testimony of physicians in relation to the question of shock from two bullet wounds immediately over the heart and within an inch of each other, and the effect of the shock, and in relation to powder burns, was properly admitted over objection that the physicians had not qualified as experts, the matter of powder burns being of common knowledge and on the question of the effect of shock on the human body no higher degree of expert knowledge being obtainable than that of qualified physicians and surgeons.—Bear v. Sovereign Camp, W. O. W. (Mo. App.) 230 S. W. 369.

Question to Medical Witness as to Result of Injuries Held Not to Invade Province of Jury.—In a personal injury case a medical witness, who had testified that the plaintiff had suffered a gradual and progressive degeneration and weakening, both physical and mental, was asked by plaintiff's counsel: "Could that result from the injuries?" and replied, "It could be produced for that reason." It was held by the Kansas City Court of Appeals that the question did not invade the province of the jury because "the most that this doctor could say would be that in his opinion it might be produced by the injury. The plaintiff could have used either the terms, "might, could, or would," and the question would have been proper under the decisions of the Missouri courts.—Roach v. Kansas City Rys. Co. (Mo. App.) 228 S. W. 520.

The Missouri Supreme Court holds that while an expert may express his opinion as to whether or not an injury is permanent, his answer, in order to stand the test of judicial criticism, must show that the result which he has indicated will follow to a reasonable degree of certainty. In other words, his opinion is held incompetent if based upon a mere possibility as to what may occur in the future.—Mahany v. Kansas City Rys. Co. (Mo.) 228 S. W. 821.

Ocular Symptoms Admitted to Prove Existence of Neurasthenia.—In an action for personal injuries the petition alleged permanent injury to the plaintiff's whole nervous system and that the plaintiff was suffering from neurasthenia. The Supreme Court of Texas, in answer to a question certified by the Court of Civil Appeals, holds that medical testimony as to ocular symptoms was admissible, the condition of plaintiff's eye being both a symptom and a result of traumatic neurasthenia, though no affection of the eye was pleaded. The court cited H. & T. C. R. Co. v. Hanks, 58 Tex. Civ. App. 298, where it was held that evidence was properly admitted of kidney trouble, because symptomatic of cellulitis, a diseased condition of the covering of the bones of the foot, the issue being whether the injured party had cellulitis, and Ft. W. & R. G. Ry. Co. v. White, 51 S. W. 856, holding that evidence was admissible to show the spitting up of blood, where this indicated an injury to the chest.—C. L. Smith Oil Co. v. Riggs, (Tex.) 230 S. W. 139.

Agreement Not to Practice by Seller of Practice.—The Iowa Supreme Court holds that an agreement on the sale of a physician's business and good will to other physicians, that the seller will not engage in the practice of medicine or surgery in the town or surrounding country for a period of 10 years is valid, but that a suit to enjoin the seller from practicing in violation of the contract would not lie where it appeared that the seller's treatments in the past had been mainly emergency cases in the vicinity of the town, that he recognized the binding obligation of the contract and that most of the transactions occurred shortly after the defendant's retirement and a considerable time before the suit was brought.—Gates v. Leonard, (Iowa) 183 N. W. 462.

Experts Testimony Invading Province of Jury.—The Nebraska Supreme Court holds that it was not error to refuse to permit a physician to testify whether he could discover any reason why the plaintiff in a personal injury case could not have been at work when examined, the physician having fully detailed the condition of the affected parts. The questions called for a conclusion, which it was the jury's duty to determine.—McGowan v. Dresher Bros. (Neb.) 183 N. W. 560.

MEDICAL RECORD.

New York, December 31, 1921.

THE NEEDS OF THE UNITED STATES PUBLIC HEALTH SERVICE.

THE World War caused of necessity a great increase in the duties and responsibilities of all the government medical services, but the greatest and most lasting increase has been in the work of the United States Public Health Service. The medical corps of the Army and Navy, although larger than before the war, are nevertheless reduced approximately to a peace footing, but the work of the Public Health Service has permanently increased and cannot for many years, if ever, be lessened to any appreciable degree. This is due in great measure to the fact that the care of the disabled veterans has been entrusted to the Service, and in nearly equal measure to the increase in the merchant marine from some 6,000,000 tons in 1914 to 16,000,000 tons in 1921. As is known, one of the duties of the Service, and the one for the performance of which it was originally established, is the care of sick and disabled sailors of the merchant marine. Furthermore, the quarantine stations of the country are now maintained by the Public Health Service, and much additional labor is also thrown upon it through the increasing cooperation with State and municipal boards of health in public health and interstate quarantine duties. An indication of these increased activities is given in the great expansion of the personnel from a total of 2,044 in July, 1917, to 15,095 in May, 1921. Of this personnel the surgeons numbered 508 in 1917 and 3,249 in 1921, but the number of regular commissioned officers fell in this time from 212 to 199, the increase being chiefly in the corps of acting assistant surgeons, whose number rose from 296 in 1917 to 2,166 in 1921; at the present time there are 884 reserve commissioned officers who may be called upon in an emergency.

This is a most unsatisfactory condition and one which cannot fail to cripple the Service in a time of stress. As one can readily understand, reliance upon an emergency personnel is very far from desirable or even safe. It is not easy to secure competent medical men for temporary service, even at high salaries; moreover such persons will not be likely to remain in the Service if a better opportunity presents itself elsewhere, and so just when they have become familiar with their duties and are getting to be of use to the Service, they may "float" away to some other more pleasant or more remunerative occupation.

To meet this situation and to raise the Public Health Service to a parity with the other government services a bill has been introduced into both Houses of Congress "To reorganize and to promote the efficiency of the United States Public Health Service." This bill provides for the transfer of not to exceed 550 officers of the Reserve Corps, including 50 dental surgeons and 50 scientists other than medical officers, to the regular corps of commissioned officers of the service. This would at once raise the number of regular medical officers to 650, the 450 new officers being already seasoned men with an experience of at least three years in the Service or in the Medical Corps of the Army or Navy. The bill also provides for admission to the regular corps of commissioned officers, of engineers and experts in various branches of science whose services are demanded in public health work. It will also secure the addition to this corps of 50 dental surgeons, the necessity for whose services needs no emphasis in these days. Finally the proposed legislation places the commissioned officers of the Public Health Service upon the same status as regards pay and promotions and provision for retirement as medical officers in the other branches of government service.

The country is to be felicitated upon the enacting of this measure of justice to the Public Health Service—for we take it for granted that Congress will pass the bill without opposition. The health of the country is largely in the keeping of this Service, especially in times of danger through threatened invasion of disease from without or of epidemics arising within our own borders, and the increased efficiency of the Service means greater security from sickness of every man in the United States and of every member of his family. The only objection to a bill of this nature which it could occur to anyone to raise would be on the score of economy, and such an objection will not hold in this case, since the measure calls for no increase in appropriation; none is necessary, indeed, for the present appropriation is ample to put into operation all the changes contemplated. The carrying into effect of the provisions of this bill will save the lives of many of our people, and the desirability of its speedy passage admits of no question.

HUTINEL'S DISEASE.

IN 1893 Hutinel described an affection which he termed cardiotuberculous cirrhosis of children. With the exception of Küssmaul's *mediastinopericarditis callosa*, which is probably the same affection, it does not reappear in literature for many years. Hutinel redescribed it in 1908, and since that period there have been a number of contributions to the subject. As described by the French pediatrist the disease begins as a bronchitis or a

pleurisy and then there supervenes an enlarged liver with ascites, with the added picture of asystolia, edema, and cyanosis. But there may be neither antecedent bronchitis nor pleurisy, the initial manifestation being an adhesive pericarditis. During life the cardiac lesions may give inconspicuous and diverse symptoms. Autopsy in advanced cases shows a large nutmeg liver, pericarditis, pleurisy, mediastinitis and at times tuberculous peritonitis. The entire process is regarded by Hutinel as a tuberculous perivisceritis. There has been much speculation as to the mechanism and sequence of these lesions. According to one view adhesive pericarditis in the child is quite capable of setting in motion the entire sequence, while another view is that the involvement of the heart is entirely secondary.

In the *Revue médicale de la Suisse romande* for October, 1921, xli, 10, Curchod contributes an article on the subject with several personal cases. Under the head of theories and differential diagnosis one certainly would expect some reference to the peculiar affection known as polyserositis, but there is none, and the bibliography contains no allusion to such a malady under any of its numerous synonyms. Nevertheless some of the cases which have been described under polyserositis might well have been cases of Hutinel's disease. The latter is indeed peculiar to children while polyserositis is regarded as an affection of adults; nevertheless the patient with Hutinel's disease may be in his twenties when he comes to consultation. Some cases of polyserositis are tuberculous and the entire syndrome has been looked upon by some internists as a paratuberculosis.

In one respect there seems to be a marked difference. Polyserositis has been essentially a medical disease ending in a cachexia while in Hutinel's disease resection of the thorax has been thought of even by the discoverer himself as a means of relieving the compression of the heart by its fibrous investment. In Curchod's three cases one was regarded as inoperable while two were subjected to operation, one result being "satisfactory." The patient lived two years after operative relief. The other case ended fatally despite operation. The latter is known as precardiac thoracectomy, the technique of which was originally formulated by Brauer. There was apparently no additional attempt at cardiolysis.

In his clinical and autopsy details Curchod on several occasions uses the term polyserositis, apparently as a convenient descriptive term, but there is no point of contact with the polyserositis of internists which has an extensive literature and which was independently isolated as an autonomous disease by a number of clinicians, as Bamberger, Pick, Curschmann, and others. Originally the clinical pictures differed among themselves, but eventually were brought under a single fundamental disease. One cannot escape the conviction that the latter broad conception can readily be made to include Hutinel's disease.

A SOMEWHAT QUESTIONABLE QUESTIONNAIRE.

As is known to those whose great privilege it is to read the *Journal of the American Medical Association*, the editor of that periodical announced a few weeks ago that a questionnaire on alcohol as a therapeutic agent had been sent to some of the physicians of the country; to be exact, it was stated that it had been sent to forty thousand members of the Association and ten thousand non-members — fifty thousand in all, or about one-third of the total number of practitioners in the United States. It seems a pity, if the Association was to be put to the great expense of this straw vote, that the finality of the result could not have been better insured. The question to be settled, assuming it could ever be settled in this loose way, is : "Does alcohol possess any therapeutic value?" The questions asked were: "Do you regard whisky as a necessary therapeutic agent in the practice of medicine; if 'yes,' in what diseases or conditions do you regard whisky as necessary?" And then the same question was repeated twice, substituting the word beer for whisky in one, and wine for whisky in the other. There were several other questions in the list, but they were irrelevant and could serve only to befog the issue.

If an all wise Congress had decided to forbid the use of arsenic in medicine for the reason that people had been killed by the drug, and it was thought desirable to get the opinion of the medical profession regarding its therapeutic value, what would be thought of a questionnaire sent out to a limited number of individuals asking if the recipient regarded Fowler's solution as a necessary therapeutic agent, and in what disease or condition he regarded it as necessary; repeating the question with the substitution of Donovan's solution, and again with that of iodide of arsenic? And what would be thought of the accuracy of the returns as indicative of the true belief of the medical profession, if the questions were sent to about one-third of the practitioners in one country of the world, and answers were received from a little over half of these? And finally, how much weight would be attached to a majority vote on one side or the other, if all practitioners were regarded by the questioner as equal in experience and knowledge, the opinion of a one year graduate being accepted as of equal weight with that of a man of fifteen or twenty years' practice, or that of an acknowledged authority in pharmacology and therapeutics?

This is the MEDICAL RECORD'S own questionnaire, and any one who wishes to answer it may do so. The answers, no doubt, like those to our esteemed contemporary's questionnaire, would be varied, mutually contradictory, and absolutely inconclusive.

INTRACARDIAC INJECTIONS.

THE emergencies of the late war gave an impetus to the practice of intracardiac injection, notably in certain shock cases. This subject had its beginnings in part at Vienna in 1905 in a series of ex-

periments in which laboratory animals "killed" with chloroform were reanimated by intracardiac injections of adrenalin. Control cases of intravenous injection proved unavailing. While in these experiments the heart was laid bare, it was suggested that in human emergencies the injection could be made through the thoracic wall. Several years later Latsko reported reanimation in cases of human cardiac arrest, in which the latter method was used. Recently Vogt was able to report fifteen collected cases of this type, to which could be added several others. All the cases in this series are examples of permanent reanimation, and do not include temporary benefit and failures. Guthmann, who reported five cases in all, had two successes and three failures. In the latter the patient had peritonitis and the rally of the heart was not permanent. His two successes were in internal hemorrhage and chloroform syncope respectively. In addition to cases in surgical and obstetrical practice there are medical indications, notably in cardiac failure due to either heart lesion or general infection. Schultz practised these injections in a child of 7 years with double pneumonia in which cardiac lesions with broken compensation preexisted. In regard to the substance to inject, one cannot depend on the usual cardiac stimulants but must make use either of adrenalin or pituitrin, or both combined. The technique is very simple, the injection being made in the left intercostal space one or two finger-breadths to the left of the sternal border. The dose is 1 cm. of a 1 1000 solution, according to Cheinisse (in *La Presse Médicale* for October 22, 1921, xxix, 85), from whose article most of the preceding data are borrowed.

"Granulie."

This term has long been used in France to express miliary tuberculosis as distinct from pulmonary consumption. In English the corresponding term would be granulia or granulosis. Both affections are due to the activities of Koch's bacillus, yet differ clinically to a noteworthy extent. But "granulie" is apt to break out in the subject with ordinary pulmonary tuberculosis, in which case the disease picture will be greatly modified, especially as the basic affection may have become latent. In *Le Progrès Médical* for October 29, 1921, xlix, 44, Ramond sketches the following picture: A girl of 23, still in apparently good condition, is undergoing the evolution of a pleuro-pulmonary tuberculosis which has only recently caused symptoms. The personal antecedents are good but the family is badly tainted. Under the indicated management the patient throws off the attack, becomes symptom-free and is back in her normal place in society. Of a sudden the author is summoned to find the patient gasping for breath with 60 respirations a minute. These symptoms had but recently set in. She had a high temperature. The entire chest seemed involved in some acute process. Had the author not known the history, he might have been much embarrassed in making a diagnosis; but the latter was only too obvious—a hopeless, miliary tuberculosis expressed clinically as a suffocative catarrh. If one were summoned suddenly to such a patient for the first time it would be necessary to exclude cardiac disease, pulmonary edema from Bright's disease, bronchopneumonia, and perhaps other maladies. It should not be difficult to do this, and we are left with the diagnosis of acute miliary tuberculosis—granulia. If the symptoms are less acute and less pronounced typhoid fever may require exclusion. Caseous pneumonia and "galloping consumption," so called, are quite different from granulia.

News of the Week.

Gorgas Memorial Medical School.—A movement has been started to raise a fund of $2,000,000 to establish a medical school as a memorial to Major General William C. Gorgas. The present plan is to have the entire nation contribute to the fund and to locate the school at Tuscaloosa, Ala., where General Gorgas lived as a boy. Dr. Seale Harris of Birmingham, Ala., is chairman of the national committee.

New State Health Department Secretary.—Mr. Curtis E. Lakeman has been appointed secretary of the New York State Department of Health to succeed Dr. John A. Smith, resigned.

The Polyclinic Hospital of this city which was loaned to the U. S. Government during the war, is soon to be returned to its trustees, according to a recent announcement of Col. C. R. Forbes, Director of the U. S. Veterans' Bureau. Complaint had been made that the Government was keeping the hospital after the necessity for so doing had passed. The ambulance service will be restored on January 1, but the entire hospital will not resume its functions until a short time after its return to the trustees.

Sale of Horsehair Shaving Brushes Prohibited.—Because it has been found that anthrax may be contracted through the use of shaving brushes made from horsehair, the Public Health Council of the State Department of Health has passed a regulation, effective January 1, prohibiting the manufacture, sale, or offering for sale of such brushes in the State of New York.

A Protest Against the Cornell Clinic.—At the November meeting of the Bronx County Medical Society resolutions were unanimously adopted protesting against the establishment of the clinic for pay patients by Cornell University. The establishment of the pay clinics is declared to be inimical to the best interests of the public at large and of the medical profession in particlar because such clinics are in direct competition with the physicians who practise in city. The resolutions condemn the conduct of the physicians who permitted their names and their positions to be used for newspaper publicity in the advance announcements of the clinic, and assert that these very men will not and cannot offer their services to the patient, but will merely act in an advisory capacity far from the clinic rooms. Finally for these reasons, the society "recommends that the respective county societies to which these men belong and under whose jurisdiction Cornell University Medical School exists shall take proper and fitting action to reprimand these men and the University and furthermore shall recommend to its members that they do not accept positions in a

dispensary that works to the economic detriment of their brethren."

Danger from Automobile Exhaust Gases.—At the suggestion of the Surgeon General of the United States Public Health Service, the State Commissioner of Health has issued a warning regarding the danger to health and life from the inhalation of exhaust gases from automobiles. The effect of these gasses is produced very quickly, usually before the victim realizes the danger. The following precautions should be observed in all garages: (1) Always open the garage door before starting the engine. (2) Do not allow the engine to run for any length of time in a closed garage. (3) Do not work near the exhaust of a running automobile engine. (4) Special precautions as to ventilation are necessary when in garage pits. (5) When the exhaust is used for heating a closed car the system must be free from leaks.

Influenza at Coblenz.—Influenza is reported to be epidemic in Coblenz. All the schools have been closed because of the outbreak, but admissions to the hospitals remain about the same as during the earlier period of the epidemic.

"Wireless Telephone Health Bulletin Service."—The United States Public Health Service has inaugurated a bi-weekly "Wireless Telephone Health Bulletin Service" by broadcasting through the Naval Radio Station at Anacostia Va., a message of holiday good cheer to the country. It is planned to send through the same facilities at 9 P.M. every Tuesday and Friday a wireless message comprising advice as to how the average man and woman may insure continued good health. The messages will be of such wave length, it was said, that any radio station, amateur or professional, which has a telephonic attachment, may be able to read them. Under very favorable weather conditions the service expects its "helpful health hints" to be heard on the Pacific Coast, in Europe, and in northern South America.

Eyesight Saving Campaign Begun.—Industrial, engineering, and educational agencies are linking their efforts in the nation-wide movement for the conservation of vision. Big industries have taken up the question with serious concern in an effort to minimize accidents and reduce the number of the nation's industrial blind, now placed at 15,000. Dr. John J. Tigert, United States Commissioner of Education, has been elected a member of the Board of Councilors of the Eyesight Conservation Council of America, which includes Dr. Arthur L. Day, director of the geophysical laboratories of the Carnegie Institution, Washington; Dr. Thomas D. Wood of Teachers College, Columbia University; Dr. Allen J. McLaughlin, United States Public Health Service, Washington; Dr. Frederick R. Green, secretary of the council on health and public instruction of the American Medical Association, Chicago, and Dr. W. S. Rankin, State Health Officer of North Carolina.

A Disease Prevention Hospital in Philadelphia.—The first integral part of a hospital devoted exclusively to the prevention of disease was recently opened at the Children's Hospital, Eighteenth and Fitzwater streets, Philadelphia. The Associated Medical Clinic, which has been operated by the children's bureau, has been transferred to the department for the prevention of disease in charge of Dr. J. Prentice Murphy. This department includes a health clinic, diphtheria clinic, preschool nutrition clinic, mothers' conference, school nutrition class, mothercraft, boys' health club, dental clinic and everything that can be taught a mother to help her in seeing that her children are healthy.

Annual Report of Henry Street Nursing Service.—The Records office of the Henry Street Settlement's Visiting Nursing Service has issued a report which shows that it has established nursing centers in the Bronx and Richmond, and conducts in all twenty-two of these centers. During the past year more than 42,000 patients were taken care of. The 212 visiting nurses made last year more than 336,722 visits, at an average cost of $1.01. The service is now 40 per cent self-supporting. The work has grown to such an extent that the Henry Street building no longer affords accommodations for the activities that it conducts. A part of the report deals with the plans for the new administration building which Mrs. Jacob H. Schiff is to erect at 97 and 99 Park Avenue as a memorial to her husband which will be used primarily for the administration of the Visiting Nursing Service.

Hospital Notes.—The largest of the hospitals which the Shriners of North America plan to build in a number of cities throughout the country has been begun in St. Louis. Ground was broken on Dec. 14 with impressive ceremonies. The hospital will be open to any crippled child regardless of race or religion and treatment will be free.

A special clinic for treatment of goiter and kindred afflictions and an additional structure for medical and surgical patients are to be added to Seton Hospital, Cincinnati.

The Garretson Hospital, Philadelphia, is to have an addition which will increase its bed capacity by sixty-three. In addition the new hospital building will have a department of oral surgery, which will be conducted in conjunction with the Philadelphia Dental College, and a training school for nurses. It is proposed to change the name of the hospital to Greatheart.

Construction on an addition to the Children's Hospital, St. Louis, is to be begun at once. The addition to the building and equipment will cost between $200,000 and $300,000, and will be covered by the hospital reserve fund and a gift of $52,500 from the Rockefeller Foundation. Special provisions are being made for the accommodation of private patients.

Plans for the collection of $150,000 for the construction of a new city hospital in Roanoke, Va., are announced. Of this sum $104,000 has already been subscribed and partly collected. Work will be begun not later than the latter part of March, 1922.

A tuberculosis hospital unit is to be constructed at the Marion, Indiana, Soldiers' Home. It is estimated that the new institution will cost upward of $140,000.

The Bikur Cholim Hospital Association laid the cornerstone for its new $1,500,000 building at 810 Bushwick Avenue, Brooklyn, on Dec. 18. The Federation of Jewish Charities has expressed its dis-

approval of this undertaking, claiming that there is no need for a Greater Bikur Cholim Hospital. It is claimed that the policy of the new institution will be unique among Brooklyn hospitals in that no charity case will ever be turned away without medical attention.

The drive for $250,000 for an addition to the New Rochelle (N. Y.) Hospital has been closed, and announcement made that a total of $275,000 has been contributed.

Gifts and Bequests.—By the will of the late Alice M. Hirst of Philadelphia one-half of the income from a residuary estate of $65,000 is bequeathed to the Hospital of the University of Pennsylvania.

By the will of the late Cora Feltus of Philadelphia the sum of $20,000 is bequeathed to the Pennsylvania Epileptic Hospital and Colony Farm at Oakbourne, Pa.

Professor Bergonie of the Faculty of Medicine in the University of Bordeaux has received the Edward Longstreth Medal in honor of his invention of the "electro-vibreur" for locating metal fragments in the bodies of wounded soldiers.

Dr. Franklin H. Martin of Chicago has received the Distinguished Service Medal by order of Adjutant General Harris. The citation read: "For exceptionally meritorious and distinguished service as Chairman of the Committee on Medicine and Sanitation of the Council of National Defense. He rendered valuable assistance in solving the important medical problems of the war."

Dr. Charles E. Perry of Athol, N. H., has been appointed by the Governor of New Hampshire to the position of superintendent to the State Hospital for Tuberculosis, Glennscliffe.

Dr. Charles A. Ravey has tendered his resignation as city health officer of Burlington, Vt., in order to succeed Dr. H. E. Buttles as serologist to the State Laboratory of Hygiene.

Dr. George Gates, former medical director of the Red Cross, returned to this country on the steamship Lorraine on Dec. 24.

Dr. A. C. Vickery has been appointed superintendent of State Hospital No. 2 at St. Joseph, Mo., to succeed Dr. Porter Williams, who has been appointed superintendent of the hospital at Nevada, Mo.

Dr. Joseph F. Londrihan has been appointed head of the staff of St. Mary's Hospital, Hoboken, N. J.

Dr. Frank B. Broderick of Detroit, Mich., has been elected State Welfare Officer of the Charles A. Larned Post of the American Legion.

Harvey Society Lecture.—Dr. George H. Whipple, Dean of the University of Rochester Medical School, will deliver the fourth Harvey Society Lecture at the New York Academy of Medicine, Saturday evening, Jan. 7, 1922. His subject will be "Pigment Metabolism and Regeneration of Hemoglobin in the Body."

Obituary Notes.—Dr. HENRY J. BERGOLD of Brooklyn, N. Y., died of arteriosclerosis at his home on December 20, at the age of seventy-two years. He was graduated from the New York University Medical College in 1871 and was the last surviving member of his class. He was long a visiting surgeon to St. Mark's Hospital.

Dr. JOSE ALEMAN of Havana, Cuba, died in New York City on Dec. 11, at the age of forty-one years. He was graduated from Havana Medical College and studied in medical schools in Europe.

Dr. JAMES M. BENTLEY of Cincinnati, Ohio, died after a prolonged illness in Baltimore, Md., at the age of thirty-four years. He was graduated from the University of Cincinnati College of Medicine in 1911. During the World War he served as regimental surgeon to the 136th Field Artillery. On his return home at the close of the war he became a member of the faculty of the University of Cincinnati and the College of Pharmacy, and was also a member of the staff of the Children's Hospital and the Cincinnati General Hospital.

Dr. LEANDER MORTON FARRINGTON of Manchester, N. H., a graduate of Harvard Medical School in 1894, died on December 10, at the age of fifty years. He was a member of the staff of Notre Dame Hospital and on the Board of Censors of the Manchester Medical Association.

Dr. BENJAMIN H. MARKLEY of Reading, Pa., a practising physician for forty-four years, who continued in active service until a few months ago, died on December 11, at the age of eighty-three years.

Dr. WILLIAM SIMONTON PACK, a graduate of the Medical College of the State of South Carolina, died at his home in Greenville, S. C., at the age of sixty years. He was a member of the American Medical Association and of the South Carolina Medical Association.

Dr. NELSON H. MESICK of Glenco Mills, N. Y., a graduate of Albany Medical College in 1868, died suddenly of heart disease on December 14, at the age of seventy-six years.

Dr. CHARLES L. BEACH of Hartford, Conn., died after a prolonged illness on December 15, at the age of seventy-three years. He was graduated from the New York Homeopathic Medical College in 1872.

Dr. LUCY EMMA WETHERBEE-ROCKWELL, a graduate of the Boston University School of Medicine in 1899, died at her home in Worcester, Mass., on December 19.

Dr. FRANZ A. R. JUNG of Washington, D. C., died of heart disease at his home on December 16, at the age of fifty-two years. He was graduated from the University of Leipsig in 1894. He organized the Red Cross station at Munich, Germany, at the outbreak of the late war.

Dr. JOHN RANKIN of Brooklyn, N. Y., died of acute dilatation of the heart on December 21. He was graduated from the Long Island College Hospital in 1882, was a Fellow of the American Medical Association, and one of the founders of the Bushwick and Caledonian Hospitals.

Dr. WILLIAM HENRY TIPPIE, a graduate of the Starling Medical College, Columbus, Ohio, in 1895, died on December 11, at his home in Tremont City, Ohio, at the age of sixty-one years.

Dr. C. BRADLEY DOANE of Allston, Mass., a graduate of Dartmouth Medical College in 1895, died at the Massachusetts General Hospital in Boston on December 19, at the age of fifty years.

Dr. REUNETTE E. BOONE, of Santa Rosa, Cal., a graduate of the Syracuse (N. Y.) College of Medicine in 1881, died on December 10, at the age of seventy-six years.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Dec. 9, 1921.

The Royal National Orthopedic Hospital.—This is the only institution of its kind in London and during the past decade there has been a tremendous increase in the calls upon it. Attendances have grown from 11,000 to 82,000 in twelve years. There is now a waiting list of 1,000 crippled children, and this statement is complemented by the tragic one, that, but for the few urgent cases, a year and a half must elapse before patients can be taken in for treatment. A dinner was held on December 7 last at the Victoria Hotel, presided over by Prince Henry, the second son of the King, to further a special appeal in aid of the funds of the hospital. The speaker said, in part, that the Royal National Orthopedic Hospital was the oldest in the country and the only one of its kind in London. It was founded in 1834, and had carried on its work steadily, often in the face of great difficulties, ever since. When he told them that it had cured or relieved well over half a million crippled children of the poorest class they would begin to realize the magnitude of the work which called for their help. The need for it was now greater than ever. If they thought how many crippled children could be noticed in London, or in any great town and considered what a small proportion of the existing cases caught the eye, they would hardly be surprised when he told them that they had over 1,000 children on the books awaiting admission. The present buildings of the hospital were new and up to date, and were opened by his grandfather, King Edward VII, in 1909. The figures showed that the need for more beds and more out-patient accommodations was very real. They appealed confidently to the generosity of the public, for they all knew that the voluntary system of maintaining hospitals had stood the test of time and must be continued. Fifteen thousand pounds were required to equip and open as a county branch, the magnificent site and hospital at Stanmore, which should provide for the waiting list. In addition they proposed to provide twenty more beds for patients of small means, accommodations for a school of orthopedic surgery and for all modern electrical and other treatments. These were urgent and necessary extensions. The financial position of the hospital was more than acute. The hospital owed £14,000 to its bankers. It had already received £3,000 from the new Hospitals Commission. The cost per bed in the hospital compared most favorably with that of any London hospital. Patients themselves contributed generously. Their great aim was to form a center of a national scheme for carrying on the work of orthopedics and to provide accommodation for the treatment of all the crippled children and adults of London and the Home Counties, and for special cases from all parts of Great Britain. Patients of the hospital came from all over the country, and there was hardly a town in the British Isles that could not show strong healthy citizens who had come as young cripples to that hospital. A school of orthopedic surgery would enable the special knowledge of the hospital to be disseminated all over the country. Their opportunity for usefulness, therefore was almost unparalleled and money only was required to enable them to take it.

Necessity for Systematic Propaganda in the Nutrition of the People.—Dr. E. C. Van Leersum delivered a Chadwick lecture at the Royal Society of Medicine on Nov. 24 last, in which he laid stress on the fact that rational feeding is made difficult by the complexity of modern life and he further pointed out that the war emphasized what was known partially before through scientfic experiments that we can do with much less food than we thought we could; but that the lesson is already forgotten again, and most people eat to their heart's content without bothering about economy or health. He took a tilt against the large consumption of meat and stated that the American workman was not satisfied unless he had meat on his table twice or three times a day, although he might very well do with it once, without harm to his health or working power. Van Leersum praised highly the propagandist measures carried on in the United States in order to instruct the masses as to scientific feeding, He said that nowhere except in Germany were found so many scientific investigators who serve industry as in America. The practical sense of the people was reflected in the work of its scientists upon problems, the solution of which promised direct profit. This explained why such men as Armsby, Francis Benedict, McCollum Graham Lusk, Lafayette Mendel, and Thomas Osborne had worked in the field of dietetics. The speaker went on to say that it would be easy to fill a volume with the enumeration and description of the ways in which, in the United States, propaganda is made for rational feeding and drew attention to the fact that the American is much freer in the choice of his means of propaganda than the European, who is more careful to observe the proprieties from an exaggerated fear of making himself ridiculous. The American is a master of advertisement and is never at a loss to find a catching phrase, a slogan to arouse enthusiasm. The operator had been greatly impressed with the attention paid to diet in the American hospitals, and he pointed out that in Europe the problem of feeding in hospitals had, in spite of its importance, not yet received much attention; the matrons, controllers, administrators, and cooks, to whose care it had been entrusted were not experts; at best, they were amateurs as regards feeding and hospital cooking, while the physician was too much taken up by his professional cares to be always able to supervise the carrying out of his dietetic prescriptions. The speaker asked why an end was not put to this unpractical state of affairs by ensuring the execution of these prescriptions in a way similar to that long since taken with regard to medical prescriptions. The work of the dietitians in the slums of American cities also greatly impressed the Dutch professor, and especially was he struck by a popular lecture given in an empty shop in Amsterdam Avenue. In fact,

Van Leersum's lecture was largely a pæan to the superior dietetic methods in America, a laudation which is no doubt, in a considerable measure deserved. However, it may be said that authorities on diet generally do not pay such scrupulous heed to caloric exactitude as formerly, nor do the vitamines constitute such a fetish as they did a short time ago. Neither caloric value nor the possession of the proper vitamine is all that is required to make a diet nutritious, and in discussing and dealing with matters of this kind the injection of some common sense is always useful and desirable. At the same time the American mode of dealing with the diet question is more scientific and sensible by far than the methods in vogue here. Our methods certainly savor somewhat of the slipshod in this direction.

Third International Congress of the History of Medicine.—The congress will be held in London, under the presidency of Sir Norman Moore, from July 17 to 22, 1922. Meetings will be held at the Royal Society of Medicine, the Royal College of Physicians, the Royal College of Surgeons, also at the Wellcome Historical Museum, where there will be an exhibition of objects connected with the history of medicine, surgery, and the allied sciences, including ancient manuscripts, early printed books, pictures, sculptures, and engravings, ancient surgical instruments, medals, and so on. The main subject suggested for discussion by the International Society of the History of Medicine is the principal seats of epidemic and endemic diseases in the middle ages, including plague, gangrenous ergotism, leprosy, and malaria.

The Endocrine Factor in the Production of Immunity and Susceptibility of the Teeth to Caries.—At the meeting of the Section of Odontology of the Royal Society of Medicine, held in the society's building on Nov. 28, last, Mr. E. W. Broderick read a paper on the above subject; his conclusions were as follows: (1) So long as the enamel remains intact there can be no caries; (2) enamel in health progressively hardens as life proceeds; (3) this hardening is due to a progressive laying down of lime salts, taken from the body store of ionic calcium; (4) this body store is, in health, equivalent to the need of the individual at the time, and is preserved by the endocrine apparatus, which is also the fixer of lime salts in the teeth; (5) if the endocrine apparatus is thrown out of balance in the direction of calcium starvation, this reserve store is diminished and fixation of lime salts in the teeth is interfered with; (6) an upset in endocrine balance in childhood, youth, and pregnancy will be in the direction of calcium starvation; (7) calcium starvation will lead to a diminished calcium index in the saliva, with a lessened alkalinity of that secretion, thus directly promoting caries; (8) endocrine derangement, leading to a loss in balance toward calcium starvation, will tend to produce a condition of acidosis by lessening the alkali reserve of the body; in the compensation of this condition the calcium salts, together with other alkaline salts, will be utilized for acid neutralization, and, therefore, not available for hypercalcifying the teeth; (9) if the acidosis be more severe, built-up and fixed inorganic lime will be torn away from bones and teeth to help build up this alkali reserve, and thus preserves life, lowering the resistance of the teeth to caries; (10) that without this susceptibility to caries, exciting causes, such as food fermentation, do not matter; but if immunity be removed, hardly any reasonable care and attention are sufficient to preserve the teeth entire; (11) that endocrine derangement will account for all the conditions leading to dental caries, whether they be diet, lack of vitamines or altered salivary secretion.

1. The Pathological and Physiological Basis of the Surgical Treatment of Chronic Gastric Ulcer. David Cheever.
2. Gastro-jejunal Ulcers. Edward R. Lampson.
3. Hemorrhagic Osteomyelitis. Ernest H. Arnold.

1. The Pathological and Physiological Basis of the Surgical Treatment of Gastric Ulcer.—David Cheever outlines the probable sequence of events in the formation of ulcer thus: As the result of an infarction embolus with thrombosis, an area of mucosa is devitalized beyond the critical degree and surface "corrosion" takes place. In the vast majority of cases this heals quickly and spontaneously, having caused no symptoms at all, or only transient symptoms, or very rarely an acute hemorrhage. In the exceptional case, as a result of the extent of the original devitalization, or of failure of the ulcerated area to obtain rest, or of mechanical irritation by gastric contents, or of constant reinfection from the original focus, or of some obscure disturbance of neurotrophic or endocrine control, or of altered gastric physiology, the ulcer does not heal, penetrates deeper into the visceral wall, and becomes chronic. Instead of the rapid proliferation of mucosal epithelium over a relatively intact submucosa and the regeneration of the secretory glands, the defect is filled with granulation tissue over which the mucosa may spread, perhaps with little impairment of its vascular nutrition. On the other hand, this may not succeed, the granulation tissue becomes converted into fibrous scar tissue, both at the base and sides of the ulcer; this tissue becomes more dense and compact and becomes progressively devascularized by the contraction and thrombosis of its vessels. Thus the vascularity upon which the mucosa depends so strongly for the maintenance of its vitality is destroyed, and healing is imperfect, or cannot be made permanent, or fails altogether. Thus is produced a pathological condition essentially similar to chronic ulcer elsewhere. That the clinical results of medical treatment are excellent does not admit a doubt. But there are cases in which the pathological condition makes healing impossible. Surgery offers a direct attack upon the pathological process, and at the same time tries to correct the physiological dysfunction by a permanent artificial expedient. Most surgeons at present place emphasis on the desirability of excision of gastric ulcers. While many favorably placed duodenal ulcers may be excised, it is justifiable not to insist on their removal since the complete rest with freedom from hydrochloric acid digestion afforded by exclusion makes it unnecessary. The figures of various surgeons are quoted, which make it clear that there is a wide discrepancy in the statistics of the results of surgical treatment of ulcer and as a contribution to this field a preliminary survey of 134 cases of gastric and duodenal ulcer from the clinic of the Peter Bent Brigham Hospital, Boston, is presented. Among these 134 patients there were six post-operative deaths, giving a mortality of 4.4 per cent. Of the total number 82 were duodenal ulcers, 51 gastric ulcers, and one was not stated. Of the 82 duodenal ulcers, 48 have been traced, and of these 60 per cent. are well, 12 or 25 per cent. have slight symptoms, and 7 or 14 per cent. have definite recurrence; no case reports a worse

condition than before operation. Of the 51 gastric ulcers, 75.8 per cent. are well, 17.2 per cent. have slight symptoms, and 6.8 per cent. have definite recurrence. When it is remembered that surgical statistics deal only with proved cases of ulcer and that it is undoubtedly true that the patients who are operated upon present more serious conditions and complications on the average than do those who are treated medically, it is reasonable for surgery to claim an honorable and accepted rôle in the treatment of chronic ulcer.

4. The Local and General Treatment of Cutaneous Anthrax.—Joseph C. Regan reviews the subject of the serum treatment of anthrax and reports a series of eight cases treated at the Kingston Avenue Hospital, Brooklyn, by the local and general administration of Eichhorn's serum combined with complete rest in bed, with resulting recovery of all eight patients. The serum should be administered both locally around the lesion and generally into the circulation by the subcutaneous, intramuscular or intravenous routes. In mild cases, with little or no constitutional symptoms and a small well circumscribed lesion with little edema, the serum need not be given more often than every twelve to twenty-four hours, and commonly not more than four injections are required of 40 to 50 c.c. each (Eichhorn advises 50 c.c.). The first may be given intravenously, the subsequent intramuscularly and subcutaneously. In severe cases with large voluminous lesions and extensive edema, with or without marked constitutional symptoms, the serum should be administered by the intravenous route in doses of from 80 to 130 c.c. (Eichhorn recommends from 100 to 200 c.c.) every six to eight hours. In septic cases the injections should be made every three to six hours in doses from 100 to 200 c.c. (Eichhorn recommends from 200 to 300 c.c.), and this type of treatment continued until septicemia subsides. Arsphenamine may yet prove a useful adjunct in the treatment of these desperately ill patients. The local injection of serum around the lesion every twelve to twenty-four hours is a most desirable method to replace the local measures until lately in common use. It possesses none of the disadvantages or dangers of the previous methods. In these cases the acute inflammation disappeared from the second to the sixth day of treatment, the eschar separated from the twelfth to the twenty-first day, and the wound healed from the twentieth to the thirty-second day. No sequels were noted in any instance and the scar left was so minute as to pass unnoticed. The acute stage was over within a week.

5. Food Infections, with an Illustrative Outbreak.—M. J. Rosenau and Harry Weiss describe an outbreak of food poisoning caused by *B. enteritidis*, and state that very few such outbreaks have been reported in this country. They occur more frequently on the continent of Europe and occasionally in England. This outbreak occurred in Washington, D. C., among a number of students of the Georgetown Medical School, following a meal partaken of by twenty-five students, eighteen of whom were made ill. They suffered from an acute infectious fever, having a short period of incubation, sudden onset and temperature of from 102° to 103° F., with gastrointestinal symptoms. A study of the situation made it quite clear that the food responsible was bread pudding. Just how it became contaminated has not been worked out. Samples of the pudding showed the presence of *B. enteritidis* and specimens of blood obtained from three of the students about ten days after the onset of symptoms showed specific reactions for a type strain of this organism, but no agglutination was obtained for organisms of the typhoid group or *B. coli*. The fact is emphasized that in the vast majority of outbreaks of food infection the food affected is not noticeably altered in either appearance, taste, or smell. The prevalent idea that poisonous foods must be "tainted" still persists, although long exploded. Bacilli belonging to the Gaertner bacillus group cannot be detected in food or water, any more than the typhoid bacillus or cholera vibrio can be detected with the unaided senses. It is not decomposed food but infected food that is likely to cause trouble. The term food poisoning is not well chosen so far as infections with the Gaertner bacillus are concerned. The bacillus produces an acute febrile infection, specific in nature. The disease in all essential particulars belongs to the group of intestinal infections, including typhoid fever, dysentery, and cholera.

10. Cultivation of Rickettsia-Like Bodies in Typhus Fever.—Leo Loewe, Saul Ritter and George Baehr refer to previous publications in which they reported the isolation of an anerobic gram-positive bacillus from the blood in typhus fever, together with considerable serological and experimental evidence, which tended to support the view that this organism played an important causative rôle in the disease. In the present article they describe the methods by which they have succeeded in recovering from the blood of typhus fever patients minute bodies which are morphologically and tinctorially similar to *Rickettsia prowazeki*. Subsequently these bodies were also cultivated from the blood, brain, and kidneys of guinea-pigs, reacting to the inoculation of blood from typhus fever patients suffering with the endemic or epidemic form of the disease. Similar studies were carried out with a strain of virus originally obtained in Poland and kept alive by numerous successive passages through animals. The same Rickettsia-like bodies were isolated from the blood, brain, and kidneys of guinea-pigs, suffering from the experimental disease induced by this Polish virus. The organisms have also repeatedly been recovered from the blood, brain, and kidneys of guinea-pigs in which the disease had been produced by a previous intraperitoneal inoculation of culture material. The bodies cultivated by these methods differ morphologically from the bacillus of Plotz in that they are even more minute, of slightly hazy outline, and do not assume polymorphous involution forms. With Giemsa stain the bodies always take a ruby red color, they are not stained by Gram's method, and are stainable with ordinary anilin dyes only with considerable difficulty. There are also differences in the cultural characteristics. It has thus far been impossible to grow bodies on a solid medium, such as Veillon's ascitic fluid glucose sugar, a medium on which the bacillus of Plotz grows readily. Attempts at conversion of one form into the other by cultural means have been unsuccessful. Furthermore, in a glucose ascitic fluid medium no acid is formed, although the Plotz organism under similar conditions rapidly produces an intense acidification. Lastly, in contrast to the numerical infrequency with which the Plotz bacillus was encountered in Veillon blood cultures, it is significant that, with the technique described, the bodies could be consistently recovered from a few drops of the blood. Concerning the question as to the identity of the bodies with *Rickettsia prowazeki*, no definite decision is yet permissible. Whether the bodies are of bacterial or of protozoan nature the writers have not been able to decide.

11. A New Sign for the Diagnosis of Pericarditis with Effusion in Children.—Sidney V. Haas describes this sign which he first observed more than ten years ago, and since has repeatedly proven to be reliable. It consists of two lines of dullness to be found in the cardiac area; an outer line to the right and left of the cardiac area, obtained by the lightest possible direct percussion, as usually practised. The cardiac dullness

is outlined in the usual manner and the line marked on the chest wall with a pencil. The bell of the stethoscope is then placed against the chest wall at approximately the center of this area, and in the presence of cardiac effusion light tapping from the periphery toward the stethoscope will reveal a second line within the first line, roughly paralleling it. Repetition of this examination shows a change in the outer line from day to day in the direction either of extension or of contraction, whereas the inner line remains more or less constant. Since the use of this sign pericarditis with effusion has become a very frequent condition in the pediatric service of the Lebanon Hospital, and dependence is placed upon it by members of the staff familiar with it.

1. Pathology and Treatment of Lupus.—W. Sampson Handley demonstrates that tuberculous lupus is not a skin disease. It is essentially and primarily a disease of the lymphatics, a destructive lymphangitis of the parietal lymphatic system. This conception is not a sterile one. It has importance both immediate and prospective with regard to the treatment of this obstinate disease. It has long been admitted that a lupoid focus, wherever situated, may sooner or later infect the lymphatic system, but the phenomenon has always been regarded as secondary, and no conclusion has been drawn from it as to the essential nature of the morbid process at the primary focus of inoculation. From Handley's point of view the essential event for the establishment of lupus is the inoculation of the bacillus into a cutaneous lymphatic vessel. The primary lesion is from the beginning a tuberculous lymphangitis, at first of the dermal lymphatics, but soon of anatomical necessity, the process spreads to the subcutaneous lymphatics and to those of the deep fascial plexus. Upon this hypothesis many hitherto unexplained phenomena of the disease become easy to uunderstand and new methods of treatment suggest themselves. It becomes necessary to recognize the existence around the apparent area of lupus of a zone of apparently normal, but really infected skin. Even in the chronic forms of lupus this zone appears to be present. If the surgeon wishes to avoid recurrence he must circumscribe this area. The following operative procedure meets the conditions described. The visibly infected skin must be circumscribed by a ring incision. In order to allow for the area of early microscopic infection, this incision must not come within a quarter of an inch of the visible edge of the disease. The skin edges must now be reflected back for a further quarter of an inch. The exposed area of deeper subcutaneous fat is then surrounded by a ring incision which marks out the area of deep fascia requiring removal. This area is raised from its edges toward its center, until the diseased deep fascia is removed. The surface of the muscles is exposed in the floor of the wound, which is sutured or skin-grafted. Such an operation is impracticable for extensive lupus of the face. Finsen light has a curative effect on the cutaneous manifestations of lupus, but does not reach the deeper tissues. It seems probable that the future will see an extension of radium therapy in lupus as the method of choice. In view of the fact that radium excites an aseptic lymphangitis and in this way obliterates normal lymphatic vessels, an encircling policy, working from the sound tissues toward the diseased areas, is suggested. To be effective treatment must be guided by microscopic conceptions, not by clinical appearances, and must be mainly directed to the invisible growing edge, to the neglect at first of the visible lesion. A rationally planned course of radium treatment on these lines should be effective.

4. The Jaw-Neck Syndrome: Its Significance in the Rheumatic Group of Diseases.—W. A. Potts asserts that while it is well known that involvement of the temporo-maxillary joint is common in certain forms of arthritis and uncommon in others, the paramount importance of this point as a differentiating symptom in the diagnosis, and consequently in the treatment of so-called rheumatic diseases is not sufficiently widely recognized. The whole heterogeneous medley of diseases, generally and vaguely classed under the heading of "rheumatic" or gouty, can be divided sharply into two groups, those in which the temporo-maxillary joint is involved and those in which it is not. When we find this joint affected we can at once conclude that we are dealing with a condition due to some bacterial toxin, and can say definitely, confidently and finally that it is *not* one of gout, however closely that disease may be simulated. If we could with any certainty define our conception of rheumatism and limit the application of the term to cover only rheumatic fever and those subacute and chronic cases which are its sequelæ or appear to be caused solely by climatic conditions, this axiom could be extended to include both gout and rheumatism. Applying the syndrome test with a view to treatment, patients can at once be classed under group A or B, a classification which helps one to find the cause. In class A the diagnosis lies between gout and true rheumatism, and is, therefore, as a rule, comparatively easy, and the treatment is more or less specific. In class B the diagnosis will lie, in nine cases out of ten, between gonorrheal, rheumatoid, and toxic arthritis; if it is the latter we may perhaps be able to remove the cause if it is a focus of infection.

5. A Method of Diminishing Mortality in Empyema in Infancy and Childhood.—F. John Poynton and F. N. Reynolds analyze a series of 71 cases of empyema in infancy from which it becomes apparent that failure to detect an empyema is a factor in an adverse prognosis. They dwell on cough, dyspnea, vomiting and wasting as a combination of symptoms suggestive of empyema. A certain proportion of these cases demonstrate that a small empyema is only one incident in a profound toxemia, and is of no practical importance in the face of a virulent infection, damaging not only the lungs and pleura, but also the meninges and pericardium. It is the cases that sink and die after operation that require special consideration and have suggested to the writers a method of treatment other than resection and drainage, namely, a method of continued aspiration. They have devised an apparatus and technique with the special object of completely emptying the pleural cavity, and maintaining continuous drainage by aspiration without at any time exposing the cavity to the outside air and secondary infection. The apparatus is a straight, round silver cannula ⅝ of an inch in length provided with a shield through which tapes are threaded, which keep it in position on the chest wall. They lay claim to no originality for the principle, but point to very definite advantages of the method and emphasize certain details in the technique. They find that with this method the period of illness is shortened. In cases treated by rib resection the average time before the wound is healed is six weeks; with this method the average time has been fifteen days. There is no secondary infection of the pleural cavity. There is no leakage or soiling of the wound. Osteomyelitis of the rib, so common after resection, does not occur. No anesthetic is required, and the whole procedure can be carried out in a few minutes. The continuous suction assists expansion of the lung. In the series of 71 cases the mortality was 55 per cent., approximately that given by Spence.

7. A Case of Decerebrate Rigidity.—A. P. Thomson and A. Piney describe this case occurring in a girl 4 months old, with a history of three days' illness, during which she vomited all her food and had twitchings of the right side of her face and legs. The clinical aspect of the case after a few days was one of complete decerebrate rigidity of the type expected after ablation

of the cerebral cortex. There was very little change in the child's condition during the two months of her illness. The clinical features of the case bore a close resemblance to the condition of decerebrate rigidity described by Kinnier Wilson. There was nothing to lead one to believe that the child suffered from any brain disease at birth. The autopsy revealed diffuse softening of the cerebral cortex and calcification of the cerebral vessels. The anatomical changes present appeared to be the effect of an inflammatory lesion of about two months standing. The writer has been unable to find an identical case in the literature of the last twenty years, and cases with even a slight similarity are rare.

British Medical Journal.

November 26, 1921. No. 3178.

1. Discussion on Blood Diseases in Children.—J. Hughes Thursfield gives a general survey of the clinical position as regards blood diseases in children at the present time, first classifying the anemias as (1) congenital; (2) secondary, that is, those in which a removable cause is operating to produce the anemia; and (3) primary, those in which an unknown, and at present usually unascertainable cause is operating. He considers von Jaksch's pseudoleucemic anemia of infants as a primary anemia, and suggests that there are only three types of severe blood disease which occur in children before the age of puberty, namely, leucemia, purpura, and a grave anemia to which a number of names have been attached, but which is most familiar, perhaps, by the title of "aplastic anemia." Personally he prefers to call the disease "the grave anemia of children," because the term aplastic seems to him to be strictly applicable to any severe grave anemia, even to some of the secondary anemias in which recovery is the rule, whereas in this disease recovery is very uncommon. In discussing the first type, leucemia, he believes there will be general agreement to the proposition that the leucemic elements of the blood belong to and are derived from the bone marrow. If this is agreed we can arrive at the position that whatever the type of cell met with in the particular case, leucemia is always a disease of the bone marrow. He is prepared to go further and to say that the character of the leucocytes depends chiefly, though certainly not entirely, on the acuteness of the affection. If one accepts this conception it does away with the mixed leucemias. The name "aleucemic leucemia should be reserved for those cases in which the leucocytes, though diminished in number, are mainly the lymphocytic or myeloblastic type, and these should be sharply differentiated from those cases in which with the same paucity of leucocytes the normal polymorphonuclear and lymphocytic cells are the majority of those present. These belong, in the writer's opinion, not to the leucemic group, but to the class of purpura and even more to that of anemia gravis. After death the bone marrow of these "aleucemic" cases is darker red than normal, and both to the naked eye and to the microscope presents a striking difference from that of the anemia gravis type. This latter takes the place of pernicious anemia in adults. There seems to be no mark which separates this type of anemia from cases of severe secondary anemia which recover. It is not a specific entity any more than the pernicious anemia of adults. It is probably dependent upon infection, and if one could only succeed in discovering the focus of infection he might succeed in saving the patient. From time to time there occur fatal profound anemias of the purpura group; almost certainly they also are of infective origin. In the treatment of these blood conditions our main efforts should be directed not so much to a study of the individual type of cell as to the early discovery of the focus of infection. This is also true in treating the leucemias, though the evidence here is not so strong. In the leucemias at present the prognosis is pessimistic and treatment empirical. In other types of severe anemia, if there is failure to detect the focus of infection, the disease progresses to death.

2. Principles of the Treatment of Tuberculous Disease of the Bones and Joints in Children.—Henry Gauvain asserts that to-day it is generally recognized that tuberculous bone or joint disease is but a local manifestation of a more general infection. Radical surgical measures are therefore rarely called for in the treatment of tuberculous bone and joint disease in children. As the indication for their employment has diminished, so the results, both as regards ultimate mortality and from orthopedic consideration, have improved. The lowered mortality is striking and worthy of record. In over 2,000 cases treated to conclusion at Alton the mortality during treatment was under 2.5 per cent. No less striking is the improvement in orthopedic results as shown by a comparison of London cripple school children observed some years ago and noted recently. In the general treatment of bone and joint tuberculosis it is important to remember the value of climatic change. A mass of valuable information is being collected on the selection of cases for marine and inland treatment. Certain cases make better progress inland; others at the seaside. A marine institution for the treatment of surgical tuberculosis should be located where the climate is bracing and mild, the air clear and free from mist and other contamination. The soil should be dry and sandy. There should be an abundance of sunshine of high actinic value. The shore should be flat and there should be considerable tidal excursion. In considering the local treatment emphasis is placed on absolute rest in the recumbent position, with immobility of the part attacked, combined with the adoption of special means to correct or prevent deformity, during the early stages of treatment. As adjuvant measures, heliotherapy, x-rays, and other electrical methods of treatment, balneotherapy, vaccine treatment, and chemiotherapy, judiciously employed, all have a place. The benefits of heliotherapy are clinically demonstrable. In English institutions the contrast between the appearance of patients during the winter months, when insolation is not possible, and during the summer, when it is available, is striking.

7. Congenital Hypertrophic Pyloric Stenosis.—H. Tyrrell Gray and F. N. Reynolds present an analysis of 50 cases of congenital hypertrophic stenosis operated upon by the Rammstedt method from which the following are reached: (1) Accumulating evidence supports Pirie's hypothesis, that hyperadrenalism causes pyloric hypertrophy, which is to be regarded as one of its manifestations. (2) Pancreatic and biliary insufficiency, also resulting from hyperadrenalism, accentuate the pyloric closure and influence the mortality. (3) The sex preponderance (two males to one female) is of similar importance. (4) Gas and oxygen anesthesia will nearly eliminate operative fatalities, both immediate and delayed. (5) Operation should never be undertaken as an emergency. (6) Systematic preparation for operation by lavage and infusion is essential. Even moribund cases can be so rendered operable, and make a good recovery. (7) Such a preparation should never exceed four days at the outside. (8) Now that the operative mortality has been so greatly reduced by the employment of gas and oxygen (37 per cent.), operation is indicated as soon after the diagnosis as the necessary preparatory treatment will permit. (9) The possible risk of performing an avoidable operation is negligible when compared with the prejudicial results of the ineffectual prolonged medical treatment.

Familial Lepra Nervosa.—Gougerot and Ruppe relate this incidence of leprosy as evidence of dualism of lepra bacilli which seemingly may, like the treponema pallidum, present a dermotropic and neurotropic form. In the neurotic type skin lesions of a certain type are always present, although doubtless only secondary to the injury to the nerve trunks. In the family in question the skin lesions were largely achromic.—*Bulletin de la Société française de dermatologie.*

Book Reviews.

TYPES OF MENTAL DEFECTIVES. By MARTIN W. BARR, M.D., Chief Physician, Pennsylvania Training School for Feeble-Minded Children, Elwyn, Pa.; and E. F. MALONEY, A. B., Professor of English, Girard College. With 31 plates, containing 188 illustrations. Price, $3.00. Philadelphia: P. Blakiston's Son & Co.

THIS book is evidently intended for those who are engaged in work among the feeble-minded. The authors classify the different forms of feeble-mindedness, define the terms used, give the prominent symptoms, and also indicate which cases are amenable to treatment by training and which are not amenable. For educational purposes this classification is all that can be desired, particularly as the authors have wisely included only those types which are most commonly met with and which can be readily recognized. The volume should prove of service to physicians, nurses, teachers and all who are interested in education.

RADIOGRAPHIC TECHNIQUE By T. THORNE BAKER, A.M.I.E.E. Price, $4.00. New York: William Wood and Company, 1921.

IT is singular that photography forms one-third of radiographic activity, despite which roentgenologists are generally uninformed on the most elementary photographic principles. In this book the author convinces one beyond doubt how important photographic essentials tend to maximum efficiency in radiographic technique. As an example, an experiment is discussed as follows: Using a radiometer of his own construction, the author plotted a curve showing the density obtained in a negative exposed through one to twelve thicknesses of 1/16 inch aluminum. The author observed that as the thickness of the aluminum increased, which is equivalent to saying that as harder and harder rays cause the photographic effect, there is a distinct fall in density to a certain point (5/16 inch of aluminum); for the next five extra thicknesses the decrease in density is quite slight; then, after 9/16 inch of aluminum, the density falls again with each successive thickness. The results of the experiment would indicate that within a certain range of *x*-ray hardness, a hardness equivalent to some 5/16 inch to 9/16 inch of aluminum, the *x*-ray negative gives a minimum of contrast; therefore, radiographs made within this range of penetration cannot be expected to give good differentiation.

In a manner that is equally forceful the author discusses intensifier screens; where he shows that overexposure is a cogent factor in producing "grain," and that the success in the use of an intensifier screen is greatly dependent upon the intimate contact that must obtain between the screen and the plate. Those of us who are using the Potter-Bucky diaphragm have learned by experience Baker's excellent teaching in this regard.

A chapter is reserved for discussions of dark room equipment, illumination, and the storage and use of dark room chemicals. In this, as in the other chapters of this valuable book, the author displays an intimate knowledge with dark room conditions and gives such advice as is useful in converting the odium of dark room work into important and pleasurable enjoyment. A chapter is devoted to the intensification and reduction of improperly exposed negatives, and another chapter to the production of photographic prints.

In a brief way some industrial applications of the *x*-rays are mentioned, as is also the recent subject of *x*-ray analysis. There is an appendix that gives valuable formulæ, recommendations for the protection of *x*-ray operators, cautions referring to the danger of shock from the high tension current of *x*-ray installations, and a discussion of the Coolidge tube.

There is no other book that contains in such a small compass so much useful information on radiophotographic technique. Says the author: "This book has been written with the object of placing before the reader, be he operator or expert, the various details of photographic technique of which a knowledge is so necessary in radiographic practice." This modest wish of the author is more than realized, for both operator and expert, in a single reading, will gain details of photographic technique of which they had little or no knowledge. This volume should win a unique prominence in every *x*-ray library.

CHIRURGIE RÉPARATRICE ET ORTHOPÉDIQUE Publié sous la Direction de MM. E. JEANBRAU, P. NOVÉ-JOSSERAND, L. OMBRÉDANNE et P. DESFOSSES, Secrétaire de la Rédaction. 2 Volumes in-8°, 1340 Pages with 1,040 Illustrations. Volume I. Contributors: MM. Baumgartner, Binet, Calvé, Claude, Cunéo, Dambrin, Ducroquet, Fredet, Froelich, Gross, Guyot, Imbert, Jeanbrau, Lambret, Lecène, Ledoux-Lebard, LeFort, Lemaitre, Leriche, Marion, Nageotte, Nové-Josserand, Ombrédanne, Patel, Policard, Pont, Réal, Roux-Berger, Sargnon, Sencert, Sicard, Silhol, Tavernier, Trèves, Valois, Villaret. Volume II. Contributors: Mme. Athanassio-Benisty, MM. Binet, Bréchot, Cestan, Chevrier, Cotte, Dambrin, Desfosses, Ducroquet, Dujarier, Duvergey, Fredet, Hendrix, Jeanbrau, Guyot, Laroyenne, LeFort, Leriche, Lhermitte, Mouchet, Nové-Josserand, Rottenstein, Tavernier, Trèves. Price, 80 francs net. Paris: Masson et Cie., 1920.

IN the course of the publishers' note which accompanied these volumes there occurred the following statement: "This book should be read, reread, meditated over, by all surgeons"; and now that we have had an opportunity to become thoroughly familiar with the work, we quite agree with them. This is not a work on war surgery of merely retrospective interest, but was designed particularly to show how the surgical lessons learned at great cost of human life and suffering during the late war may be applied to the problems which arise in civil practice following severe injuries from whatever source. Its purpose is to prevent our making some of the same mistakes in the future which were made before and during the early stages of the war and to point out the methods found most useful in dealing with the immediate and, more especially, the remote results of severe traumatisms of whatever source; for whether the injury is caused by a shell fragment or is received in a factory, a mine, or in an automobile or other street accident, the principles of treatment are essentially the same. As has been seen by the transcription of the title pages, a large number of specialists, many of whom are among the best known surgeons of France, have contributed to these volumes; and this fact in itself affords a guaranty of value.

In Vol. I there is first an introductory discussion of the treatment of wounds in general, fractures and wounds of the articulations, and the localization and extraction of foreign bodies, all this covering about sixty-five pages. Then follow ten chapters, about 325 pages, devoted to exhaustive discussion of the following subjects: Extraction of projectiles; evolution and repair of wounds of the skin, with discussion of the treatment of cicotrices, plastic repair and the building up of a supporting substructure by cartilaginous, osteoperiosteal, or fat grafts; evolution and repair of wounds of muscles, tendons, aponeuroses, blood vessels and nerves; evolution and repair of injuries of bone, including osseous regeneration in general and various complications such as vicious union, excessive callus, adhesions, osteomyelitis; nonunion, or pseudarthroses; evolution and repair of wounds of the articulations; pathology of stumps; general information regarding orthopedic and prosthetic apparatus; and finally certain complications following injuries, including nervous troubles, latent microbism and late infections, traumatisms in connection with tuberculosis, cancer and other affections, chronic edema and elephantiasis.

The remainder of this volume and the entire second volume, about 900 pages altogether, are devoted to the discussion of the injuries of each special region and their treatment under all sorts of conditions by operative or nonoperative methods. Practically all methods developed or found useful during the war are described and their proper application indicated; and it seems as if every conceivable complication and sequel has been mentioned and proper treatment suggested. The section on the abdomen is too brief, but that is perhaps to be expected, as this work is primarily for the orthopedic surgeon; otherwise it seems pedantic to call attention to minor faults when the work as a whole is of such merit; and we thoroughly agree with the publishers that this work should be read and thoroughly digested by all surgeons who have anything to do with traumatic surgery, civil as well as military. For the benefit of those who do not read French it is to be hoped that an English edition will not be long delayed.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

One Hundred and Sixteenth Annual Meeting, Held November 28, 1921.

THE PRESIDENT, DR. GEORGE GRAY WARD, JR., IN THE CHAIR.

Report of Reference Committee.—Dr. DANIEL S. DOUGHERTY read this report, which stated that at the meeting of October 24, 1921, Dr. John P. Davin offered as a substitute for the recommendation of the Comitia Minora a resolution to the effect that the Medical Society of the County of New York petition Congress not to incorporate in pending legislation any restrictions upon the form of standard alcoholic beverages which might be prescribed by duly licensed physicians. The recommendations of the Comitia was adopted and the substitute resolution referred to the Comitia as a reference committee. The Comitia Minora, sitting as a reference committee, had considered this resolution and recommended that the Society take no action thereon.

This recommendation was adopted.

Annual Reports.—Report of the Board of Censors.—Dr. G. G. FISH submitted this report, in which it was stated that one special and eight regular meetings of the board of censors had been held during the year, each attended by more than a majority of the board. Many complaints had been received of unethical conduct on the part of physicians. These had been disposed of. The board of censors had about completed a plan whereby they would render to the Society a monthly report.

Report of Committee on Membership.—Dr. FREDERICK N. DILLINGHAM submitted this report, which showed that monthly meetings of the committee had been held, each of which was attended by at least four out of five of the members. During the year the committee had considered 199 applications for membership and at the present time twenty-three applications were still under investigation. Of this number 177 had thus far been recommended for membership.

Report of Committee on Legislation.—Dr. WILLIAM P. HEALY submitted this report. He stated that the committee had held nine meetings, each attended by a majority of the members. Many bills introduced into the Legislature had been considered. The Health Center bill was again introduced and also the bill to license chiropractors. The chairman and members of the committee attended the hearings on these bills. While the bills failed to pass at the last session of the Legislature, no doubt they would be presented again this year, so that unrelaxed vigilance was required. As to the drug laws, as they all knew the Whitney law had been repealed, so that now physicians were subject only to the Harrison law. A serious effort would probably be made by the magistrates to have a measure enacted along the lines of the Whitney law.

Report of the Committee on Civic Policy.—Dr. SAMUEL J. KOPETZKY submitted this report, in which he stated that a year ago the Medical Society of the County of New York appointed a committee on civic policy. Its duties were outlined in the amended constitution of the Society. These duties consisted in receiving information from the committee on legislation and from other sources on the bills affecting the medical profession and the public health pending before the Federal, State, and municipal legislative bodies. It should conduct investigations, gather facts, make studies or surveys on the subject matter of the pending measures or upon legislation which might be introduced subsequently, or upon any other subject which affected the medical profession in its relation to the public health, or in the matter of medical economics, so as to be in a position to render service to the Comitia Minora or to the Society upon such matters. Likewise, it might study and when called upon report on all questions relating to medical practice. Conclusions arrived at by the committee on any given topic should be communicated through its chairman in the form of a report to the Comitia Minora at its monthly meetings, and, after approval by the majority of the Comitia Minora or by the Society, such data and conclusions as constituted the reports of this committee should be made available to the committee on legislation, to be used as the latter might desire in the accomplishment of the expressed wishes of the Society upon the given topic. A committee of this kind had become necessary in virtue of the fact that so many new circumstances surrounded the practice of medicine and so many changes entered into the relationship between the doctor and his patients. Dr. Kopetzky then reviewed in brief outline some of the topics considered by the committee, speaking first of commercial laboratories. He stated that it was quite obvious that as a class commercial laboratories were unreliable and untrustworthy, nor were they, as a rule, even run by medical men. The same was true of many so called x-ray laboratories. These laboratories could not and would not exist if they did not receive financial support from physicians. When the profession would heed advice and cease to send patients to these places they would cease to exist. Eliminating them in other ways was not an easy task, as they had in most instances protected themselves by the aid of legal talent. The committee had taken up the study of narcotic drug law enforcement, and after due consideration of the subject had recommended the repeal of the drug laws for reasons often discussed before the Society. Certain interests had tried to have a city ordinance passed containing the unsatisfactory terms of the Whitney bill. The regulations that were finally adopted permitted the police to handle the matter and to have all the power they needed to do this. The physician was now permitted to go unhampered by the reduplication of blanks and other forms and thus far, from his standpoint, a strategic position had been gained. The committee thought a word of commendation was due Dr. Carleton Simon, who, with his police force, had really performed notable work to which the committee heartily subscribed and wished to express the hope that the work would be continued. Another matter which had engaged the attention of the committee was the care of deaf school children. Heretofore nothing had been done for the deaf child; his affliction separated him from his fellows and he was given no opportunity to acquire an education or a means of livelihood, and finally reached a condition of dependency upon his family or the public. This committee, in cooperation with representatives of the American Otological Society and the assistance of Dr. Thomas J. Harris, Dr. Wendell C. Phillips, Dr. L. E. Meierhof, and others, and in cooperation with the Department of Health and the Department of Education, had provided a plan whereby these deaf children would be taught lip reading where they were. A survey of the blind children in the city was made and the work was progressing as rapidly as could be expected. A further report on this subject would be presented later. It was gratifying to know that in this work the committee had the cooperation of the Department of Health, the Department of Education, and the League of the Hard of Hearing. The committee had also been interested in the matter of instituting examination of immigrants for venereal disease at Ellis Island. It was well known that venereal disease had increased to a considerable extent among the peasants of Europe and their entrance into this country was a potential menace. The Surgeon General of the Public Health Service now had this matter under advisement and it was hoped that he would aid in controlling venereal disease among immigrants and thus prevent its spread from this source. Still another subject which the committee had had under consideration was the Workmen's Compensation law. Dr. Miller had appointed a new commission to investigate the entire subject of workmen's compensation. A committee on Medical Questions had been appointed and hearings had been held throughout the State. Dr. Delphey was on that committee. A fact that stood out was that insurance carriers realized that their attitude had been mistaken and that the workmen's compensation law could not be enforced without the cooperation of physicians. It was now recommended that physicians caring for compensation cases keep very careful records of those cases. In this connection the point chiefly to be emphasized was that the profession

were still directing their efforts to secure free choice of physician to the patient under the compensation law and adequate pay for those coming under the workings of the law. The committee also directed attention to the code of ethics promulgated by the American Medical Association, particularly to the employment by physicians of methods designed to attract the attention of the public for the purpose of getting patients. In this respect the foreign press had been a great offender. There were in this country thirty-two races, constituting a population of eight million, who were reached by 2,000 newspapers and periodicals. Through these quacks made an appeal to the foreign element. The method was to suggest that a person was suffering from disease and then when the patient was convinced that he had the disease they cured him and obtained his testimonial. In 1915 the Medical Society of the State of New York and the Medical Society of the County of New York, cooperating with the Department of Labor, had conducted a campaign against these illegal practitioners, which was quite successful. It should be our endeavor to convince the immigrant and his descendant that the advertising quack should not be given support. The matter should be brought to the attention of labor organizations, so that this class of the population would not become a fruitful soil for exploitation in this direction. The committee also called attention to the evils of the "mushroom hospital." By this was meant the kind of an institution that was established when a group of men of no particular talent got together and persuaded some prominent physician or surgeon to permit his name to be used as heading their staff and then obtained a charter under which they practised very mediocre medicine and surgery. This could not happen if eminent men did not allow their names to be used as consultants, and if a really honest attitude were adopted the State Board of Charities would not license these institutions. Cornell Medical College had recently established a pay clinic which was the subject at the present time of considerable controversy. This clinic had not been established long enough to warrant any conclusion. The committee would only ask the leaders of the profession and of the Cornell Clinic whether they had taken due account of the effect such a clinic would have on the medical profession and whether it was not a move toward State medicine. This step would tend to the formation of other groups, for the Cornell pay clinic was only the forerunner of others to come. Their opinion was open to revision, but they felt that today the patient was getting the same clinic treatment that he received before only that he was paying more money than he paid before. The committee disapproved very strongly of the publicity this clinic received in the lay press. Several pictures clipped from the lay press showing scenes at the clinic were shown, and it was declared that it was no answer to these to disclaim responsibility or to disavow them after they had appeared. This put the early activities of the Cornell Clinic on a level with those of the Life Extension Institute, of which this committee had repeatedly expressed its disapproval. It had been well said that the most worthy advertisement that any physician could have was a well merited reputation for ability and fidelity. It was a little difficult to condemn the quack when one found this kind of publicity within the ranks of the profession. The report then went on to deal with the subject of reregistration. It was stated that Dr. Augustus S. Downing had said that if the medical profession would submit to reregistration it would eliminate the quacks. He said that a large majority of the people who employed doctors of electrotherapy and chiropractic thought they were employing licensed doctors and that re-registration would be an effective way of informing the public as to who were and who were not legitimate practitioners of medicine. Reregistration had been very effective in eliminating quacks from the practice of dentistry. The report further called attention to a bill designed to prevent fee-splitting that had been prepared for the last Legislature. The committee had endorsed the bill as it was presented. If it was presented again this winter the committee would again give it their approval. Finally, the report outlined the plans for the new official organ of the Society. It was to be published as a newspaper or bulletin and would contain all the detail that would be of interest to the membership and all matters of general importance, such as programs of medical meetings, hospital news items, and all matters of interest to the profession. It would contain no scientific papers. Its advertising would be conducted in accordance with the standards of the American Medical Association. The paper would be of no expense to the Society either directly or indirectly. It was hoped to have the initial issue appear during January.

Dr. WALTER L. NILES begged permission to speak for Cornell University. He said that no one regretted the unfortunate publicity given the Cornell pay clinic more than did they. They had done their best to guard against it. They had a committee formulate one or two letters and a pamphlet. One letter was sent to the Academy of Medicine and one to the County Society and the pamphlet was given out at Cornell. Nothing was given to the newspapers; whatever they had was formulated from these. Men at the head of the clinic did not know the pictures were to be taken or published. To the best of his knowledge a nurse allowed a photographer to take the pictures, but she did not know for what purpose they were to be used. He regarded this publicity as most unfortunate. The clinic had been established upon the recommendation of the public health committee of the Academy of Medicine and was encouraged and fostered by the dispensary development committee. They wished the cooperation of the medical profession in every way and would welcome an investigation from this organization. They would be very happy to show the workings of the clinic in its every detail. The idea of advertising was always looked upon as implying monetary gain and this clinic was not being run for gain, but, on the contrary, had been operated with the aid of the dispensary development committee. He invited any and all to come and watch the operation of the clinic and to give suggestions with reference to organization and methods of conducting it.

Dr. EDEN V. DELPHEY said that in order that the Society might be informed of the position of the trustees of the American Medical Association on the subject of pay clinics he wished to call to their attention the report of the autumn session of the board of trustees. A committee was appointed to study this question. The principles deemed basic by them were: "(1) that patients should be received by the clinic only when sent by the family physician or received with his knowledge and approval; (2) so far as feasible the patient should be returned to the family physician with written information and suggestions; (3) that the fee charged by such clinic should not be less than that usually charged in general practice, so that, as far as possible, competition of the clinic with the general practitioner should not occur, and the chief consideration should be the public and the medical profession."

Report of the Counsel.—Dr. GEORGE W. WHITESIDE submitted this report, in which he reviewed the activities of the counsel for the year ending November 21, 1921. The report stated that the counsel had attended regularly the meetings of the Comitia Minora and the board of censors and in many instances the meetings of the Society. In the past year there had been quite a number of occasions when legal advice was necessary. On account of the great expense the Society had abandoned the employment of investigators to obtain evidence leading to the prosecution of illegal practitioners of medicine. Arrangements had been made whereby the police department co-operated in complaints of violation of the public health law. Under this arrangement the counsel had forwarded a large number of complaints to the police department and the fifth deputy police woman had appeared before the magistrates in courts of special sessions. A list of the cases handled in this way was included in the report. Dr. Whiteside stated that a number of chiropractors had been tried in the court of special sessions on the charge of practising medicine illegally and had been fined $50 each. Complaints had been received by the counsel from many sources, all of which had received due attention. Conferences had been held on various matters with city, State, and Federal representatives. Matters connected with the violation of the Harrison narcotic law had been referred to the district attorney and when such violations occurred outside of the city they were re-

ferred to the district attorney of the county in which they had occurred. The report further set forth the work of the counsel with legislators in his endeavor to defeat the chiropractor bill and of the advice he had given to various departments of city and State in an endeavor to check the practice of medicine by unlicensed chiropractors and other illegal practitioners of medicine. It was pointed out that the duties of the counsel required considerable time and effort; there was seldom a day when he did not give one or two hours to the work of the Society. In closing, the report commended the police and health departments for the courteous and efficient cooperation extended to the counsel in the performance of his duties.

Report of the Milk Commission.—Dr. WALTER LESTER CARR submitted this report. The figures presented showed that a total of 14,950 quarts of milk was certified daily and that the inspector in the prosecution of his duties had traveled upward of 40,000 miles during the year. The books of the milk commission showed a balance of $1,144 in favor of the Society.

Report of the Special Committee on New Members.—Dr. ERNEST FAHNSTOCK presented this report, in which he stated that this committee, in its efforts to increase the membership of the Society, had districted the city and gone over it thoroughly. They had included men on the interne staffs of hospitals, and had made an effort to get men of character and ability rather than simply a large number. Through their efforts 199 applications for membership had been filed, of this number 176 had been elected to membership and thirty-two were still awaiting the action of the committee on membership.

Report of the Public Health Education Committee.—Dr. JOSEPHINE H. KENYON reported that the committee held its first meeting last April, when it was decided that each member of the committee be held responsible for one or more meetings, which it was decided would be held from October 14 to December 14, 1921. The public health committee of the New York Academy of Medicine had given them most efficient cooperation. Several meetings had been arranged in connection with organized societies, as for instance, the Society for the Control of Cancer, the New York Nutrition Council, the New York Tuberculosis Association, etc. To date the program had been carried out as planned. The audiences thus far had averaged 250 persons; there had been a total attendance of 1,500 to November 28.

Annual Report of the Comitia Minora.—Dr. DANIEL S. DOUGHERTY submitted this report, which consisted in the assembled reports of the Comitia presented at the stated meetings during the past year. The total attendance at the meetings of the Society during the past year was 1840, an average of 230 persons at each meeting. One hundred and seventy-six names had been added to the membership of the society. The net membership of the society on November 28, 1921, was 2,917, an increase of ninety-nine for the year.

Address.—The Law Risks of Medical Practice and Adequate Protection Therefor.—Mr. GEORGE W. WHITESIDE delivered this address, in which he said, in part, that this subject was one of peculiar interest to every practicing physician. This interest remained rather latent as long as everything went well, but became of paramount importance when unfortunate results occurred. The physician in dealing with the human body was dealing with a very variable subject. It was useless before this society to speak of the numerous variations and idiosyncrasies of the human body or of the possibilities of variations in results from the same treatment in different individuals. These the physicians had to face in his work and he might obtain bad results even when applying the most modern and well sanctioned methods. In other words, the practice of medicine involved a law hazard or risk well defined but little appreciated. Taking up some of the liabilities to which the physician was exposed, Mr. Whiteside said that the State maintained that the physician went into the practice of medicine with his eyes open and accepting certain liabilities. There was the liability growing out of his duty or a breach of that duty. When a physician accepted a patient he became a party to a contract. That did not mean that he sat down and signed an agreement, but by accepting and treating a patient he had entered into a contract. The fact that a man was licensed to practice medicine and held himself as being licensed and ready to practice medicine, and the fact that a person came into his office for treatment, ready, able, and willing to pay for such treatment, created a contract if the physician accepted that person as a patient. This created a contract under the terms of which, although a word had not been spoken, the physician assumed a liability in treating that patient. It meant that the physician possessed a reasonable degree of skill and would use reasonable care, his best judgment, and proper precautions as to what he should do. It meant that the physician should use methods of diagnosis and treatment which were approved and sanctioned by those practising in his locality or State. All these representations a physician made simply by putting a shingle in the window, and when he accepted a person as a patient he assumed these obligations. If bad results occurred due to failure on the part of the physician in any one of these particulars—not all, but in one—then the law said the physician was liable. The liabilities of the physician differed very materially from ordinary liabilities because ordinary liabilities were well defined and well understood. The reason was that the medical profession was not sufficiently self-centered and self-interested. The physician became absorbed in treating his patient and forgot to protect himself. He was interested in performing an expert and scientific service and left the door wide open for attack upon himself. In the event of a bad result he then found himself the subject of an attack that brought him before the court and the public in a way that worked very material injury to him because it struck at his most precious possession, his reputation. His reputation was not a concrete thing; it was a psychological condition impressed upon the minds of people that he had certain qualities—skill, application, and fidelity to duty. It was against this more or less intangible thing that the attack was made, and every physician was open to such an attack. Mr. Whiteside said he had known of cases in which the result of the physician's treatment was good, but it took a week to establish that fact before a jury because the patient thought the result was bad. He had known instances in which that thought had been instigated in the mind of the patient because another physician looked with jealousy upon the reputation of his fellow-practitioner. The physician faced problems of that kind, not only in relation to the public but unfortunately in relation to other physicians. There was no particular type of practitioner free from this type of attack. He had heard an obstetrician say that he did not require malpractice defence; that it did not apply to him. Mr. Whiteside cited a case showing that such a view was erroneous. Another physician said he only did diagnostic work and therefore did not need this kind of protection. Mr. Whiteside said that he had seen cases in the last twelve months that showed quite the contrary. Of the cases coming under his observation during this period 20 per cent. were fractures, a large proportion being treated by general practitioners; 19 per cent. were obstetrical cases. Mr. Whiteside cited a case showing the difficulties a physician might get into if he did not treat a case according to well sanctioned accepted methods. If a physician departed from sanctioned practice the court said he did it at his own peril. Another case was cited to bring out the fact that when a physician assumed charge of a case he was supposed to continue to care for the patient unless he was discharged or the patient no longer needed his care. It was not an easy matter to get rid of a patient. Cases were cited to emphasize the fact that a surgeon must have consent to operate. In one instance a surgeon was to operate for an affection of the left ear. When the patient was under the anesthetic he found that the right ear was in greater need of the operation than the left. He operated upon the right ear. He obtained a good result but not a perfect result. Suit was brought because he had operated upon the right ear when he had consent to operate upon the left ear and not upon the right. The element of consent was exceedingly important. Many of these mistakes occurred because the physician thought more about the patient than he did about himself, though he might be doing the best thing in a scientific way. All the advances in modern medicine increased the physician's liability. The improve-

ments in the use of the *x*-ray, in serum therapy, and the myriad of applications in diagnosis and practice of the various laboratory methods, all resulted in greater benefit to the patient and were a wonderful assistance in treatment, but every advance added to the responsibility of the physician, for the law required him to keep abreast of the times, to know these improvements, and to employ them. They also made it easier to discover mistakes. Formerly things passed as proper and approved practice because of ignorance. Now liability could more often be fixed as, for instance, where it was possible to give the ocular demonstration of a mistake by means of an *x*-ray. Cases were cited to show that the *x*-ray might be perverted in court to serve the devil's purpose. It was sometimes forgotten in court that it took an expert roentgenologist to demonstrate what the *x*-ray showed. In most instances an ordinary damage suit was safe in the hands of the jury, but it was better to non-suit a case than to allow it to go to the jury to be speculated with. Malpractice suits against physicians were becoming an increasing burden, and there were, indeed, very few meritorious cases. Mr. Whiteside said that when he had found a meritorious case against a physician he had gone to the physician and advised him to settle the suit out of court and in most instances this advice had been followed. As to malpractice defense, not only was the State society at increased expense to maintain malpractice defense, but insurance companies had increased their rates from 100 to 300 per cent. One company had increased its rates from $15 to $45 per year for $5,000 to $15,000. Insurance companies stated that their experience with this type of cases had been most disastrous; they had, therefore, raised their rates. Under present living conditions it was recognized that it was well to have these various types of indemnities, fire insurance, automobile insurance, life insurance, etc. Why should the physician neglect himself by not insuring himself against the liabilities to which he was exposed in the practice of his profession? Mr. Whiteside then described the plan for an adequate indemnity insurance for physicians at a very moderate rate under which he would defend the cases for the company carrying the insurance. He also stated that after much difficulty he had succeeded in finding a reliable company which would carry this insurance.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

OBSTETRICS AND GYNÆCOLOGY. Edited by JOHN S. FAIRBAIRN. 950 pages with illustrations. Published by Oxford University Press, American Branch, New York.

CLINICAL SURGICAL DIAGNOSIS. By F. DEQUERVAIN. 914 pages with 731 illustrations and 7 plates. Price, $14. Published by William Wood & Company, New York.

COLLECTED PAPERS OF THE MAYO CLINIC (1920). Edited by Mrs. M. H. MELLISH. 1392 pages with illustrations. Price, $12. Published by W. B. Saunders Company.

THE FOLLY OF NATIONS. By FREDERICK PALMER. 408 pages, published by Dodd, Mead & Co.

ÉTUDE SUR LE TRAITEMENT DE LA TUBERCULOSE PULMONAIRE. By Dr. C. M. DESVERNINE. Price, 5fr. 74 pages. Published by L'Expansion Scientifique Française, Paris.

TUBERCULOSE PULMONAIRE CHRONIQUE. By Dr. C. M. DESVERNINE. 45 pages with illustrations. Price, 5fr. Published by L'Expansion Scientifique Française, Paris.

SURGICAL EXPOSURE OF THE DEEP-SEATED BLOOD-VESSELS. By FIOLLE and DELMAS. 87 pages with illustrations. Price, 8s. 6d. net. Published by William Heinemann, London.

Miscellany.

Brillat-Savarin.—This eminent dietitian, as he might be termed, was a student of both chemistry and medicine. To the world at large he is known only as a French gastronomist. From a biography published by Genty, we learn that he was born in 1755, the son of a State Attorney. At the beginning of his career he practised the paternal profession of law. (*Le Progrès Médical*). The possession of private means obviated the necessity for hard work and allowed him to dabble in many things. As an amateur cook he soon became known through his recipes, such as stuffed pheasant, tunny omelet, etc. These dishes he probably picked up through mixing with all sorts of people, and he improved them by experiment. He gave little parties to his friends and on such occasions his formulæ became public property. The Revolution cut short these pleasures, and during this period he held important offices. Being on the side of the Royalists, matters finally went against him. When the Revolutionists sought his arrest he fled to Switzerland and eventually to New York, residing there from 1793 to 1796. Here he supported himself by playing the violin in a theatre and teaching French. He never regretted his American sojourn. Returning to France in 1796, he seems to have made peace with the new Republic, under which he held several important offices. His near relationship to Madame Recamier was a social help to him, and after quiet was restored he divided his time between Paris and the country. He published several romances and eventually his famous work "The Physiology of Taste," the latter at his own expense. He was a man of unusual physique, robust and so tall and large as to merit his nickname of "drum major." In 1826 he caught cold at a funeral and died in a few days of pneumonia, aged 73. A statue in his honor is to be rected at Belley in the Ain Department, where he was born, says a correspondent of the Manchester *Guardian*. The ceremony is to be made the occasion for a Brillat-Savarin week at Belley, where the most famous French chefs will serve throughout the celebrations only dishes especially praised by the "master."

Napoleon's Physicians at Saint Helena.—Despite numerous accounts by English writers in justification of the conduct of Napoleon's guardians and medical men toward the eminent exile, the French keep alive the old traditions of neglect and hardship. In an article by Masson which is reviewed in *Le Progrès Médical* for July 2, 1921, xlix, 27, it is asserted that the prisoner was not permitted to see the daily bulletins sent by the Surgeon O'Meara to Lowe, the governor. The reason for this attitude seems to have been that the medical man thought Napoleon was shamming sickness to obtain sympathy. Despite this behavior, Napoleon seems to have preferred the attentions of this surgeon to those of any other. Soon afterwards O'Meara resigned his post and demanded to be sent home. An English fleet surgeon named Verling was assigned by the governor as his successor, but Napoleon refused to see him or anyone excepting O'Meara. He went without counsel until an attack of vertigo, when he demanded the services of a fleet surgeon named Stoköe, who had once visited him with O'Meara. This man was asked by the exile to

become the latter's successor and accepted, but because he did not act under the authority of his chief Verling, was punished and reduced in rank. After another interregnum of some months one Antommarchi became the nominal medical adviser but he was not a graduate physician. He neglected the Emperor, either making very brief daily visits or none at all. As he was nothing more than an ex-prosector, his patient was doubtless better off for this want of attention. When death approached an effort was made to procure a reputable medical man agreeable to the patient. Death occurred while the well-known French physician Pelletan was *en route* for the island. The friendliest criticism must admit that the Emperor never received the services of any medical man of great prominence or repute for skill during his six years' imprisonment.

Latin in Education.—Callamand discusses this subject at length and questions the existence of a special Latin genius in stating that there are profound ethnic differences between the French and Spanish. Comparing the Latin and English cultures or genius he shows that for every eminent Frenchman there is an Englishman of the same type. The worship of Napoleon is nowhere greater than among Anglo-Saxons, and this is also true of Joan of Arc. In idolatry of Greco-Latin culture we have ignored the cultures of Arabia, India, China, and Japan. On the other hand, it has been claimed that the Jesuits carried to France a pedagogic culture which they borrowed from the Far East. Quite recently in England Crookes, Ramsay, and other great scientists advocated the abandonment of Greco-Roman culture, pointing out that the great general institutes of learning in England have no scientists among the directorates, not even of the military schools. The great French mathematical genius, Poincaré, believed, however, that every man of science must be trained in the "humanities." In the United States Carnegie and other money kings have been outspoken against the study of dead languages, pointing out that great financial magnates usually begin as ordinary bureau employees, or in other humble capacities. Three distinguished American writers without much schooling were Whitman, Mark Twain, and Jack London. Among the French George Sand had hardly any Latin, Alexander Dumas refused to study it and got his education from Shakespeare, Scott, and Schiller, while Zola funked Latin to read Montaigne, Rabelais, Shakespeare, and Hugo. The author advocates the study of English, Spanish, or even German in place of the dead classical tongues.—*Le Progrès Médical.*

Sneezing.—The anthropology of these acts is much less studied than the symptomatology, or, rather, has been less in evidence, but quite recently a French author, Saintyves, has published a monograph entitled in English translation "Sneezing and Yawning in Magic, Ethnography, and Medical Folklore." The sections devoted to sneezing are briefly reviewed in *Le Progrès Médical* for November 5, 1921, xlix, 45. Among many primitive peoples a sneeze signified the critical moment at which an apparition became visible or a danger had passed. It was the occasion for felicitations and good wishes, just as it still is among the "civilized" whites of today. When one barbaric monarch sneezed the word was quickly passed along by word of mouth until all of the subjects had been informed and the latter then made solemn wishes for His Majesty's health. At another African court the courtiers turned their backs and slapped themselves on the thigh at the royal sneeze. In a third country at the sneeze of any important personage those within earshot fell to their knees, kissed the ground and wished the sneezer all manner of good luck. The Roman emperor, Tiberius, made all hands salute him whenever he sneezed, but this seems to have been a personal matter, for Pliny had never heard the like. Among the ancient Greeks artificial sneezing, produced doubtless with a feather, was used for a variety of troubles—hiccough, crusts in the nasal passages, headache, and difficult labor. It was also used for migraine in the Middle Ages and, after the introduction of tobacco, snuff was used in a variety of disorders. Sneezing powders were also in common use, and attempts were made to break up epileptic seizures by their exhibition. Certain peoples believed that sneezing by a sick man was of bad prognostic significance, while others took the exactly opposed view that if a sneeze could not be provoked the patient could not recover. In 1817 Double, a writer on symptomatology, believed that both prognostics could hold good, according to the case.

The Nature of X-Rays.—Erculisse attempts to determine the nature of the *x*-ray by considering in succession the phenomena of Crooke's tube, the relation of *x*-rays to light rays, the polarization and diffraction of *x*-rays, the relation of the latter to the structure of the atom, and the relation of the rays to crystallography. He mentions the remarkable relationship between the *x*-ray spectrum of an element and the position of the latter in the classification of Mendelejeff. According to the Law of Bragg, every tube emits a continuous spectrum and another which is characteristic of that tube. The latter depends on the metal which enters into the formation of the anticathode. The continuous spectrum is always the same, despite the material composing the anticathode. When the young English physicist, Moseley, was killed in the Dardanelles campaign in 1915 it was said that he possessed a knowledge quite unique concerning the structure of the atom and that he was able to count the electrons in the latter. This knowledge came in part from his study of spectra obtained from anticathodes composed of different metals. As a class these spectra are very simple, consisting of few lines. A grouping of them according to wave lengths—expressed in millionths of a millimeter—shows the correspondence to Mendelejeff's law of atomic weights. The loss of Moseley while practically in the midst of this study was irreparable, but his discovery as it stands marks one of the greatest of achievements in physics. The two English physicists, Bragg, father and son, have used the diffraction of the *x*-rays to determine the crystallization of substances, the method being likewise founded on the wave length of the rays. The problem here is one of ions, as the other was one of electrons. The number of strictly amorphous substances has been greatly reduced by this discovery.—*Annales de la Société Royale de Bruxelles*, 4, 1921.

Cerebrospinal Meningitis in Portuguese India.—Prof. Froiland de Melo of the Medical School at Goa writes interestingly of this affection in the tropics. Apparently epidemics of the latter have hardly been known to occur in hot countries until recently. In 1908 Haan of Java announced its appearance in that island and about the same time it was heard of in the Gold Coast of Africa. In 1916 it cropped out in French Guinea and in 1918 in the Belgian Congo, and recently it has been recognized in several other tropical localities. However, the author is able to show that there were foci in Hindustan before 1908. It was certainly encountered in Portuguese India as early as 1904, having apparently been carried thither by Portuguese sailors. In various points in British India it was seen as far back as 1906, but the incidence was evidently slight and without significance. These early cases in Portuguese India were quickly recognized and isolated so that no epidemic resulted, and the subject was evidently quickly forgotten. Recently, as late as December, 1918, new cases appeared and were at first completely unrecognized. The condition suggested pernicious malaria with bulbar symptoms. Even by March, 1919, the true nature of the cases was unrecognized. The resemblance to cerebrospinal meningitis was noted, but that was all. Some of the cases were very mild, while there was much want of type. The blood tests, as a matter of fact, sometimes showed the plasmodium. Intestinal parasitism, also extremely common, seemed to explain some of the symptoms. Finally it occurred to one of the sanitary officials to look for the meningococcus, which was at once found in the spinal fluid. It now became possible to trace cases backward over the three months of the disease incidence, and it was evident that at least 500 of the 2500 families of the affected district had presented one or more cases. The mortality was but 18 per cent. practically untreated, which shows the relative benignity of the malady in the tropics.—*La Medicina Ibera.*

Monument to Lombroso at Verona.—On September 25, 1921, was started a project to erect a monument to the late Cesare Lombroso in the city of Verona, where he was born in 1835. The deceased, by the way, was opposed to all memorials as appealing too much to human vanity. The sculptor is Leonardo Bistolfi. The monument will bear the inscription, "Dedicated by his natal city, by all Italy, and twenty-three foreign nations." It will comprise a statue of the man in classic habiliments seated on a bench, and the figure will be of bronze. His prejudices against statuary and the like doubtless were limited to works instigated by the subjects themselves during life, or provided for by wills or by requests made to relatives. A spontaneous tribute of global origin, erected years after the death of the subject, is certainly exempt from the objection of motivation by individual vanity. Lombroso's reputation will rest rather on his humanitarian labors than his scientific attainments, great as were the latter. As a penologist and criminologist, as a reformer of penal codes and of the custodial care of the insane and delinquent, and as the founder of a school of alienists and penologists, he will be best remembered. In State Medicine and Sanitation he will be remembered for his pioneer and revolutionary work on pellagra, which, incidentally, is, of course, one of the causes of insanity.—*La Riforma Medica.*

The Franco-Polish Medical Congress.—The special correspondent of *La Presse Médicale* has been writing a series of letters to his paper on this topic. The Congress was held at Cracow, the ancient monuments of which city have evidently escaped defacement during the war. The medical school has a bacteriological institute, which includes experimental medicine, as part of its own equipment. Laboratory animals are cheap, a rabbit which would cost 18 francs in Paris bringing but 35 centimes in Cracow. An institute of this kind under faculty control is evidently a desideratum, as the French correspondent envies his Cracovian colleagues and hopes to see a corresponding institution as part of the Paris school, the Pasteur Institute in Paris being entirely independent of the medical faculty. Despite the postbellum stagnation supposed to prevail in Poland, the medical men appear to have enjoyed themselves as much as in the remote days when war had not been thought of. There were enough social functions to exhaust the delegates. One was a performance at the Municipal Theatre, where was produced a play by Fredo, who is termed the "Polish Molière." Doubtless few Americans have so much as heard of him. Restaurants and saloons were crowded, and the author found the wines of the Rhine and Moselle districts in abundance. Dancing seems to have been almost a craze. The gaiety is probably motivated in part by the uncertainty of the future — a defense reaction against the prospect of more war or national bankruptcy. The correspondent notes that war materials, such as arms, explosives, etc., are being manufactured and the Poles evidently do not propose to be caught napping.

Death of Eichhorst.—This celebrated German clinician was born at Königsberg in 1849, and in 1874 had the good fortune to be assistant to Frerichs in Berlin. After filling minor positions with credit, he was called to the chair of medicine at Zürich when but 34 years of age, and soon acquired the repute of one of the leading internists on the continent. His work on internal medicine, which went through many editions and translations, aided in making him famous. He refused offers from German clinics, but when the war broke out he returned to Prussia. His military experiences were too much for his health and vigor and on his return to Zürich he resumed his duties only to be forced to abandon them. His malady seems to have been angina pectoris. The necrologist does not portray the career of his subject so much as his character. Aside from his professional and family duties he had few activities. In this respect he differs strikingly from the familiar type of the successful medical man who travels widely and is interested in all that pertains to mankind. The devotion of Eichhorst to his daily duties suggested that of the pious man in his religious observances. He liked the maxim, "Hospital work is divine worship." The necrologist believes that Eichhorst's play during his long years at Zürich was limited to a single two-day excursion to the Rigi, which he had never before visited.—*Schweizerische medizinische Wochenschrift.*
